Cummings Otolaryngology Head & Neck Surgery

FIFTH EDITION

Paul W. Flint, M.D.
Professor and Chair
Department of Otolaryngology–Head and Neck Surgery
Oregon Health and Science University
Portland, Oregon

Bruce H. Haughey, M.B.Ch.B., F.A.C.S., F.R.A.C.S.
Professor and Director
Head and Neck Surgical Oncology
Department of Otolaryngology–Head and Neck Surgery
Washington University School of Medicine
St. Louis, Missouri

Valerie J. Lund, C.B.E., M.S., F.R.C.S., F.R.C.S.Ed.
Professor of Rhinology
University College London
Honorary Consultant ENT Surgeon
Royal National Throat, Nose, and Ear Hospital
Royal Free Hospital
Moorfields Eye Hospital
London, United Kingdom

John K. Niparko, M.D.
George T. Nager Professor
Department of Otolaryngology–Head and Neck Surgery
Director
Divisions of Otology, Neurotology, Skull Base Surgery, and Audiology
Johns Hopkins University School of Medicine
Baltimore, Maryland

Mark A. Richardson, M.D.
Professor
Department of Otolaryngology–Head and Neck Surgery
Dean
School of Medicine
Oregon Health and Science University
Portland, Oregon

K. Thomas Robbins, M.D.
Director
SimmonsCooper Cancer Institute at Southern Illinois University
Professor
Division of Otolaryngology–Head and Neck Surgery
Southern Illinois University School of Medicine
Springfield, Illinois

J. Regan Thomas, M.D.
Francis L. Lederer Professor and Chairman
Department of Otolaryngology–Head and Neck Surgery
University of Illinois at Chicago
Chicago, Illinois

Illustrator:

Tim Phelps, M.S., F.A.M.I.
Associate Professor and Medical Illustrator
Art as Applied to Medicine
Johns Hopkins University School of Medicine
Baltimore, Maryland

Notices

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary. Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility. With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions. To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors assume any liability for any injury and/or damage to persons or property as a matter of product liability, negligence, or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

Assistant Professor
Department of Otolaryngology
Division of Pediatric Otolaryngology
Johns Hopkins University School of Medicine
Baltimore, Maryland

Derald E. Brackmann, M.D.

Clinical Professor
Department of Otolaryngology–Head and Neck Surgery
David Geffen School of Medicine at UCLA
Clinical Professor
Department of Neurological Surgery
University of Southern California Keck School of Medicine
President
House Ear Clinic
Los Angeles, California

Carol R. Bradford, M.D., F.A.C.S.

Professor and Chair
Department of Otolaryngology–Head and Neck Surgery
University of Michigan Medical School
Ann Arbor, Michigan

Barton F. Branstetter, IV, M.D.

Associate Professor
Departments of Radiology, Otolaryngology, and Biomedical Informatics
University of Pittsburgh School of Medicine
Director
Head and Neck Imaging
University of Pittsburgh Medical Center
Pittsburgh, Pennsylvania

Edward B. Braun, M.D.

Assistant Professor
Department of Anesthesiology
University of Kansas School of Medicine
University of Kansas Hospital
Kansas City, Kansas

Robert J. S. Briggs, M.B.B.S., F.R.A.C.S.

Clinical Associate Professor
Department of Otolaryngology
The University of Melbourne Faculty of Medicine
Melbourne, Australia

Hilary A. Brodie, M.D., Ph.D.

Professor and Chair
Department of Otolaryngology
University of California, Davis, School of Medicine
UC Davis Medical Center
Sacramento, California

Carolyn J. Brown, Ph.D.

Professor
Department of Communication Sciences and Disorders
Department of Otolaryngology–Head and Neck Surgery
University of Iowa Carver College of Medicine
Iowa City, Iowa

David J. Brown, M.D.

Assistant Professor of Otolaryngology
Medical College of Wisconsin
Children's Hospital of Wisconsin
Milwaukee, Wisconsin

Kevin D. Brown, M.D., Ph.D.

Assistant Professor
Department of Otolaryngology
Weill Cornell Medical College
Assistant Attending Otorhinolaryngologist
NewYork–Presbyterian Hospital
New York, New York

J. Dale Browne, M.D, F.A.C.S.

Professor and Chair
Department of Otolaryngology–Head and Neck Surgery
Wake Forest University School of Medicine
Winston-Salem, North Carolina

John M. Buatti, M.D.

Professor and Head
Department of Radiation Oncology
University of Iowa Carver College of Medicine
University of Iowa Hospitals and Clinics
Iowa City, Iowa

Luke Buchmann, M.D.

Assistant Professor
Department of Otolaryngology–Head and Neck Surgery
University of Utah School of Medicine
Salt Lake City, Utah

Patrick J. Byrne, M.D.

Associate Professor
Departments of Otolaryngology–Head and Neck Surgery and Dermatology
Johns Hopkins University School of Medicine
Director
Division of Facial Plastic and Reconstructive Surgery
Johns Hopkins Hospital
Baltimore, Maryland

Gabriel G. Galzada, M.D.

Department of Head and Neck Surgical Oncology
Kaiser Permanente
Downey, California

John P. Carey, M.D.

Associate Professor
Department of Otolaryngology–Head and Neck Surgery
Division of Otology, Neurotology, and Skull Base Surgery
Johns Hopkins University School of Medicine
Baltimore, Maryland

Margaretha L. Casselbrant, M.D., Ph.D.

Eberly Professor of Pediatric Otolaryngology
Department of Otolaryngology
University of Pittsburgh School of Medicine
Director
Department of Pediatric Otolaryngology
Children's Hospital of Pittsburgh of UPMC
Pittsburgh, Pennsylvania

Paolo Castelnuovo, M.D.

Professor
University of Insubria
Chairman
Ospedale di Circolo e Fondazione Macchi
Varese, Italy

Steven Chang, M.D.

Resident
Department of Otolaryngology–Head and Neck Surgery
Johns Hopkins Medical Institutions
Baltimore, Maryland

Burke E. Chegar, M.D.

Clinical Assistant Professor
Department of Dermatology
Indiana University School of Medicine
Indianapolis, Indiana
Director
Center for Facial Plastic Surgery–Head and Neck Surgery
Fayette Regional Health System
Connersville, Indiana

Amy Chen, M.D., M.P.H.

Associate Professor
Department of Otolaryngology–Head and Neck Surgery
Emory School of Medicine
Atlanta, Georgia

Eunice Y. Chen, M.D., Ph.D.

Assistant Professor
Dartmouth Medical School
Hanover, New Hampshire
Pediatric Otolaryngologist
Dartmouth Hitchcock Medical Center
Lebanon, New Hampshire

Theodore Chen, M.D.

Department of Head and Neck Surgery
Kaiser Permanente Los Angeles Medical Center
Los Angeles, California

Douglas B. Chepeha, M.D., M.P.H.

Associate Professor
Department of Otolaryngology–Head and Neck Surgery
University of Michigan Medical School
Director
Microvascular Program
A. Alfred Taubman Health Care Center
Ann Arbor, Michigan

Alice Cheuk, M.D.

Resident Physician
Los Angeles County Hospital and USC Medical Center
Los Angeles, California

Neil N. Chheda, M.D.

Assistant Professor
Department of Otolaryngology
Division of Laryngology
University of Florida College of Medicine
Shands at the University of Florida
Gainesville, Florida

Wade Chien, M.D.

Clinical Fellow
Department of Otolaryngology
Johns Hopkins University School of Medicine
Johns Hopkins Hospital
Baltimore, Maryland

Sukgi S. Choi, M.D.

Professor
Departments of Otolaryngology and Pediatrics
George Washington University School of Medicine and Health Sciences
Vice Chief
Department of Pediatric Otolaryngology
Children's National Medical Center
Washington, D.C.

Richard A. Chole, M.D., Ph.D.

Lindburg Professor and Head
Department of Otolaryngology–Head and Neck Surgery
Washington University in St. Louis School of Medicine
Chief of Staff
Department of Otolaryngology
Barnes-Jewish Hospital
St. Louis, Missouri

James M. Christian, D.D.S., M.B.A.

Visiting Associate Professor
Department of Otolaryngology–Head and Neck Surgery
Johns Hopkins University School of Medicine
Director
Division of Dentistry and Oral Surgery
Johns Hopkins Hospital
Baltimore, Maryland

Eugene A. Chu, M.D.

Clinical Instructor in Rhinology and Sinus Surgery
Department of Otolaryngology–Head and Neck Surgery
Johns Hopkins University School of Medicine
Baltimore, Maryland

Martin J. Citardi, M.D.

Professor and Chair
Department of Otolaryngology–Head and Neck Surgery
University of Texas Medical School at Houston
Chief
Otorhinolaryngology
Memorial Hermann–Texas Medical Center
Houston, Texas

Marc A. Cohen, M.D.

Resident
Department of Otorhinolaryngology–Head and Neck Surgery
University of Pennsylvania Health System
Philadelphia, Pennsylvania

Savita Collins, M.D.

Physician
Departments of Otolaryngology–Head and Neck Surgery and Audiology
South Bend Clinic
South Bend, Indiana

Nancy A. Collop, M.D.

Professor
Department of Medicine
Division of Pulmonary/Critical Care Medicine
Johns Hopkins University School of Medicine
Medical Director
Sleep Disorders Center
Johns Hopkins Hospital
Baltimore, Maryland

Philippe Contencin, M.D., Ph.D.

Senior Consultant
Department of Otorhinolaryngology
Hôpital Necker
Paris, France

Raymond Cook, M.D.

Assistant Professor
Department of Otolaryngology–Head and Neck Surgery
University of North Carolina at Chapel Hill School of Medicine
Chapel Hill, North Carolina
WakeMed Health and Hospitals
Raleigh, North Carolina

Jacquelynne Corey, M.D.

Professor of Surgery
Department of Otolaryngology–Head and Neck Surgery
University of Chicago Pritzker School of Medicine
Director
ENT Allergy Program
University of Chicago Medical Center
Chicago, Illinois

Robin T. Cotton, M.D., F.A.C.S., F.R.C.S.C

Professor
Department of Otolaryngology–Head and Neck Surgery
University of Cincinnati College of Medicine
Director
Pediatric Otolaryngology–Head and Neck Surgery
Cincinnati Children's Hospital
Cincinnati, Ohio

Marion Everett Couch, M.D., Ph.D.

Associate Professor
Department of Otolaryngology–Head and Neck Surgery
University of North Carolina at Chapel Hill School of Medicine
Chapel Hill, North Carolina

Mark S. Courey, M.D.

Professor
Department of Otolaryngology–Head and Neck Surgery
Director
Division of Laryngology
University of California, San Francisco, School of Medicine
Director
UCSF Voice and Swallowing Center
San Francisco, California

Benjamin T. Crane, M.D., Ph.D.

Assistant Professor
Departments of Otolaryngology and Neurobiology
University of Rochester School of Medicine and Dentistry
Department of Otolaryngology
Strong Memorial Hospital
Rochester, New York

Roger L. Crumley, M.D.

Professor and Chair
Department of Otolaryngology–Head and Neck Surgery
University of California, Irvine, School of Medicine
Orange, California

Oswaldo Laércio M. Cruz, M.D.

Associate Professor and Chief
Division of Otology-Neurotology
Department of Otolaryngology
Federal University of São Paulo
São Paulo, Brazil

Frank Culicchia, M.D.

Professor and Chair
Department of Neurosurgery
Louisiana State University Health Sciences Center
New Orleans, Louisiana

Charles W. Cummings, M.D.

Distinguished Professor
Johns Hopkins University School of Medicine
Executive Medical Director
Johns Hopkins International
Baltimore, Maryland

Calhoun D. Cunningham, III, M.D.

Assistant Consulting Professor of Surgery
Division of Otorhinolaryngology–Head and Neck Surgery
Duke University School of Medicine
Durham, North Carolina
Associate Physician
Carolina Ear and Hearing Clinic
Raleigh, North Carolina

Greg E. Davis, M.D., M.P.H.

Assistant Professor
Department of Otolaryngology–Head and Neck Surgery
University of Washington School of Medicine
Seattle, Washington

Larry E. Davis, M.D.

Distinguished Professor of Neurology
Research Professor
Departments of Neuroscience and Molecular Genetics and Microbiology
University of New Mexico School of Medicine
Chief
Neurology Service
New Mexico VA Health Care System
Albuquerque, New Mexico

Terry A. Day, M.D.

Professor and Clinical Vice Chair
Department of Otolaryngology–Head and Neck Surgery
Medical University of South Carolina
Charleston, South Carolina

Antonio De la Cruz, M.D.

Clinical Professor
Department of Otolaryngology–Head and Neck Surgery
University of Southern California Keck School of Medicine
Director of Education
House Ear Clinic
Los Angeles, California

Charles C. Della Santina, M.D., Ph.D.

Associate Professor
Departments of Otolaryngology–Head Neck Surgery and Biomedical Engineering
Director
Vestibular NeuroEngineering Laboratory
Division of Otology, Neurotology, and Skull Base Surgery
Johns Hopkins School of Medicine
Baltimore, Maryland

Chadrick Denlinger, M.D.

Assistant Professor
Department of Surgery
Medical University of South Carolina
Charleston, South Carolina

Craig S. Derkay, M.D., F.A.A.P., F.A.C.S.

Professor of Otolaryngology and Pediatrics
Vice Chair
Department of Otolaryngology
Eastern Virginia Medical School
Director of Pediatric Otolaryngology
Children's Hospital of the King's Daughters
Norfolk, Virginia

Assistant Professor of Otology, Neurotology, and Skull Base Surgery
Department of Otolaryngology–Head and Neck Surgery
University of California, Davis, School of Medicine
Sacramento, California

Robert A. Dobie, M.D.

Professor
Department of Otolaryngology–Head and Neck Surgery
University of California, Davis, School of Medicine
Sacramento, California

Suzanne K. Doud Galli, M.D., Ph.D.

Department of Otolaryngology
Inova Fairfax Hospital
Washington, D.C.

Newton O. Duncan, M.D.

Clinical Assistant Professor
Departments of Otorhinolaryngology and Pediatrics
Baylor College of Medicine
Attending Surgeon
Texas Children's Hospital
Houston, Texas

Scott D. Z. Eggers, M.D.

Assistant Professor
Department of Neurology
Mayo Medical School
Ann Arbor, Michigan
Associate
Department of Neurology
Mayo Clinic
Rochester, Minnesota

Avraham Eisbruch, M.D.

Professor
Department of Radiation Oncology
University of Michigan Medical School
Associate Chair of Clinical Research
University of Michigan Health System
Ann Arbor, Michigan

David W. Eisele, M.D., F.A.C.S.

Professor and Chair
Department of Otolaryngology–Head and Neck Surgery
University of California, San Francisco, School of Medicine
San Francisco, California

Hussam K. El-Kashlan, M.D.

Associate Professor
Department of Otolaryngology
University of Michigan Medical School
Medical Director
Vestibular Testing Center
University of Michigan Health System
Ann Arbor, Michigan

Ravindhra G. Elluru, M.D., Ph.D.

Associate Professor
Department of Otolaryngology–Head and Neck Surgery
University of Cincinnati College of Medicine
Division of Pediatric Otolaryngology
Cincinnati Children's Hospital
Cincinnati, Ohio

Kevin H. Ende, M.D.

Clinical Instructor
Plastic Surgery and Facial Surgery
University of California, San Francisco, School of Medicine
San Francisco, California

Audrey B. Erman, M.D.

Resident
Department of Otolaryngology
University of Michigan Health System
Ann Arbor, Michigan

Samer Fakhri, M.D.

Associate Professor
Department of Otolaryngology–Head and Neck Surgery
University of Texas Medical School at Houston
Houston, Texas

Carole Fakhry, M.D., M.P.H.

Resident
Department of Otolaryngology–Head and Neck Surgery
Johns Hopkins Hospital
Baltimore, Maryland

Edward H. Farrior, M.D.

Visiting Clinical Associate Professor
Department of Otolaryngology
University of Virginia School of Medicine
Charlottesville, Virginia
Founder and Physician
Farrior Facial Plastic and Cosmetic Surgery Center
Tampa, Florida

Richard T. Farrior, M.D.

Boca Grande, Florida

Russell A. Faust, M.D., Ph.D.

Assistant Professor
Department of Otolaryngology, College of Medicine
Department of Oral Triology, College of Dentistry
The Ohio State University
Staff Attending Physician
Department of Otolaryngology
Nationwide Children's Hospital
Columbus, Ohio

Berrylin J. Ferguson, M.D.

Associate Professor
Department of Otolaryngology
University of Pittsburgh School of Medicine
Director
Division of Sino-Nasal Disorders and Allergy
University of Pittsburgh Medical Center
Pittsburgh, Pennsylvania

Paul W. Flint, M.D.

Professor and Chair
Department of Otolaryngology–Head and Neck Surgery
Oregon Health and Science University
Portland, Oregon

Howard W. Francis, M.D.

Associate Professor
Residency Program Director
Department of Otolaryngology–Head and Neck Surgery
Johns Hopkins University School of Medicine
Baltimore, Maryland

Marvin P. Fried, M.D.

Professor and University Chairman
Albert Einstein College of Medicine
Department of Otorhinolaryngology–Head and Neck Surgery
Montefiore Medical Center
Bronx, New York

David R. Friedland, M.D., Ph.D.

Associate Professor
Department of Otolaryngology and Communication Sciences
Chief
Division of Otology and Neuro-otologic Skull Base Surgery
Medical College of Wisconsin
Milwaukee, Wisconsin

Oren Friedman, M.D.

Assistant Professor
Department of Otolaryngology
Mayo Medical School
Director
Facial Plastic and Reconstructive Surgery
Mayo Clinic
Rochester, Minnesota

John L. Frodel, Jr., M.D., F.A.C.S.

Clinical Professor
Department of Otolaryngology–Head and Neck Surgery
Temple University School of Medicine
Philadelphia, Pennsylvania
Associate
Geisinger Medical Center
Danville, Pennsylvania

Gerry F. Funk, M.D., F.A.C.S.

Professor
Department of Otolaryngology–Head and Neck Surgery
University of Iowa Carver College of Medicine
Director
Division of Head and Neck Oncology
University of Iowa Hospitals and Clinics
Iowa City, Iowa

Bruce J. Gantz, M.D.

Professor
Department of Otolaryngology–Head and Neck Surgery
University of Iowa Carver College of Medicine
Head
Department of Otolaryngology–Head and Neck Surgery
University of Iowa Hospitals and Clinics
Iowa City, Iowa

C. Gaelyn Garrett, M.D.

Professor
Vanderbilt University School of Medicine
Medical Director
Vanderbilt Voice Center
Nashville, Tennessee

Jackie Gartner-Schmidt, Ph.D.

Assistant Professor
Department of Otolaryngology
University of Pittsburgh School of Medicine
Associate Director
University of Pittsburgh Voice Center
UPMC Mercy Hospital
Pittsburgh, Pennsylvania

William Donald Gay, D.D.S.

Hawes Professor of Maxillofacial Prosthetics (retired)
Department of Otolaryngology
Washington University in St. Louis School of Medicine
Attending Dentist
Barnes Hospital
St. Louis, Missouri

Norman N. Ge, M.D., M.S.E.E., F.A.C.S.

Associate Professor
Department of Otolaryngology
University of California, Irvine, School of Medicine
Orange, California
Chief
Department of Head and Neck Surgery
VA Long Beach Healthcare System
Long Beach, California

M. Boyd Gillespie, M.D., M.S.

Associate Professor
Department of Otolaryngology–Head and Neck Surgery
Medical University of South Carolina
Charleston, South Carolina

Douglas A. Girod, M.D., F.A.C.S.

Professor and Russell E. Bridwell Chair
Department of Otolaryngology–Head and Neck Surgery
Senior Associate Dean for Clinical Affairs
University of Kansas School of Medicine
University of Kansas of Medical Center
Kansas City, Kansas

George S. Goding, Jr., M.D.

Associate Professor
Department of Otolaryngology
University of Minnesota Medical School
Faculty
Department of Otolaryngology
Hennepin County Medical Center
Minneapolis, Minnesota

Andrew N. Goldberg, M.D., F.A.C.S.

Professor
Departments of Otolaryngology–Head and Neck Surgery and Neurological Surgery
University of California, San Francisco, School of Medicine
Director
Rhinology and Sinus Surgery
UCSF Medical Center
San Francisco, California

David Goldenberg, M.D.

Associate Professor
Department of Surgery
Division of Otolaryngology–Head and Neck Surgery
Penn State University College of Medicine
Director
Head and Neck Surgery
Penn State Milton S. Hershey Medical Center
Director
Head and Neck Cancer Program
Penn State Cancer Institute
Hershey, Pennsylvania

Daniel O. Graney, Ph.D.

Professor
Department of Biological Structure
University of Washington School of Medicine
Seattle, Washington

Nazaneen N. Grant, M.D.

Assistant Professor
Department of Otolaryngology–Head and Neck Surgery
Georgetown University School of Medicine and Health Sciences
Georgetown University Hospital
Washington, D.C.

Vincent Grégoire, M.D., Ph.D., Hon.F.R.C.R.

Professor of Radiation Oncology
Catholic University of Louvain
Louvain-la-Neuve, Belgium
Head of Clinics
St. Luc University Hospital
Brussels, Belgium

Heike Gries, M.D., Ph.D.

Assistant Professor of Anesthesiology and Pediatrics
Division of Pediatric Anesthesiology
Department of Anesthesiology and Peri-Operative Medicine
Oregon Health and Science University School of Medicine
Portland, Oregon

Samuel P. Gubbels, M.D.

Assistant Professor
Department of Surgery
University of Wisconsin–Madison School of Medicine and Public Health
Madison, Wisconsin

Joel Guss, M.D.

Attending Physician
Department of Head and Neck Surgery
Kaiser Permanente Medical Center
Walnut Creek, California

Patrick Ha, M.D., F.A.C.S.

Assistant Professor
Department of Otolaryngology–Head and Neck Surgery
Johns Hopkins University School of Medicine
Physician
Johns Hopkins Head and Neck Surgery at the Greater Baltimore Medical Center
Milton J. Dance, Jr., Head and Neck Center
Baltimore, Maryland

Grant S. Hamilton, III, M.D.

Assistant Professor
University of Iowa Carver College of Medicine
University of Iowa Hospitals and Clinics
Iowa City, Iowa

Ehab Y. Hanna, M.D., F.A.C.S.

Lecturer
University of Arkansas for Medical Sciences
Little Rock, Arkansas
Professor and Vice Chairman
Department of Head and Neck Surgery
Director of Skull Base Surgery
Medical Director of Head and Neck Center
University of Texas M.D. Anderson Cancer Center
Houston, Texas

Lee A. Harker, M.D.

Formerly Deputy Director
Boys Town National Research Hospital
Vice Chair
Department of Otolaryngology and Human Communication
Omaha, Nebraska

Uli Harréus, Dr.Med.

Assistant Professor
Department of Otolaryngology–Head and Neck Surgery
Ludwig-Maximilians University
Grosshadern Clinic
Munich, Germany

Robert V. Harrison, Ph.D.

Professor and Director of Research
Department of Otolaryngology–Head and Neck Surgery
University of Toronto Faculty of Medicine
Senior Scientist
Neuroscience and Mental Health
Hospital for Sick Children
Toronto, Ontario, Canada

Bruce H. Haughey, M.B.Ch.B., F.A.C.S., F.R.A.C.S.

Professor and Director
Head and Neck Surgical Oncology
Department of Otolaryngology–Head and Neck Surgery
Washington University in St. Louis School of Medicine
St. Louis, Missouri

John W. Hellstein, D.D.S.

Clinical Professor of Oral and Maxillofacial Pathology
University of Iowa Carver College of Medicine
Iowa City, Iowa

Kurt Herzer

Marshall Scholar
Department of Social Policy and Social Work
University of Oxford
Oxford, United Kingdom
Woodrow Wilson Fellow
Departments of Public Health Studies and Anesthesiology and Critical Care Medicine
Johns Hopkins University School of Medicine
Baltimore, Maryland

Michael S. Hildebrand, Ph.D.

Postdoctoral Fellow
Department of Otolaryngology
University of Iowa Carver College of Medicine
University of Iowa Hospitals and Clinics
Iowa City, Iowa

Frans J. M. Hilgers, M.D., Ph.D.

Professor
Amsterdam Center for Language and Communication (Institute of Phonetic Sciences)
Academic Medical Center
University of Amsterdam
Emeritus Chairman
Department of Head and Neck Oncology and Surgery
The Netherlands Cancer Institute–Antoni van Leeuwenhoek Hospital
Amsterdam, The Netherlands

Justin D. Hill, M.D.

Physician
Central Oregon Ear, Nose & Throat
Bend, Oregon

Michael L. Hinni, M.D.

Associate Professor and Residency Program Director
Mayo Clinic College of Medicine
Consultant
Department of Otolaryngology–Head and Neck Surgery
Mayo Clinic
Phoenix, Arizona

Henry T. Hoffman, M.D., F.A.C.S.

Professor
Department of Otolaryngology–Head and Neck Surgery
University of Iowa Carver College of Medicine
Director
Voice Clinic
University of Iowa Hospitals and Clinics
Iowa City, Iowa

Eric H. Holbrook, M.D., M.S.(Anat.)

Assistant Professor
Department of Otology and Laryngology
Harvard Medical School
Associate Surgeon
Department of Otolaryngology
Massachusetts Eye and Ear Infirmary
Boston, Massachusetts

Lauren D. Holinger, M.D.

Professor
Department of Otolaryngology–Head and Neck Surgery
Northwestern University Feinberg School of Medicine
Head
Division of Pediatric Otolaryngology
Children's Memorial Hospital
Chicago, Illinois

Allison MacGregor Holzapfel, M.D.

Volunteer Clinical Professor
Department of Otolaryngology–Head and Neck Surgery
University of Cincinnati College of Medicine
Cincinnati, Ohio

David B. Hom, M.D., F.A.C.S.

Professor
Department of Otolaryngology–Head and Neck Surgery
University of Cincinnati College of Medicine
Director
Facial Plastic and Reconstructive Surgery
University of Cincinnati Medical Center
Cincinnati Children's Hospital Medical Center
Cincinnati, Ohio

John W. House, M.D.

Clinic Professor
Department of Otorhinolaryngology–Head and Neck Surgery
University of Southern California Keck School of Medicine
Associate Physician
House Clinic
President
House Ear Institute
Los Angeles, California

Joyce Colton House, M.D.

Chief Resident
Boston Medical Center
Boston, Massachusetts

Timothy E. Hullar, M.D.

Assistant Professor
Department of Otolaryngology–Head and Neck Surgery
Washington University in St. Louis School of Medicine
St. Louis, Missouri

Murad Husein, M.D.

Assistant Professor
London Health Sciences Centre
Victoria Hospital
Children's Hospital of Western Ontario
London, Ontario, Canada

Steven Ing, M.D.

Assistant Professor of Medicine
The Ohio State University College of Medicine
Columbus, Ohio

Tim A. Iseli, M.B.B.S., F.R.A.C.S.

Staff Surgeon
Royal Melbourne Hospital
Melbourne, Victoria, Australia

Stacey Ishman, M.D.

Assistant Professor
Department of Pediatrics
Department of Otolaryngology–Head and Neck Surgery
Johns Hopkins University School of Medicine
Director
Center for Snoring and Sleep Surgery
Johns Hopkins Hospital
Baltimore, Maryland

Robert K. Jackler, M.D.

Edward C. and Amy H. Sewall Professor and Chair
Department of Otolaryngology–Head and Neck Surgery
Associate Dean
Stanford University School of Medicine
Attending Physician
Lucile Packard Children's Hospital at Stanford
Stanford, California

Brian Jameson, D.O.

Clinical Assistant Professor
Temple University School of Medicine
Philadelphia, Pennsylvania
Attending Endocrinologist
Geisinger Wyoming Valley Medical Center
Wilkes-Barre, Pennsylvania

Herman A. Jenkins, M.D.

Professor and Chair
Department of Otolaryngology
University of Colorado, Denver, School of Medicine
University of Colorado Hospital
Aurora, Colorado

Hong-Ryol Jin, M.D., Ph.D.

Professor
Department of Otolaryngology–Head and Neck Surgery
Seoul National University College of Medicine
Seoul, Korea

John K. Joe, M.D.*

Assistant Professor
Department of Surgery
Division of Otolaryngology–Head and Neck Surgery
Yale University School of Medicine
New Haven, Connecticut

Stephanie A. Joe, M.D.

Assistant Professor
Department of Otolaryngology–Head and Neck Surgery
University of Illinois at Chicago College of Medicine
Director
Sinus and Nasal Allergy Center
Codirector
Skull Base Surgery
University of Illinois Hospital
Chicago, Illinois

*Deceased

Gary Johnson, M.D.
Professor
Department of Obstetrics and Gynecology
Director of Gynecologic Oncology
Clerkship Director
Southern Illinois University School of Medicine
Springfield, Illinois

Rhonda Johnson, M.Ed., Ph.D.
Assistant Professor
Department of Psychiatry
Southern Illinois University School of Medicine
Psychologist
SimmonsCooper Cancer Institute
St. John's Hospital
Memorial Medical Center
Springfield, Illinois

Tiffany A. Johnson, Ph.D.
Assistant Professor
Department of Speech-Language-Hearing: Sciences and Disorders
University of Kansas
Lawrence, Kansas

Timothy M. Johnson, M.D.
Professor
Department of Dermatology and Otorhinolaryngology–Head and Neck Surgery
University of Michigan Medical School
Ann Arbor, Michigan

Nick S. Jones, M.D., F.R.C.S., F.R.C.S.(ORC)
Professor
Department of Otorhinolaryngology–Head and Neck Surgery
University of Nottingham
Queens Medical Centre
University Hospital
Nottingham, United Kingdom

Sheldon S. Kabaker, M.D.
Professor
Department of Otolaryngology
University of California, San Francisco, School of Medicine
San Francisco, California

Lucy H. Karnell, Ph.D.
Research Scientist
University of Iowa Hospitals and Clinics
Iowa City, Iowa

Matthew L. Kashima, M.D., M.P.H.
Assistant Professor
Johns Hopkins University School of Medicine
Chair
Department of Otolaryngology–Head and Neck Surgery
Johns Hopkins Bayview Medical Center
Baltimore, Maryland

Robert M. Kellman, M.D.
Professor and Chair
Department of Otolaryngology and Communication Sciences
SUNY Upstate Medical University
Syracuse, New York

Paul E. Kelly, M.D.
Staff Surgeon
Eastern Long Island Hospital
Greenport, New York
Peconic Bay Medical Center
Riverhead, New York

David W. Kennedy, M.D.
Professor of Rhinology
Department of Otolaryngology–Head and Neck Surgery
Vice Dean for Professional Services
University of Pennsylvania School of Medicine
Philadelphia, Pennsylvania

Ayesha N. Khalid, M.D.
Clinical Instructor
Oregon Health and Science University School of Medicine
Portland, Oregon

Merrill S. Kies, M.D.
Professor of Medicine
University of Texas M.D. Anderson Cancer Center
Houston, Texas

Paul R. Kileny, Ph.D.
Professor
Departments of Otolaryngology and Pediatrics
University of Michigan Medical School
Academic Program Director
Audiology and Hearing Rehabilitation
University of Michigan Health System
Ann Arbor, Michigan

David W. Kim, M.D.
Clinical Associate Professor
Department of Otolaryngology–Head and Neck Surgery
Division of Facial Plastic Surgery
University of California, San Francisco, School of Medicine
San Francisco, California

Jason H. Kim, M.D., F.A.C.S.
Assistant Professor
Department of Otolaryngology–Head and Neck Surgery
University of California, Irvine, School of Medicine
Orange, California

Theresa B. Kim, M.D.
Resident
Department of Otolaryngology–Head and Neck Surgery
UCSF Medical Center
San Francisco, California

William J. Kimberling, Ph.D.
Professor of Ophthalmology
Departments Ophthalmology and Visual Sciences and Otolaryngology
University of Iowa Carver College of Medicine
Iowa City, Iowa
Senior Scientist
Boys Town National Research Hospital
Omaha, Nebraska

Jeffrey Koh, M.D., M.B.A.
Professor of Anesthesiology and Pediatrics
Oregon Health and Science University School of Medicine
Chief
Division of Pediatric Anesthesiology and Pain Management
Doernbecher Children's Hospital
Portland, Oregon

Niels Kokot, M.D.

Assistant Professor
Department of Otolaryngology–Head and Neck Surgery
University of Southern California Keck School of Medicine
Los Angeles, California

Peter J. Koltai, M.D., F.A.C.S., F.A.A.P.

Professor of Otolaryngology
Department of Otolaryngology–Head and Neck Surgery
Stanford University School of Medicine
Chief
Division of Pediatric Otolaryngology
Lucile Packard Children's Hospital at Stanford
Stanford, California

Frederick K. Kozak, M.D.

Clinical Professor
University of British Columbia Faculty of Medicine
Head
Division of Pediatric Otolaryngology
Medical/Surgical Director
Cochlea Implant Program
B.C. Children's Hospital
Vancouver, British Columbia, Canada

Paul R. Krakovitz, M.D.

Assistant Professor
Department of Surgery
Cleveland Clinic Lerner College of Medicine of Case Western Reserve University
Section Head, Pediatric Otolaryngology
Head and Neck Institute
Cleveland Clinic
Cleveland, Ohio

Russell W. H. Kridel, M.D., F.A.C.S.

Clinical Professor
Department of Otolaryngology–Head and Neck Surgery
Division of Facial Plastic and Reconstructive Surgery
University of Texas Medical School at Houston
Houston, Texas

Parvesh Kumar, M.D.

Professor and Chair
Department of Radiation Oncology
University of Southern California Keck School of Medicine
Chair
Department of Radiation Oncology
Los Angeles County Hospital–USC Medical Center
Director
Division of Radiation Oncology
USC Norris Cancer Center Hospital
Los Angeles, California

Melda Kunduk, Ph.D.

Assistant Professor
Department of Communication Sciences and Disorders
Louisiana State University School of Medicine at New Orleans Health Sciences Center
Speech Pathologist
Department of Otolaryngology–Head Neck Surgery
Louisiana State University Health Sciences Center New Orleans, Lourisiana
Our Lady of the Lake Voice Center
Baton Rouge, Louisiana

Ollivier Laccourreye, M.D.

Professor
Department of Otorhinolaryngology–Head and Neck Surgery
Paris Descartes University
Hôpital Européen Georges Pompidou
Paris, France

JoAnne Lacey, M.D.

Assistant Professor
Department of Radiology
Division of Neuroradiology
Washington University in St. Louis School of Medicine
Neuroradiologist
Barnes-Jewish Hospital
St. Louis, Missouri

Stephen Y. Lai, M.D., Ph.D.

Assistant Professor
Department of Head and Neck Surgery
University of Texas M.D. Anderson Cancer Center
Houston, Texas

Devyani Lal, M.D.

Chief Resident
Department of Otolaryngology–Head and Neck Surgery
Loyola University Medical Center
Maywood, Illinois

Anil K. Lalwani, M.D.

Mendik Foundation Professor and Chair
Department of Otolaryngology
New York University School of Medicine
New York, New York

Paul R. Lambert, M.D.

Professor and Chair
Department of Otolaryngology–Head and Neck Surgery
Medical University of South Carolina
Charleston, South Carolina

Amy Anne Lassig, M.D.

Assistant Professor
Department of Otolaryngology–Head and Neck Surgery
University of Minnesota Medical School
Minneapolis, Minnesota

Richard E. Latchaw, M.D.

Professor
Department of Radiology
University of California, Davis, School of Medicine
Director
Neuroradiology Division
Department of Radiology
UC Davis Medical Center
Sacramento, California

Kevin P. Leahy, M.D., Ph.D.

Assistant Professor
Department of Otorhinolaryngology–Head and Neck Surgery
University of Pennsylvania School of Medicine
Philadelphia, Pennsylvania

Daniel J. Lee, M.D.

Assistant Professor
Department of Otology and Laryngology
Harvard Medical School
Department of Otolaryngology
Massachusetts Eye and Ear Infirmary
Boston, Massachusetts

Ken K. Lee, M.D.
Associate Professor
Departments of Dermatology, Surgery, and Otolaryngology
Director
Department of Dermatologic and Laser Surgery
Oregon Health and Science University School of Medicine
Portland, Oregon

Nancy Lee, M.D.
Associate Attending
Department of Radiation Oncology
Memorial Sloan-Kettering Cancer Center
New York, New York

Jean-Louis Lefebvre, M.D.
Professor and Chief
Head and Neck Cancer
Center Oscar Lambret
Lille, France

Maureen A. Lefton-Greif, Ph.D.
Associate Professor
Department of Otolaryngology–Head and Neck Surgery
Department of Pediatrics
Johns Hopkins University School of Medicine
Speech-Language Pathologist
Johns Hopkins Hospital
Baltimore, Maryland

Donald A. Leopold, M.D., M.S.(Bus.)
Professor and Chair
Department of Otolaryngology–Head and Neck Surgery
University of Nebraska School of Medicine
Omaha, Nebraska

James S. Lewis, Jr., M.D.
Assistant Professor of Pathology and Immunology
Department of Anatomic and Molecular Pathology
Director, Research Histology and Tissue Microarray Laboratory
Washington University in St. Louis School of Medicine
St. Louis, Missouri

Daqing Li, M.D.
Associate Professor
Department of Otorhinolaryngology–Head and Neck Surgery
University of Pennsylvania School of Medicine
Director
Gene and Molecular Therapy Laboratory
Director
Temporal Bone Laboratory
Hospital of the University of Pennsylvania
Philadelphia, Pennsylvania

Timothy S. Lian, M.D.
Associate Professor
Department of Otolaryngology–Head and Neck Surgery
Residency Program Director
Louisiana State University Health Sciences Center School of Medicine Shreveport
Shreveport, Louisiana

Greg R. Licameli, M.D., M.H.C.M., F.A.C.S.
Assistant Professor
Department of Otology and Laryngology
Harvard Medical School
Interim Chief
Department of Otolaryngology
Children's Hospital
Boston, Massachusetts

Charles J. Limb, M.D.
Associate Professor
Department of Otolaryngology–Head and Neck Surgery
Johns Hopkins University School of Medicine
Johns Hopkins Hospital
Baltimore, Maryland

Jeri A. Logemann, Ph.D.
Ralph and Jean Sundin Professor
Department of Communication Sciences and Disorders
Northwestern University
Evanston, Illinois
Professor
Departments of Neurology and Otolaryngology–Head and Neck Surgery
Northwestern University Feinberg School of Medicine
Director
Voice, Speech, and Language Service and Swallowing Center
Northwestern Memorial Hospital
Chicago, Illinois

Thomas Loh, M.B.B.S., F.R.C.S.
Associate Professor
Department of Otolaryngology
National University of Singapore
Senior Consultant
Department of Otolaryngology–Head and Neck Surgery
National University Hospital
Singapore

Brenda L. Lonsbury-Martin, Ph.D.
Professor
Department of Otolaryngology–Head and Neck Surgery
Loma Linda University School of Medicine
Senior Research Scientist
VA Loma Linda Healthcare System
Loma Linda, California

Manuel A. Lopez, M.D.
Chief
Facial Plastic Surgery
Wilford Hall Medical Center
San Antonio, Texas

Rodney P. Lusk, M.D.
Director
Ear, Nose, and Throat Institute
Boys Town National Research Hospital
Omaha, Nebraska

Lawrence R. Lustig, M.D.
Francis A. Sooy, M.D., Chair in Otolaryngology
Chief
Division of Otology and Neurotology
Department of Otolaryngology–Head and Neck Surgery
University of California, San Francisco, School of Medicine
San Francisco, California

Anna Lysakowski, Ph.D.
Professor
Department of Anatomy and Cell Biology
University of Illinois at Chicago College of Medicine
Chicago, Illinois

Carol J. MacArthur, M.D.
Associate Professor
Department of Otolaryngology–Head and Neck Surgery
Oregon Health and Science University School of Medicine
Portland, Oregon

Robert H. Maisel, M.D.
Professor
Department of Otolaryngology
University of Minnesota Medical School
Chief of Otolaryngology
Hennepin County Medical Center
Minneapolis, Minnesota

James P. Malone, M.D.
Associate Professor
Division of Otolaryngology
Southern Illinois University School of Medicine
Springfield, Illinois

Ellen M. Mandel, M.D.
Associate Professor
Department of Otolaryngology
University of Pittsburgh School of Medicine
Children's Hospital of Pittsburgh
Pittsburgh, Pennsylvania

Susan J. Mandel, M.D., M.P.H.
Professor and Associate Chief
Division of Endocrinology, Diabetes and Metabolism
Department of Medicine
University of Pennsylvania Health System
Philadelphia, Pennsylvania

Scott C. Manning, M.D.
Professor
Department of Otolaryngology
University of Washington in St. Louis School of Medicine
Chief
Division of Pediatric Otolaryngology
Seattle Children's Hospital
Seattle, Washington

Lynette Mark, M.D.
Associate Professor
Departments of Anesthesiology and Critical Care Medicine and Otolaryngology–Head and Neck Surgery
Johns Hopkins University School of Medicine
Johns Hopkins Hospital
Baltimore, Maryland

Jeffery C. Markt, D.D.S.
Associate Professor and Director
Department of Otolaryngology–Head and Neck Surgery
Division of Oral Facial Prosthetics/Dental Oncology
University of Nebraska School of Medicine
Omaha, Nebraska

Michael Marsh, M.D.
Physician
Arkansas Center for Ear, Nose, Throat and Allergy
Fort Smith, Arkansas

Glen K. Martin, Ph.D.
Professor
Department of Otolaryngology–Head and Neck Surgery
Loma Linda School of Medicine
Loma Linda, California

Douglas E. Mattox, M.D.
Professor and William Chester Warren, Jr., M.D., Chair
Department of Otolaryngology–Head and Neck Surgery
Emory School of Medicine
Atlanta, Georgia

Thomas V. McCaffrey, M.D., Ph.D.
Professor and Chair
Department of Otolaryngology–Head and Neck Surgery
University of South Florida College of Medicine
Program Leader and Senior Member
Head and Neck Oncology
H. Lee Moffitt Cancer Center
Tampa, Florida

Timothy M. McCulloch, M.D., F.A.C.S.
Professor
Department of Surgery
University of Wisconsin School of Medicine and Public Health
Chair
Division of Otolaryngology–Head and Neck Surgery
University of Wisconsin Hospitals and Clinics
Madison, Wisconsin

JoAnn McGee, Ph.D.
Scientist
Developmental Auditory Physiology Laboratory
Boys Town National Research Hospital
Omaha, Nebraska

John F. McGuire, M.D.
Attending Physician
Department of Otolaryngology
Fallbrook Hospital
Fallbrook, California

Jonathan McJunkin, M.D.
Resident
Department of Otolaryngology–Head and Neck Surgery
Washington University Medical Center
St. Louis, Missouri

J. Scott McMurray, M.D.
Associate Professor
Departments of Surgery and Pediatrics
University of Wisconsin School of Medicine and Public Health
American Family Children's Hospital
Madison, Wisconsin

Albert L. Merati, M.D.
Associate Professor and Chief
Division of Laryngology
Department of Otolaryngology–Head and Neck Surgery
Department of Speech and Hearing Sciences
University of Washington School of Medicine
Adjunct Associate Professor
Seattle, Washington

Saumil N. Merchant, M.D.
Gudrun Larsen Eliasen and Nels Kristian Eliasen Professor of Otology and Laryngology
Harvard Medical School
Surgeon in Otolaryngology
Massachusetts Eye and Ear Infirmary
Boston, Massachusetts

Anna H. Messner, M.D.
Professor
Departments of Otolaryngology–Head and Neck Surgery and Pediatrics
Stanford University School of Medicine
Stanford, California
Vice Chair
Department of Otolaryngology–Head and Neck Surgery
Lucile Packard Children's Hospital at Stanford
Palo Alto, California

James Michelson, M.D.

Professor
Department of Orthopedics and Rehabilitation
University of Vermont College of Medicine
Medical Informaticist
Fletcher Allen Health Care
Burlington, Vermont

Henry A. Milczuk, M.D.

Associate Professor of Pediatric Otolaryngology
Oregon Health and Science University School of Medicine
Portland, Oregon

Lloyd B. Minor, M.D.

Andelot Professor and Director
Department of Otolaryngology–Head and Neck Surgery
Johns Hopkins University School of Medicine
Johns Hopkins Hospital
Baltimore, Maryland

Steven Ross Mobley, M.D.

Associate Professor
Facial Plastic and Reconstructive Surgery
Department of Otolaryngology
University of Utah School of Medicine
Salt Lake City, Utah

Harlan Muntz, M.D., F.A.C.S., F.A.A.P.

Professor
Department of Otolaryngology–Head and Neck Surgery
University of Utah School of Medicine
Director
Department of Pediatric Otolaryngology
Primary Children's Medical Center
Salt Lake City, Utah

Craig S. Murakami, M.D.

Clinical Associate Professor
Department of Otolaryngology–Head and Neck Surgery
University of Washington School of Medicine
Director
Department of Facial Plastic Surgery
Virginia Mason Medical Center
Seattle, Washington

Charles M. Myer, III, M.D.

Professor and Vice Chair
Department of Otolaryngology
University of Cincinnati College of Medicine
Director
Hearing Impaired Clinic
Cincinnati Children's Hospital Medical Center
Cincinnati, Ohio

Robert M. Naclerio, M.D.

Professor and Chief
Department of Otolaryngology–Head and Neck Surgery
University of Chicago Pritzker School of Medicine
Chicago, Illinois

Joseph B. Nadol, Jr., M.D.

Walter Augustus Lecompte Professor and Chair
Department of Otology and Laryngology
Harvard Medical School
Chief
Department of Otolaryngology
Massachusetts Eye and Ear Infirmary
Boston, Massachusetts

Paul S. Nassif, M.D., F.A.C.S.

Assistant Clinical Professor
Department of Otolaryngology
University of Southern California Keck School of Medicine
Los Angeles, California
Partner
Spalding Drive Cosmetic Surgery and Dermatology
Beverly Hills, California

Julian Nedzelski, M.D.

Professor
Department of Otolaryngology
University of Toronto Faculty of Medicine
Otolaryngologist-in-Chief
Sunnybrook Health Sciences Centre
Toronto, Ontario, Canada

Piero Nicolai, M.D.

Professor
University of Brescia School of Medicine
Chairman
Spedali Civili
Brescia, Italy

David R. Nielsen, M.D.

Executive Vice President and CEO
American Academy of Otolaryngology–Head and Neck Surgery
Alexandria, Virginia

John K. Niparko, M.D.

George T. Nager Professor
Department of Otolaryngology–Head and Neck Surgery
Director
Divisions of Otology, Neurotology, Skull Base Surgery, and Audiology
Johns Hopkins University School of Medicine
Baltimore, Maryland

Susan J. Norton, Ph.D.

Professor
Department of Otolaryngology–Head and Neck Surgery
Adjunct Professor
Department of Speech and Hearing Sciences
University of Washington School of Medicine
Chief
Department of Pediatric Audiology
Seattle Children's Hospital
Seattle, Washington

S. A. Reza Nouraei, M.A.(Cantab.), M.B.B.Chir., M.R.C.S.

Researcher
The Laryngology Research Group
University College London
Academic Specialist Registrar
Charing Cross Hospital
London, United Kingdom

Daniel W. Nuss, M.D., F.A.C.S.

G. D. Lyons Professor and Chair
Department of Otolaryngology–Head and Neck Surgery
Louisiana State University Health Sciences Center School of Medicine at New Orleans
New Orleans, Louisiana

Brian Nussenbaum, M.D.

Associate Professor of Otolaryngology
Vice Chair for Clinical Affairs
Patient Safety Officer
Washington University in St. Louis School of Medicine
Attending Surgeon
Barnes-Jewish Hospital
St. Louis, Missouri

Rick M. Odland, M.D., Ph.D.

Associate Professor
Department of Otolaryngology
University of Minnesota Medical School
Staff Surgeon
Departmental of Otolaryngology
Hennepin County Medical Center
Minneapolis, Minnesota

Gerard O'Donoghue, M.Ch., F.R.C.S.

Professor of Otology and Neurotology
University of Nottingham
Codirector
National Biomedical Unit in Hearing
Department of Otolaryngology
Queen's Medical Centre
Nottingham, United Kingdom

Eric R. Oliver, M.D.

Chief Resident
Department of Otolaryngology–Head and Neck Surgery
MUSC University Hospital
Charleston, South Carolina

Bert W. O'Malley, Jr., M.D.

Gabriel Tucker Professor and Chairman
Department of Otorhinolaryngology–Head and Neck Surgery
Professor of Neurosurgery
Abramson Cancer Center
University of Pennsylvania School of Medicine
Codirector
Center for Cranial Base Surgery
Codirector
Head and Neck Cancer Center
University of Pennsylvania Health System
Philadelphia, Pennsylvania

Robert C. O'Reilly, M.D.

Clinical Associate Professor
Department of Otolaryngology and Pediatrics
Jefferson Medical College
Thomas Jefferson University
Philadelphia, Pennsylvania
Pediatric Otology/Neurotology
A. I. duPont Hospital for Children
Wilmington, Delaware

Juan Camilo Ospina, M.D.

Assistant Professor
Javeriana University School of Medicine
Head
Division of Otorhinolaryngology and Maxillofacial Surgery
San Ignacio University Hospital
Director
Division of Otorhinolaryngology
Roosevelt Institute
Bogota, Colombia

Robert H. Ossoff, D.M.D., M.D.

Guy M. Maness Professor of Laryngology and Voice
Department of Otolaryngology–Head and Neck Surgery
Vanderbilt University School of Medicine
Assistant Vice Chancellor for Compliance and Corporate Integrity
Vanderbilt Medical Center
Nashville, Tennessee

Kristen J. Otto, M.D.

Assistant Professor
Department of Otolaryngology and Communicative Sciences
University of Mississippi School of Medicine
Jackson, Mississippi

Mark D. Packer, M.D.

Assistant Clinical Professor
University of Texas Health Science Center at San Antonio School of Medicine
San Antonio Uniformed Services Health Education Consortium
San Antonio, Texas
Staff Neurotologist
Wilford Hall Medical Center
Lackland Air Force Base, Texas

John Pallanch, M.D.

Assistant Professor
Department of Otolaryngology
Mayo School of Graduate Medical Education
Chair
Division of Rhinology
Department of Otorhinolaryngology
Mayo Clinic
Rochester, Minnesota

James N. Palmer, M.D.

Associate Professor
Department of Otorhinolaryngology–Head and Neck Surgery
University of Pennsylvania School of Medicine
Director
Division of Rhinology
Hospital of the University of Pennsylvania
Philadelphia, Pennsylvania

Stephen S. Park, M.D.

Professor and Vice Chair
Department of Otolaryngology
Director
Division of Facial Plastic Surgery
University of Virginia School of Medicine
Charlottesville, Virginia

Sundip Patel, M.D.

Resident
Department of Otolaryngology–Head Neck Surgery
University of Illinois Hospital
Chicago, Illinois

G. Alexander Patterson, M.D.

Professor
Department of Surgery
Washington University in St. Louis School of Medicine
Barnes-Jewish Hospital
St. Louis, Missouri

Bruce W. Pearson, M.D.
Emeritus Professor
Department of Otolaryngology–Head and Neck Surgery
Mayo Clinic College of Medicine
Jacksonville, Florida

Phillip K. Pellitteri, D.O., F.A.C.S.
Clinical Professor
Department of Otolaryngology–Head and Neck Surgery
Temple University School of Medicine
Philadelphia, Pennsylvania
Chief, Section of Head, Neck, and Endocrine Surgery
Department of Otolaryngology–Head and Neck Surgery
Geisinger Health System
Danville, Pennsylvania

Jonathan A. Perkins, D.O.
Associate Professor
Department of Otolaryngology–Head and Neck Surgery
University of Washington School of Medicine
Attending Pediatric Otolaryngologist
Seattle Children's Hospital
Seattle, Washington

Stephen W. Perkins, M.D.
Clinical Associate Professor
Department of Otolaryngology
Indiana University School of Medicine
President
Meridian Plastic Surgeons
Meridian Plastic Surgery Center
Indianapolis, Indiana

Colin D. Pero, M.D.
Volunteer Clinical Faculty
University of Texas Southwestern Medical School
Dallas, Texas
Private Practice
Plano, Texas

Shirley S. N. Pignatari, M.D., Ph.D.
Associate Professor
Department of Otolaryngology–Head and Neck Surgery
Federal University of São Paulo
Head
Pediatric ENT Division
ENT Center of São Paulo
Professor
Edmundo Uasconcelos Hospital
São Paulo, Brazil

Steven D. Pletcher, M.D.
Assistant Professor
Department of Otolaryngology–Head and Neck Surgery
University of California, San Francisco, School of Medicine
San Francisco, California

Aron Popovtzer, M.D.
Physician
Davidoff Comprehensive Cancer Center
Consultant
Department of Otolaryngology
Rabin Medical Center
Petah-Tikva, Israel

Gregory N. Postma, M.D.
Professor
Department of Otolaryngology
Medical College of Georgia
Director
Center for Voice and Swallowing Disorders
Augusta, Georgia

William P. Potsic, M.D., M.M.M.
Professor
Department Otolaryngology–Head and Neck Surgery
University of Pennsylvania School of Medicine
Senior Surgeon
Division of Otolaryngology
The Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

Sheri A. Poznanovic, M.D.
Clinical Instructor
University of Colorado School of Medicine
Clinical Staff
The Children's Hospital
Denver, Colorado
Pediatric Otolaryngologist
Colorado Otolaryngology Associates
Colorado Springs, Colorado

Vito C. Quatela, M.D.
Clinical Associate Professor
Department of Otolaryngology
University of Rochester School of Medicine and Dentistry
Quatela Center for Plastic Surgery
Rochester, New York

C. Rose Rabinov, M.D.
Bakersfield, California

Virginia Ramachandran, Au.D
Senior Staff Audiologist
Department of Otolaryngology–Head and Neck Surgery
Division of Audiology
Henry Ford Hospital
Detroit, Michigan

Gregory W. Randolph, M.D., F.A.C.S
Associate Professor
Department of Otolaryngology–Head and Neck Surgery
Harvard Medical School
Director
Endocrine Surgery, General Otolaryngology, and General and Thyroid Services
Massachusetts Eye and Ear Infirmary
Boston, Massachusetts

Christopher H. Rassekh, M.D., F.A.C.S
Associate Professor
Department of Otolaryngology–Head and Neck Surgery
Chief
Division of Head and Neck Oncology
West Virginia University School of Medicine
Co-Director, Center for Cranial Base Surgery
Morgantown, West Virginia

Steven D. Rauch, M.D.
Associate Professor
Department of Otology and Laryngology
Harvard Medical School
Coordinator
Medical Student Education
Department of Otolaryngology–Head and Neck Surgery
Massachusetts Eye and Ear Infirmary
Boston, Massachusetts

Lou Reinisch, Ph.D.
Professor of Physics and Head
Department of Physical and Earth Sciences
Jacksonville State University
Jacksonville, Alabama

Mark, A. Richardson, M.D.
Professor
Department of Otolaryngology–Head and Neck Surgery
Dean
School of Medicine
Oregon Health and Science University
Portland, Oregon

Gresham T. Richter, M.D.
Assistant Professor
Department of Otolaryngology–Head and Neck Surgery
The University of Arkansas for Medical Sciences College of Medicine
Division of Pediatric Otolaryngology
Vascular Anomalies Center
Arkansas Children's Hospital
Little Rock, Arkansas

James M. Ridgway, M.D.
Fellow
Facial Plastic and Reconstructive Surgery
Department of Otolaryngology–Head and Neck Surgery
University of Washington School of Medicine
Seattle, Washington

K. Thomas Robbins, M.D.
Director
SimmonsCooper Cancer Institute at Southern Illinois University
Professor
Division of Otolaryngology–Head and Neck Surgery
Southern Illinois University School of Medicine
Springfield, Illinois

Frederick C. Roediger, M.D.
Resident
Department of Otolaryngology–Head and Neck Surgery
UCSF Medical Center
San Francisco, California

Jeremy Rogers, M.D.
Chief Resident
Department of Otolaryngology–Head and Neck Surgery
USF Medical Center
Head and Neck Program
H. Lee Moffitt Cancer Center
Tampa, Florida

Ohad Ronen, M.D., F.A.C.S.
Attending Surgeon
Department of Otolaryngology–Head and Neck Surgery
Lady Davis Carmel Medical Center
Haifa, Israel

Richard M. Rosenfeld, M.D., M.P.H.
Professor and Chairman
Department of Otolaryngology
SUNY Downstate School of Medicine
Chairman
Department of Otolaryngology
Long Island College Hospital
Brooklyn, New York

Bruce E. Rotter, D.M.D.
Professor
Oral and Maxillofacial Surgery
Associate Dean for Academic Affairs
Southern Illinois University School of Dental Medicine
Alton, Illinois
Consultant
Oral and Maxillofacial Surgeon
John Cochrane VA Medical Center
St. Louis, Missouri

Jay T. Rubinstein, M.D., Ph.D.
Professor
Departments of Otolaryngology and Bioengineering
University of Washington School of Medicine
Seattle, Washington

Michael J. Ruckenstein, M.D., F.A.C.S., F.R.C.S.C.
Professor
Residency Program Director
Department of Otorhinolaryngology–Head and Neck Surgery
Vice Chair for Education and Academic Affairs
University of Pennsylvania School of Medicine
Philadelphia, Pennsylvania

Zoran Rumboldt, M.D.
Associate Professor
Department of Radiology
Medical University of South Carolina
Charleston, South Carolina

Christina L. Runge-Samuelson, Ph.D.
Associate Professor
Department of Otolaryngology and Communication Sciences
Medical College of Wisconsin
Director
Koss Cochlear Implant Program
Children's Hospital of Wisconsin
Froedtert Hospital
Milwaukee, Wisconsin

Leonard P. Rybak, M.D., Ph.D.
Professor
Department of Surgery
Division of Otolaryngology
Southern Illinois University School of Medicine
Springfield, Illinois

Babak Sadoughi, M.D.
Resident and House Officer
Department of Otorhinolaryngology–Head and Neck Surgery
Montefiore Medical Center
Bronx, New York

John R. Salassa, M.D.
Associate Professor
Department of Otolaryngology–Head and Neck Surgery
Mayo Clinic College of Medicine
Jacksonville, Florida

Thomas J. Salinas, D.D.S.
Associate Professor of Dentistry
Department of Dental Specialties
Mayo Clinic
Rochester, Minnesota

Department of Otolaryngology
University of Michigan Medical School
Director
Cochlear Implant Program
University of Michigan Health System
Ann Arbor, Michigan

Preface

The fifth edition of *Cummings Otolaryngology–Head and Neck Surgery* is written in response to the vast expansion of medical knowledge and technological advancements impacting our specialty and presents the most up-to-date information, covering new topics from surgical robotics and image guidance to evidence-based performance measurements. Nonetheless, we have worked hard to keep the fifth edition concise, removing overlapping content to make for easier reading, yet still covering in detail all major developments in the field.

Building on the success of the past four editions, the fifth edition also reflects a technology-driven change in curriculum, featuring access to the Expert Consult website, with text and images from the book as well as online video demonstrating the ACGME Key Indicator Procedures. The video component provides residents with a new opportunity to better understand the critical elements of these core procedures.

As with past editions, the field of otolaryngology–head and neck surgery is represented in all of its diversity. The table of contents has been restructured to reflect the extensive interrelationship of its various components. Every chapter contains Key Points at the start and a "most relevant" Suggested Readings list. A full reference list for each chapter is available online to supplement the overall content. Combined with the online version, the fifth edition remains the definitive resource for our specialty.

In acknowledgement of all those who have contributed to the specialty, the list of authors includes worldwide representation. Adding to excellence at the editorship level, Drs. Valerie Lund and John Niparko have assumed leadership roles, and Dr. Howard Francis has assumed an associate editorship position for the online video content. Through the combined effort of all contributors, our goal is to further the education of those now associated with otolaryngology–head and neck surgery and provide a foundation for continued progress by the generations to follow.

Acknowledgments

For those individuals privileged to serve and train under Dr. Charles Cummings, we recognize him as mentor, colleague and friend, physician and healer; we are grateful for his leadership and everlasting imprint on our mission in academic medicine.

Charlie, thank you. From your student, colleague, and friend,

Paul W. Flint

It has been a distinct honor and pleasure to be part of the editorial and publishing team assembled for this edition of *Cummings Otolaryngology–Head and Neck Surgery*. The authors have been tireless in their efforts and have worked strongly to produce chapters that are truly comprehensive in scope and depth. My sincere thanks goes to each one of them and their families, who inevitably have put up with liberal amounts of "burning the midnight oil." My loyal assistant of 20 years, Debbie Turner, has kept us to our deadlines and liaised with both authors and publishers in a highly organized way, while my office nurses have provided generous amounts of patient care to cover for my time away from the front lines during this textbook's creation. Similarly, the residents and fellows at Washington University in St. Louis have "held the fort" when necessary.

The ability to purvey knowledge starts, and continues, with one's education, for which thanks goes to my parents, the late Thomas and Marjorie Haughey, my teachers, medical professors, Otolaryngology residency mentors in Auckland, New Zealand, and at the University of Iowa, and colleagues in the specialty, from whom I have and will continue to learn.

My family has unswervingly endorsed the time required for this project, so heartfelt love and thanks go to my wife, Helen, as well as to Rachel and Jack, Chris, Will and Rachel, and Gretchen.

Finally, as we enjoy the teaching of this book and its ensuing online components, I try to keep in mind the source of all knowledge and truth: in the words of Proverbs 2 v.6 "…the Lord gives wisdom and from his mouth come knowledge and understanding." My sincere hope is that the readers everywhere will benefit from this textbook, better accomplishing our specialty's common goal of top quality patient care.

Bruce H. Haughey

I would like to thank Paul Flint and his colleagues for inviting me to participate in this prestigious project, the publishers for their exemplary efficiency in its management, and my partner, David Howard, for his constant support and encouragement.

Valerie J. Lund

Otolaryngology is a specialty of immense power. Scholarly work such as this text shows that in the tools of our specialty is the potential to address unmet challenges. I am grateful to Drs. Charles Cummings and Paul Flint, who showed confidence in me in inviting me to join a marvelously collaborative editorial team, and to the many chapter authors who have given their very best efforts in composing this essential resource.

My work is dedicated to those who have provided my guidance. To my parents, my family, my colleagues, and my ever thoughtful patients, you have taught me the importance of dedication to others and that true compassion is shown in action. Through you I've learned that this is not a world of scarcity but one of abundance that is to be shared.

John K. Niparko

The process of learning is truly lifelong. Participating in the creation of this text allows another way for me to continue to become invigorated and inspired by my specialty field. To my invaluable support mechanism, my wife, children, and family: Thank you.

Mark A. Richardson

I am deeply appreciative and honored to again serve as an editor of this important book. I would like to take this opportunity to recognize some individuals who have influenced my career: John Fredricksen; Douglas Bryce; the late Sir Donald Harrison; Robert Byers; Oscar Guillamondegui; Helmuth Goepfert; Robert Jahrsdoerfer; Charles Cummings; and the late Edwin Cocke. Also, I would like to remember and honor my parents, the late Elizabeth and Wycliffe Robbins, for the values they instilled in me. Finally, and

most of all, I cherish the love and support of my wife, Gayle Woodson, and the children, Phil, Nick, Greg, and Sarah, who together provide the caring background for making it all meaningful.

K. Thomas Robbins

It is a great privilege and honor to serve as an editor for this outstanding textbook. Although the knowledge base for our specialty and indeed all of medicine is continually evolving and growing, this contribution serves otolaryngologists and their patients throughout the world with the current expertise required for best ultimate treatment. As an academic department head, I treasure the wealth of information available to my resident physicians in training. As an individual who has centered his career in a subspecialty of Otolaryngology, I am especially proud to help enhance the information available to the reader in the area of Facial Plastic and Reconstructive Surgery.

On a personal note, I want thank and acknowledge the great help and assistance I received from my administrative assistant, Denise McManaman, in editing this textbook. Her tireless work ethic is always admirable and appreciated. Finally, thank you to my wife, Rhonda, and my children, Ryan, Aaron, and Evan, for their enthusiastic and never-wavering support in my professional activities.

J. Regan Thomas

CHAPTER ONE

Genetics and Otolaryngology

William J. Kimberling

Key Points

- Probably more than half of all hearing losses have a genetic basis.
- Genetic hearing loss can be inherited in several different ways: autosomal dominant, autosomal recessive, x-linked, and mitochondrial.
- Identification of specific genes that cause hearing loss has led to a remarkable increase in the understanding of the pathogenic process underlying genetic hearing loss disorders.
- Genetic testing has become a useful tool in diagnosing genetic hearing loss.
- Complex disorders such as tinnitus, vertigo, and susceptibility to otitis media are amenable to genetic study that will identify individuals at risk for developing these common disorders.

Genetics plays a role in just about everything, although the magnitude of that role may be, in a few cases, barely detectable. It is important—and quickly becoming even more so—for the otolaryngologist to understand genetics to carry out his or her medical obligations effectively. There are hundreds of syndromes that affect the head and neck,[1] and people with most of these syndromes come under the care of an ear, nose, and throat (ENT) surgeon at one time or another during their lives. Furthermore, hearing is an important aspect of the otolaryngologist's practice, and more than 50 different genes have been identified that cause nonsyndromic hearing loss (see the Hereditary Hearing Loss home page at http://webh01.ua.ac.be/hhh/). The identification of the basic dysfunction underlying all of these single-gene disorders is the first step to effective prevention and treatment, whether surgical or pharmacologic. An understanding of complex (presumably polygenic) disorders has become an extremely important objective for medical research. Liability for a variety of diseases (e.g., head and neck cancer, otosclerosis, otitis media, dyslexia) is controlled by several genes.[2-5] It is thought that the day is near when knowledge about an individual's genotype will identify those who are at high risk for development of these and other disorders.[6]

The genome revolution has placed mankind at the brink of the development of new and exciting therapies for both rare and common genetic disorders. It has thus become increasingly important for the ENT practitioner to recognize those disorders that have a strong genetic component and to be aware of the new and developing approaches to their treatment.

The Genome

The term *genome* refers to the collection of all of the genes that an organism possesses. It has been estimated that there are between 40,000 and 140,000 genes in the human genome. The genes are assembled into lengthy strands of deoxyribonucleic acid (DNA), which are organized linearly into chromosomes. The chromosomes are made up of the DNA that forms the genes and the intervening DNA as well as chromatin, which is a protein that assists in the maintenance of the structure and regulation of chromosomal expression. The nuclei of most human cells contain 46 chromosomes that are organized as 23 pairs. Except for the mitochondria, all genes that are contained within the human genome lie on one or the other of these chromosomes. The linear order of the genes on the chromosomes allows one to create maps of the human gene order; these maps are generally invariant throughout any given species. It is these maps that allow us to associate specific genes with specific traits through gene mapping.[7,8] Genes are transmitted in groups that correspond with the chromosomes. Aside from cases of the exception known as "crossing over," all of the genes of one chromosome (e.g., the paternal one) are transmitted together to the exclusion of the other one. Crossing over allows one chromosome to become a mosaic of both paternal and maternal genes; the frequency with which crossing over occurs has been studied and forms the basis for one of the two ways of measuring distances between genes. The physical distance between two genes is the number of bases between genes and is measured in megabases or kilobases. The genetic distance between two genes, however, is based on the frequency of observed recombination between them and can only be estimated by the study of informative matings and their offspring. Genetic distance is the result of a biologic phenomenon and is imperfectly correlated with physical distance. The order of genes on a chromosome is constant.

The amount of information stored in the genome is tremendous. In the human genome there are approximately 3×10^9 base pairs of DNA that make up the haploid genome. The largest chromosome, 1, contains about 10% of the total, whereas the smallest autosome, 21, contains about 2.5%. Given that the estimated number of genes is between 20,000 and 30,000, the expected number of genes per megabase is between 20 and 30. The average high-resolution chromosome band is about three megabases in size and would be expected to contain between 60 and 90 genes.

Another way of appreciating the size of the genome is to compare the amount of information in it with that in the typical encyclopedia. The encyclopedia would need to have 200 volumes of 1000 pages each to contain the information found in the human genome. In this analogy, gene size would vary from about a third of a page up to several pages. In actuality, the human genetic encyclopedia is packaged into 23 volumes, and the genes are not as easily demarcated as are chapters in a real encyclopedia. However, the analogy serves well when trying to understand the importance of deciphering the genome. This biologic encyclopedia is in truth a manual for the construction and maintenance

of a human being. By understanding the information contained within the genes, we will come to understand the basics of our own biology.

Unfortunately, the information in the genome is simply not organized into rational groupings. One purpose of the genome project had been to develop an index of the genome that would allow researchers who are trying to connect specific genes with specific disorders to do so efficiently.[9,10] From the perspective of the otolaryngologist, this means first that gene-specific diagnoses are now available for many ENT-related disorders and that ultimately better therapies will emerge as more is learned about the basic nature of hereditary disorders that affect hearing, speech, and the structures of the head and neck.

The genome revolution has placed mankind at the brink of the development of new and exciting therapies for both rare and common genetic disorders.[11] It will thus become increasingly important for the ENT practitioner to recognize those disorders that have a strong genetic component.

DNA Structure and the Genetic Code

Humans store genetic information in DNA, which is a linear polymer made up of four different nucleotides: adenine (A), guanine (G), thymidine (T), and cytosine (C). Nucleotides (also called bases) are linked together by phosphodiester bonds into a single strand. Nucleotides also have the capability of pairing with each other (A with T and G with C) through hydrogen bonds. Two strands of DNA can pair with each other in a complementary fashion (again, A with T and G with C) to form a double helix. The two strands are perfectly complementary; for example, if one strand has an order of ATGGGCCATA, its complement would be TACCCGGTAT. During replication, the two strands separate, and the base sequence of each strand would dictate the construction of a new, complementary strand. In this way, the sequence of the double strands is preserved in the two new identical double strands that are produced.

A single strand has an orientation that reflects the direction of the phosphodiester bond, which is usually referred to as going from the 5′ to the 3′ end; genes are transcribed in this direction. Because there is a double helix, the actual transcription occurs from only one strand, called the *template strand*. The antiparallel strand is referred to as the *coding strand*, because its base sequence corresponds with the sequence of the message; however, uracil is substituted for thymidine in the message.

The sequence of bases is what determines all parts of the gene, and it specifically determines the sequence of amino acids in the protein that results from the process of translation. The nucleotides within the coding region are arranged in groups of three, called *codons*, which determine the precise amino acid sequence. Because there are four bases, there are 64 possible combinations of nucleotides, but there are only 20 amino acids. Thus the code is said to be *degenerate*, because most amino acids are specified by more than one codon. For example, the code for valine can be GTT, GTC, GTA, or GTG. The third nucleotide can vary for most amino acids and is often called the *wobble nucleotide*. A specific codon, ATG, codes for methionine and also indicates the beginning of a coding sequence. There are three stop codons: TAA, TAG, and TGA.

Gene Structure and Expression

The definition of a gene has gone through several stages and is now neither simple nor straightforward. The gene is the basic unit of biologic information that can be transmitted from parents to offspring, and it typically provides information about structural or functional components of the cell. The information transfer occurs not only between parent and daughter cells but also between the nucleus and the cytoplasmic machinery. The transfer of this information is called *inheritance* when it occurs between parent and child. The transfer of information from genome within the nucleus to the cell proper would be referred to as *gene expression*. Gene structure has presumably evolved in a way that facilitates the transfer of genetic information, but the true molecular boundaries that define any specific gene are often poorly recognized.

The basic eukaryotic gene is made up of exons and introns. Exons make up the coding part of the gene; the intron is DNA that is interspersed between the exons. During the process of creating a message, introns are spliced out of the message, thus leaving only the exons to be translated into protein. The gene is thus an interrupted sequence of code that must be further processed into a usable message. Figure 1-1 illustrates how the structure of the gene is related to the process of transcription. During transcription, the whole gene is copied—exons and introns together—into a premessage. The premessage is then processed by excising the introns and joining the exons together to make a series of bases that code for a protein. The sites at which the excisions and rejoining take place are called *splice sites,* and specific sequences of bases are used to signal the cellular machinery to recognize these places. There are specific start and end points for the transcription of the gene as well; within the genes, there are specific signals in the form of three-base sequences (the start and stop codons) that indicate where translation into protein is to begin and end. The gene is thus made up of a coding sequence and punctuation.

In addition to the basic structure of a gene, there are elements that are both 5′ and 3′ of the gene that regulate its expression. These are called *cis-acting elements,* because they are on the same strand of DNA as the gene they regulate. Some of the regulatory elements may be inside one or more introns. In fact, the first few introns of a gene frequently contain such regulatory elements. Although some of the cis-acting elements are close to the actual start of the gene, others may be as much as 50 kilobases in front of (upstream) or in back of (downstream) the genes. Regulatory elements act predominantly by controlling the rate of transcription, and they respond to signals in the nucleoplasm to control the cellular specificity of gene action.

A basic understanding of gene structure is critical to an understanding of how mutations can disrupt gene function. Mutations can change the code, the punctuation, or the elements that regulate the expression of the gene; their detection and analysis are discussed in more detail in subsequent paragraphs.

The Molecular Basis of Patterns of Inheritance

There are three broad categories of genetic disease: chromosomal, monogenic, and complex. Chromosomal disorders are those in which relatively large segments of one or more chromosomes occur in only one copy or in more than the expected two copies. Examples would be Down syndrome (trisomy 21) and Turner's syndrome (missing an X or a Y, depending on your perspective). The term single-gene disorder refers to the large group of disorders that are due to mutations in only one gene. Many hearing loss disorders are known to be the result of mutations in specific genes; almost all single-gene disorders show a specific pattern of inheritance (e.g., dominant, recessive, X-linked). Complex traits are those in which the genetics are not clear. The commonly accepted idea is that complex disorders—like cleft lip and/or palate, reading disability, cancer, and hypertension, to name a few—are the result of the interaction between several genes, the environment, and random factors. The otolaryngologist will encounter each category of genetic disease. Chromosomal disorders are generally severe but will frequently present with hearing and head and neck problems. Single-gene disorders are also severe, but many are not associated with multiple anomalies and/or mental retardation. The bulk of an ENT physician's practice involves individuals with complex disorders, because these are typically more frequent.

Chromosomal Disorders

With some exceptions, chromosomal disorders are generally not heritable. Physical abnormalities associated with chromosomal imbalance are the result of rather extensive duplications or deletions of genetic material and involve multiple genes. The most common chromosomal disorder that involves the autosomes is trisomy 21.[12] Chromosomal disorders can be classified into one of four groups:

1. Aneuploidy: the excess or loss of a whole chromosome.

2. Deletion: the breakage or loss of a piece of a chromosome.

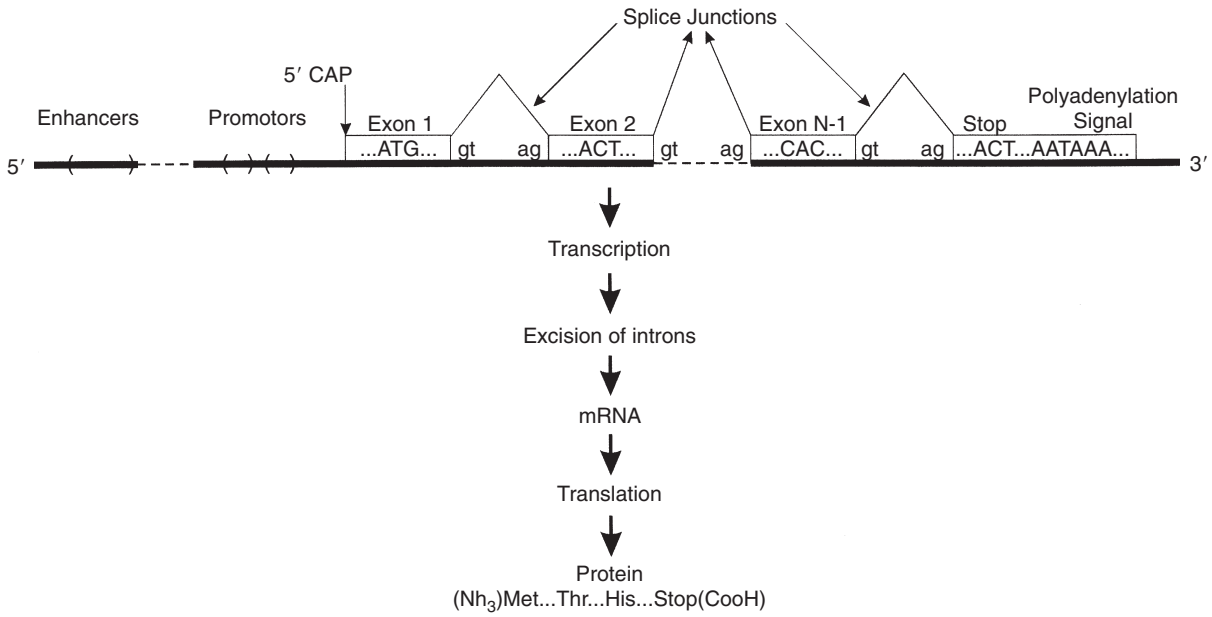

Figure 1-1. Gene structure and transcription. The ultimate primary function of most genes is to produce a protein in a cell at a time at which it is needed. Genes have structures that are adapted to this function. Not only does a gene have syntax that establishes the amino acid sequence of the protein, but it also has punctuation and regulatory sequences that control its expression. The exons make up the coding or information content of the gene; these are interspersed with introns, which are DNA sequences with a function that is only poorly understood. The first step of expression is transcription. The gene is transcribed from the 5′ cap to the end of the polyadenylation signal. This transcript contains both introns and exons, and so the next step is for the introns to be excised. Recognizable splice-site junctions are needed for this to occur normally, and so are other sites that assist in the recognition of the appropriate splice sites. The final mRNA product contains the code that is necessary for the final step of translation, after which a protein is made.

3. Duplication: the insertion of an extra partial copy of a chromosome onto an existing chromosome. This sometimes involves a different chromosome but it is often a tandem duplication that yields a second copy of the same set of genes just adjacent to the original DNA segment.

4. Rearrangement: two breaks of a chromosome or chromosomes and the subsequent refusion of the ends of the chromosome into a different order. When this involves two different chromosomes, it is called a *translocation*; when the same chromosome is involved and the order is reversed, it is called an *inversion*.

A chromosomal abnormality can occur in all or just some of the cells; the latter instance is called *mosaicism*. For example, most malignant cell lines show extensive chromosomal mosaicism, with multiple cell lines present in the tumor. Many females with only one X chromosome (designated as 45,X) are mosaic with a minor cell line that has a normal female constitution, 46,XX. The degree of mosaicism and the distribution in different tissues is believed to determine the severity of some cytogenetic disorders.

Aneuploidies

A trisomy is demonstrated when three copies of a whole chromosome occur in an offspring. This happens because of nondisjunction, which is the movement of a pair of chromosomes to the same pole during cell division; this results in one daughter cell lacking that chromosome and the other daughter cell possessing an extra copy of that chromosome.[13] The three major autosomal trisomies are 21, 18, and 13.

Trisomies 13 and 18 are not compatible with long life, and the average life span of individuals with either of these conditions is less than 1 year. The majority of infants with trisomy 13 are profoundly deaf and have a cleft lip and palate in addition to multiple other congenital anomalies.[14,15] Hearing loss is frequent in trisomy 18 as well.[16] However, hearing and head and neck anomalies are unlikely to be a serious concern because of the limited survival.

Patients with trisomy 21 have ears that are smaller than normal. About 75% have hearing loss, which can be sensorineural, conductive, or mixed.[17] The prognosis of a child with trisomy 21 is generally good, and correction to normal hearing is important for helping such a child achieve maximal abilities.[18]

The common aneuploidies that involve the sex chromosomes include 45,X (Turner's syndrome, phenotypic female) and 47,XXY (Klinefelter's syndrome, phenotypic male). Although profound hearing loss is infrequent, mild to moderate hearing loss is common in 45,X individuals.[19-21] Females with Turner's syndrome are highly susceptible to otitis media, but whether this changes with hormone replacement therapy remains to be investigated.[20,22,23] About 25% of children with Klinefelter's syndrome have a mild sensorineural hearing loss.[24,25] Hearing losses in both Turner's and Klinefelter's syndromes often remain undetected.

Chromosomal Rearrangements

Usually aneuploidies are not heritable; however, rearrangements, translocations, and inversions can be. There is a heritable form of trisomy 21 that involves a translocation between chromosome 21 and another chromosome, usually chromosome 14. This is a so-called centric fusion translocation that results in the loss of both short arms and the fusion of the two long arms of chromosomes 21 and 14. A balanced chromosome complement would be 45 chromosomes. Because of the abnormal way in which the chromosomes need to be paired, this translocation sets the stage for an abnormal separation of chromosomes during meiosis. The result can be a balanced carrier, like the parent (a normal), or a carrier who has three copies of chromosome 21 material. Both translocations and inversions can be heritable and could result in a family that has multiple instances of children with multiple anomalies. The heritable forms can be distinguished by a straightforward cytogenetic evaluation.

Single-Gene Disorders

The terms *dominant* and *recessive* usually refer to the pattern of inheritance of a particular disorder, but, more importantly, they communicate the way in which combinations of two alleles produce a specific (usually abnormal) phenotype. With a dominant inheritance pattern, individuals who carry one copy of the mutant allele (heterozygote) or two copies of the mutant allele (homozygote) are equally affected. With recessive inheritance, a person must be homozygous for the mutant alleles; individuals who are heterozygous are normal. When using these terms to describe a disease, if the disease is called dominant, then normal is recessive, and vice versa. True dominance is probably uncommon. Branchio-oto-renal syndrome (BOR) is described as dominant,[26] but because it is uncommon a true mutant homozygous individual has probably never been born. Most geneticists would expect that patients with the homozygous mutant form of BOR would have a more severe phenotype, one that is possibly even lethal. Similarly, one might expect that patients with many of the recessive nonsyndromic deafness disorders could have a mild manifestation in the heterozygote, possibly contributing to the liability of the development of age-related hearing loss. An example of true dominance occurs with Huntington's disease, in which a homozygous patient who is affected has the same phenotype as heterozygous individuals.[27,28]

Dominant Disorders

Figure 1-2 shows a typical family pedigree of an autosomal dominant disorder. Under full penetrance, each affected individual has an affected parent. Because they are heterozygous, each affected individual has a 50% chance of transmitting the abnormal gene to offspring, each of whom would be similarly affected. The only reasonable instance in which a person could be homozygous and affected would be if both parents were affected. Dominant mutations are recognized through their pattern of inheritance, which typically shows vertical transmission and the involvement of several generations and several sibships.

Affected patients are typically equally distributed between the sexes. However, a few sex-limited and sex-modified dominant disorders do exist.[29]

Dominance occurs with X-linked genes as well. The biochemical basis of the action of dominance is the same, but the pattern of inheritance is distinctly different. Twice as many females as males are expected to be affected. X-linked dominant pedigrees can mimic the characteristics of an autosomal dominant one, but they would not be expected to show male-to-male transmission. When the distinction between autosomal and X-linked dominant is in question, the observation of male-to-male transmission establishes an autosomal position of the gene.

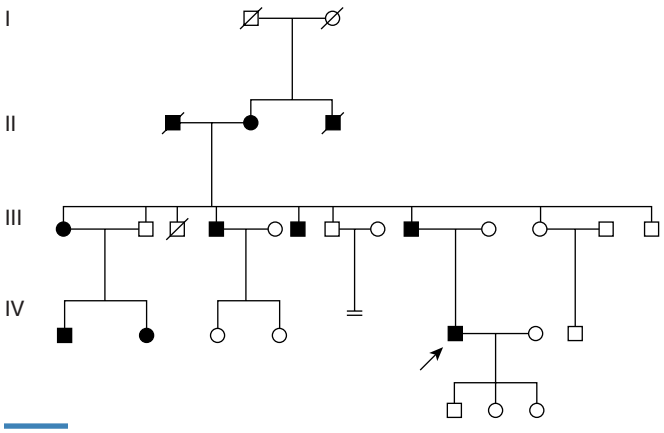

Figure 1-2. Pedigree typical of a dominantly inherited trait; in this case, autosomal dominant congenital deafness. The arrow points to the proband of the family (a proband is the person though whom the family came to your attention). Note that the pattern of transmission in the family covers multiple generations and that both sexes are affected equally. A slash though a circle or square indicates that the person is deceased.

There are three major mechanisms by which dominant genes generally influence phenotype: haploinsufficiency, the dominant-negative effect, and the two-hit effect.[30,31] *Haploinsufficiency* refers to the situation in which the inactivation of one gene reduces the gene product to a point where it is insufficient to maintain some cellular function at its normal level. Genes that contain proteins that regulate metabolic activity or transport are likely candidates for this mechanism. A *dominant-negative effect* occurs when the gene product actively interferes with normal cellular processes; the gene is producing a protein that either has acquired a new function or that competes with the action of the normal protein. The *two-hit effect* refers to the situation (e.g., retinoblastoma) in which one allele is inactive, and the disease results from its homologue being inactivated by second mutation. At the organism level, the inheritance appears to be dominant, but the mechanism of action at the cellular level is recessive. This is an important mechanism for the development of tumors in dominantly inherited cancer syndromes. For example, it is probably the mechanism of the carotid body tumor. The mechanism by which a dominant gene causes pathology is an important consideration in the search for treatments. For those disorders that are caused by insufficient gene products, the addition of a gene (or accompanying products) may be considered a reasonable approach to treatment and is likely to be easier to achieve. A dominant-negative effect, however, requires that the action of the gene and/or its product be stopped; this is a far more difficult task conceptually than is that of product replacement.

Examples of dominantly inherited disorders that are important in otolaryngology include all of the dominantly inherited nonsyndromic hearing losses, Waardenburg syndrome,[31,32] BOR syndrome,[33,34] Treacher-Collins syndrome,[35,36] and many others.[1]

Recessive Disorders

Autosomal recessive disorders result only when a person has two abnormal copies of the same gene. Because the affected person must be homozygous, both unaffected parents are heterozygous and thus carriers. In many families, the heritability of a recessive trait is not obvious. Given today's small family sizes, most individuals with recessive disorders present to the clinician as singleton cases lacking any family history of the same disorder. More than 50% of all cases of Usher's syndrome in the United States represent the only affected individuals in their respective families; most of the rest have a few affected siblings. When normal parents have a child with a recessive disorder, the chance of it occurring in any other children they may have is 25%. Although many of the unaffected relatives may also be normal heterozygotes (e.g., aunts and uncles have a 50% chance of being a carrier; first cousins have a 25% chance), one only infrequently observes recurrence outside of the initial sibship involved. One important clue to recessive inheritance is the presence of consanguinity. Important disorders that are inherited via autosomal recessive routes include nonsyndromic deafness,[37] Pendred syndrome,[38,39] Usher syndrome,[40,41] Alstrom syndrome,[42] and many others.[1]

It is the nature of recessive disorders that the abnormal gene is in a much higher frequency than would be appreciated on the basis of the relative rarity of the disorder. For example, Usher's syndrome type Ib, which is due to a defect of MYO7A,[43] is present in about 1 in 25,000 births; heterozygote frequency is estimated at about 1 in every 80 persons. For every affected person, there are more than 300 heterozygotes; if there are 10,000 patients with type Ib Usher's syndrome in the United States, there should be 3,000,000 carriers. For all rare recessive conditions, most of the gene pool resides with the asymptomatic carriers. In some disorders, the carrier rate is quite high; connexin 26 deafness (caused by a defect of GJB2) is the most common form of deafness in the United States,[44] and carrier rates may be as high as 1 in every 25 persons. Some recessive disorders appear to have a high frequency in certain populations. For example, cystic fibrosis is common among people of European extraction,[45] Tay-Sachs among Ashkenazi Jews,[46] and sickle cell anemia (hemoglobin beta S disease) in individuals of African ancestry.[47,48]

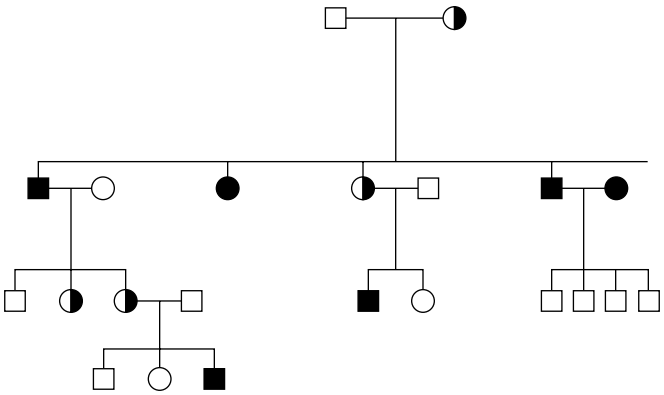

Figure 1-3. X-linked recessive disorders show a very characteristic pattern of inheritance. Females are carriers, and they are usually asymptomatic. They are indicated here by the half-colored circle; the diagnosis of carrier status was done here by inference from the parents having an affected son; however, for many disorders, carrier tests are available.

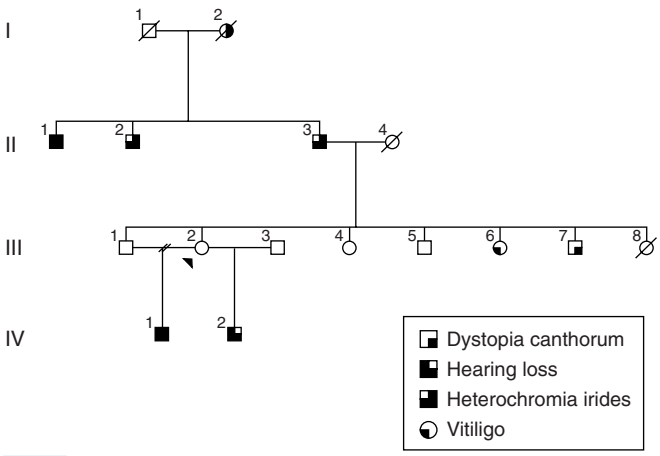

Figure 1-4. This is a pedigree of a family with dominant Waardenburg's syndrome. It shows variable expression and nonpenetrance. Such variability is usual for many dominant hearing-related disorders. Individual III-2 is inferred to be nonpenetrant by virtue of having an affected son.

Sometimes the increase in frequency of certain conditions in certain populations is a result of what is referred to as the *founder effect*. A good example of the founder effect is the very high frequency of Usher's syndrome type IC (due to a defect in the harmonin gene) among the French Acadians of Louisiana.[49] This gene is presumed to have been present in a few individuals who represented a significant part of the small number of immigrants to that region. The French Acadians stayed genetically isolated, and their numbers increased. Because of the chance occurrence of the gene in the founder population, the high frequency has been maintained to this day. Other recessive disorders have a unexpectedly high frequency believed to be caused by certain patterns of selection, such as those that are seen when the heterozygote has a selective advantage over both homozygotes, such as with sickle cell anemia. Selection was important when establishing the high frequency of the hemoglobin beta S allele in Africans. One of the most interesting genetic puzzles now surrounds the reason for the high frequency of connexin 26 deafness alleles. If this is due to a founder effect, then why is there a high frequency of different mutations in Jews, Europeans, and Asians? The high frequency across ethnic lines suggests that the heterozygotes may have (or may have had) a selective advantage over the homozygous normal.

X-linked genes may also harbor recessive mutations. The molecular mechanisms are the same, but the pattern of inheritance is unique and remarkable. Females, who have two X chromosomes, are heterozygotes/carriers. Males, with only one X, are affected; they have only one copy of the abnormal gene, because the Y chromosome carries little in the way of genetic information. The pattern of inheritance is shown in Figure 1-3. Carrier females have a 50% chance of transmitting the abnormal gene, which means that half of a carrier female's sons will be affected and that half of her daughters will be carriers as well. An affected male cannot transmit the gene to his sons, because he would need to transmit a Y to have a son; however, all of his daughters would be carriers, which would mean that 25% of his grandsons could be affected. The two best known X-linked traits are hemophilia[50] and Duchenne's muscular dystrophy.[51] X linkage plays only a minor role in nonsyndromic hearing loss. To otolaryngologists, perhaps the most notable disorders are X-linked deafness with perilymphatic gusher,[9,52] Alport's syndrome,[53,54] and Mohr-Tranebjaerg's syndrome.[55]

Biochemical defects underlying recessive disorders were among the first for human geneticists to understand. Early work in human genetics focused on metabolic defects. Many recessive disorders were found to be due to enzyme deficiencies that interrupted a specific metabolic pathway. Heterozygotes had sufficient enzymes for a typically dosage-tolerant pathway to operate and maintain a normal phenotype. Pathologic results occur either because some product is lacking or because the interruption of the pathway diverts the metabolism to the excessive production of a toxic substance. Some metabolic disorders are treatable by either supplying the missing product or enzyme, or by removing or reducing toxins. Refsum's disease is a metabolic disorder that involves the inability to metabolize phytanic acid, thereby causing a lysosomal storage disorder.[56] The symptoms of Refsum's syndrome can be minimized by a diet that is low in phytanic acid. From the perspective of potential gene therapy, recessive disorders seem ideal, because replacement of the gene—if active—should replace the missing protein. Most recessive disorders are the result of almost total ablation of the gene function, and a reasonably normal phenotype would be expected with only minor restoration of gene function and protein levels.

Penetrance and Expressivity

Penetrance is a frequently misused word; it should refer to a simple "yes" or "no" with regard to the presence of any aspect of the phenotype. A genetic disorder is said to show *reduced penetrance* if some cases fail to show the phenotype (i.e., if the geneticist is unable to make a clinical diagnosis). For example, Figure 1-4 shows a pedigree of a family with Waardenburg's syndrome type I. Waardenburg's syndrome is an autosomal dominant disorder that is characterized by variable hearing loss, pigmentary anomalies (i.e., white forelock, heterochromia irides, vitiligo), and a characteristic broad face with widely spaced inner canthi.[57] Mutations of the PAX3 gene on chromosome 2 are responsible for the majority of cases of this type of Waardenburg's syndrome.[12,58] There is considerable variability in the extent to which the different symptoms appear in different family members. Individual III-7 in Figure 1-4 has dystopia canthorum but no pigmentary anomaly or hearing loss. Still, the gene would be considered to be penetrant, because the diagnosis can be made as a result of the presence of dystopia. On the other hand, individual III-2 shows none of the characteristics expected from having the mutant PAX3 gene, and her genotype can only be inferred by the presence of her two affected children.

The term *expressivity* is used to describe the continuum of the severity of the phenotype. Zero expression is equivalent to nonpenetrance. The expressivity of dominant genes is often quite variable, whereas that of recessive disorder is more consistent, especially within families. Variable expression implies that there is some mechanism by which the severity of the disorder can be modified. These mechanisms may include background genes and/or environmental effects. The investigation of the causes of variable expression could lead to new approaches to therapy.

Pleiotropism is a term used to describe a gene that affects multiple organ systems in an apparently unconnected manner. For example, BOR syndrome can influence renal development as well as hearing.

Oligogenic Disorders

Some disorders are believed to be caused by the interactions among a few genes. Deafness as a result of connexins 26 and 30 is one possible example. The two genes, GJB2 and GJB6, are adjacent to each other on chromosome 13, and deafness has been observed in children with mutations in each of the two genes, each on separate homologues.[11,59,60] This is a digenic effect, and it has also been proposed to occur in certain cases of retinitis pigmentosa.[61,62] In the case of deafness, it is not yet clear whether the effect is truly digenic or whether the deletion in GJB6 interferes with the control of expression of GJB2. It would be expected that many human disorders may have their severity and/or their pleiotropic effects modified by other major genes.

X Linkage

Pedigrees of dominant and recessive X-linked disorders are discussed above and are presented in Figures 1-2 and 1-3. X-linked dominant and recessive traits show more variable expression in females than in males. One reason for this has to do with inactivation of one X chromosome in females, a phenomenon that is also referred to as the Lyon hypothesis. One X from each cell is randomly selected to be inactivated early during development, and all of the daughter cells will have the same X inactivated; this occurs in all cells except germinal line cells. When a female is heterozygous for an X-linked gene, the fraction of cells that have the normal gene inactivated would be expected to vary but to be around 50%. If, by chance, a significant proportion of normal genes are inactivated, a mild phenotype may result; this has been observed in patients with hemophilia and muscular dystrophy. The impact of X inactivation on the few X-linked hearing loss disorders has not been extensively studied. Occasionally, a fully affected female will be observed; many such patients have one or another form of Turner's syndrome, others may have nonrandom X inactivation, and a few may be true homozygotes.

Sporadic Cases

When only one case of a particular disorder occurs in a family, its heritability is not evident; this is an especially frequent event with childhood deafness. The etiology of the sporadic case can be dominant as a result of a new mutation that has not yet had an opportunity to be transmitted and show the typical inheritance pattern. A sporadic case could also be recessive, because most recessive disorders present as sporadic cases. X linkage, if the patient is male, is also a possibility, and so are more complex patterns of inheritance. In the case of childhood hearing loss, obviously there are many nongenetic factors that may be responsible as well. The pattern of inheritance can help with the diagnosis of many ENT-related disorders, but close examination of the clinical phenotype is critical, especially for sporadic cases.

Mitochondrial Disorders

The mitochondria represent the only nonchromosomal DNA that is inherited. Each cell has several hundred copies of usually identical mitochondria. Mitochondria are inherited solely through the maternal line, with the father giving few, if any, mitochondria to his offspring. This makes for a curious pattern of inheritance: all of the children of an affected mother are affected, but there is never transmission through the father (Fig. 1-5). Susceptibility to aminoglycoside-induced hearing loss is the result of a mutation (A1555G) in the 12S rRNA gene of the mitochondrion.[63-65] There are other, more severe disorders that result from mitochondrial mutations. One is the Kearns-Sayre syndrome, in which the hearing loss is extremely variable[66]; this is presumably because not all of the mitochondria carry the causative mutations. A mixed population is called *heteroplasmy*; this is a frequent occurrence in those disorders that may well be lethal if all the mitochondria carried the mutant gene (homoplasmy).

Complex Traits

Common disorders are believed to involve some mix of genetic and environmental causes. The genetics that underlie such traits have been labeled *multifactorial* or *polygenic*. Data indicate that several genes interact to produce a liability for a particular abnormal phenotype. Each gene is presumed to have a small effect. Actually, the number of genes involved remains unknown, and it is possible that some complex disorders could be due to a few major genes that have very reduced penetrances. The idea of using linkage and gene mapping to identify liability genes has become appealing during the last decade, primarily because of the great interest in common disorders and because molecular and gene mapping tools have become quite sophisticated. Some types of neurosensory hearing loss are thought to be inherited in a complex manner. Naturally, age-related hearing loss (presbycusis) is a likely possibility.[67,68] Liability for otitis media has also been hypothesized to be under some genetic control.[69] In the previous section, it was mentioned that liability for aminoglycoside-induced hearing loss is associated with a change in a mitochondrial gene. It would be reasonable to expect that other liabilities for infection (e.g., rubella) may be under genetic control.[70] The discovery of liability genes promises to have a great payoff in terms of the diagnosis of high-risk groups, as well as highlighting new possibilities for treatments that might mimic whatever mechanisms the genes use to confer resistance.

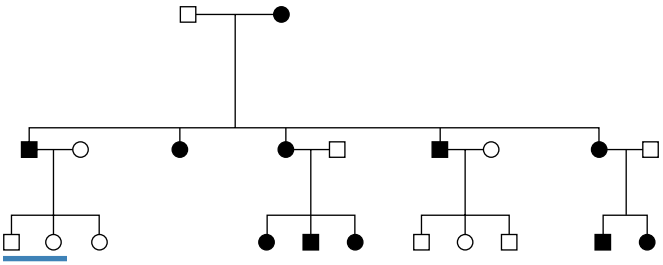

Figure 1-5. Mitochondrial disorders show several generations involved. Transmission is from a mother to all of her children. Males do not transmit the disease to their children. There can be variable expression, which is sometimes due to variable proportions of the mutant-type and wild-type mitochondria.

Genetic Heterogeneity

Genetic heterogeneity refers to the existence of cases with similar phenotypes but with differing causes. Childhood deafness, Usher's syndrome, and retinitis pigmentosa are good examples of this phenomenon. With Usher's syndrome, there are at least five different genes that all cause the severe form of Usher's syndrome type 1.[71] The phenotypes appear to be indistinguishable, and a differential diagnosis can be made only with molecular testing. However, if a man with Usher's syndrome type Ib produces offspring with a woman with Usher's syndrome type Id, all of the children would be expected to have hearing and normal vision, but they would be carriers of both Usher's syndrome types Ib and Id.

Testing Human DNA

DNA and ribonucleic acid (RNA) have two useful properties. One is that of easy replication; DNA generally makes copies of itself. The second is their ability to hybridize; they are sticky. If one starts with a double strand of DNA and heats it sufficiently, the two strands will dissociate (melt) into a mixture of single-stranded nucleic acid chains. If this mixture is cooled, complementary strands will reassociate (hybridize). The replication property is what makes the polymerase chain reaction (PCR) work, and the hybridization property has allowed a variety of DNA and RNA detection systems to be developed.

Polymerase Chain Reaction

PCR is a method of amplifying targeted sequences of DNA.[72] Oligonucleotide primers are constructed that are complementary to the 5′ and 3′ ends of the DNA fragment to be amplified. The size of the fragment is typically only a few hundred bases, but techniques like long PCR may involve several thousand bases. A specific thermostable DNA polymerase is used. The DNA is heated until it melts, and the temperature is then slowly lowered; at the time at which the primers anneal to the test DNA, the PCR is run and the fragment is duplicated. The heating-cooling cycle is then repeated 20 to 30 times; each time, the

DNA fragment between the two primers is duplicated, eventually resulting in several thousand fragments that each have the same length and DNA sequence. PCR is easy to carry out and can be used on minimal samples of DNA; these large quantities of manufactured DNA can then be subjected to a variety of experimental investigations. For example, the DNA can be electrophoresed, stained with ethidium bromide or silver stain, and visualized on a simple agarose or acrylamide gel. The size of the fragment and—more importantly—slight changes in its size can be easily noted. The DNA can be directly used in a sequencing reaction to verify that the sequence of the fragment is as expected. Almost all modern molecular diagnostics start with PCR.

Nucleic Acid Hybridization and Southern Blotting

The early 1980s analysis of genes involved a blotting procedure developed by E. M. Southern that involved hybridizing DNA in a solution (the probe), with the DNA on a stable membrane support, usually filter paper.[73] The probe is labeled with radiolabeled bases (fluorescent tags can be used as well), and the migration of the target DNA can be visualized by autoradiography. Southern hybridization of genomic DNA has limited use in today's molecular genetics laboratories; however, it is still useful for detecting and analyzing large fragments of DNA.

DNA Chips

DNA chips are referred to in two contexts: one when they are used for the analysis of patterns of gene expression,[74] and the other when they are used for the detection of single-base variation in individuals.[10,75] There are several different chip systems, but the basis of the functionality of the chip lies in the ability of antiparallel nucleic acid strands to hybridize.

Oligonucleotides that are typically 8 to 20 bases long and that are each of known sequence are arrayed onto a surface by a photolithographic method. These oligonucleotides can be linked, for example, to a fluorescent detection system. When bathed in a sample, RNA or DNA with homology to the oligonucleotides on the chip can be detected. One use of chips is to analyze changes in the pattern of expression of cells as they change; for example, they have been used to determine which genes are up- and down-regulated during the process of repair after cochlear cells have been damaged by high levels of noise.[76] Chips can help determine which (if any) genes change their pattern of expression in response to different disease processes.

Chips can also be used to detect single-base differences. Many single-base changes are polymorphic (i.e., they have a frequency of heterozygosity of more than 2%); these are called *single-nucleotide polymorphisms,* or *SNPs.* There are thousands of these polymorphisms, and they can be employed effectively for the mapping of complex disorders. Not all single-base changes are clinically neutral; some inactivate or change the gene in which they occur. Chips are an inexpensive and rapid way of detecting single-gene pathologic mutations, and they are likely to become the principal means of diagnosis of many genetic disorders. However, chips cannot be used to detect novel mutations, so the lack of a positive "hit" does not disprove a diagnosis.

Mutation Testing

The detection of pathologic mutations is the essential step toward making a definite molecular diagnosis. Although there are several different strategies to use, the initial evaluation depends on whether one is looking for a known mutation or whether the patient has a novel mutation that has never been seen before. When the mutation is known, molecular techniques that focus on specific base changes can be employed. One method relies on changes in restriction sites. A restriction enzyme is one that recognizes a specific short sequence of bases (usually 4 to 8 bases long) and that cleaves the DNA at that site or nearby. The DNA site that is recognized by a restriction enzyme is usually palindromic, which means that the sequence reads the same in both directions. For example, the restriction enzyme Taq I recognizes the palindromic sequence TCGA and the complementary AGCT, and it cuts the DNA between the T and the C. If there is a change in DNA, it can either disrupt an existing restriction site or create a new one; this can be detected by amplifying the appropriate DNA fragment, cutting it with the restriction enzyme, and running the product on an electrophoresis gel. Fragments with one or more restriction sites will show multiple bands; if a restriction site is added or lost, it can be easily detected by noting the position and number of DNA bands. However, not all DNA changes involve a restriction site. Methods based on the innate annealing capacity of DNA can also be employed. The use of DNA chips in this regard is discussed previously.

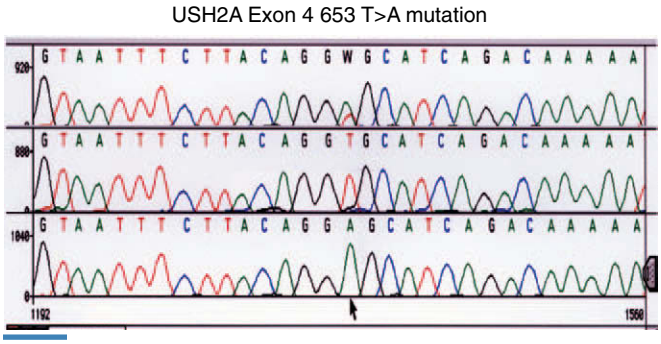

Figure 1-6. Sequencing is currently the best way of determining the genetic constitution of a gene or of part of a gene. This figure shows sequencing that was done to identify the mutation found in a patient with Usher's syndrome type IIa. Each row corresponds to a separate person. The arrow indicates the precise base position at which the mutation was found. The peaks and their colors correspond with each of the four bases in DNA. The control/normal sequence is shown in the middle frame. At position 653 in exon 4, there has been a change in the T (thymine) to an A (adenine). The affected patient in the bottom frame shows only an A at that position, which indicates that he is most likely homozygous for the mutation. His parent is shown in the first frame, and it is evident at that position that both the adenine and thymine bases are being detected by the sequencing reaction; this is typical of a heterozygote.

It is generally thought that screening for known mutations in a gene is a reasonable and less expensive strategy for making a molecular diagnosis. However, if a patient does not show one of the known mutations, this does not rule out the patient as having a pathologic mutation; it could be that the mutation has not yet been observed. In fact, many mutations are extremely rare and occur in only one case or family. Many mutations are limited to a specific family because they have not had time to spread throughout the population. As a result, molecular diagnosis must rely on techniques that can pick up novel mutations. Direct sequencing of a gene is one approach (Fig. 1-6). However, if the gene is large, the sequencing effort can be time consuming and expensive. There are two popular methods that help with screening DNA for mutations: heteroduplex testing and single strand conformation polymorphism (SSCP). In heteroduplex testing, a fragment is amplified, heated, and allowed to anneal with itself.[77,78] If the patient is heterozygous, then the fragment will contain two populations of DNA, one with each of the two DNA variants. When the DNA is heated, it melts. Then, when it cools, it anneals back onto itself. However, three different forms of double-stranded DNA are formed. Two forms are like the original mother strands; the third, however, contains two strands that have mismatched bases—a so-called heteroduplex. This produces a double strand that migrates slightly differently under certain conditions. This can be easily visualized using denaturing high performance liquid chromatography (DHPLC) (Fig. 1-7). After a potential mutation is recognized, the fragment can then be sequenced and the specific base change can be precisely identified. Other methods of mutation detection include allele-specific oligonucleotide hybridization, reverse dot blots, and amplification refractory mutation systems.[79]

Ethical Issues

Genetics has raised a host of ethical issues that had not been of much concern before the 1990s. From the physician's perspective, one issue relates to his or her "duty" to inform patients who are at risk for genetic

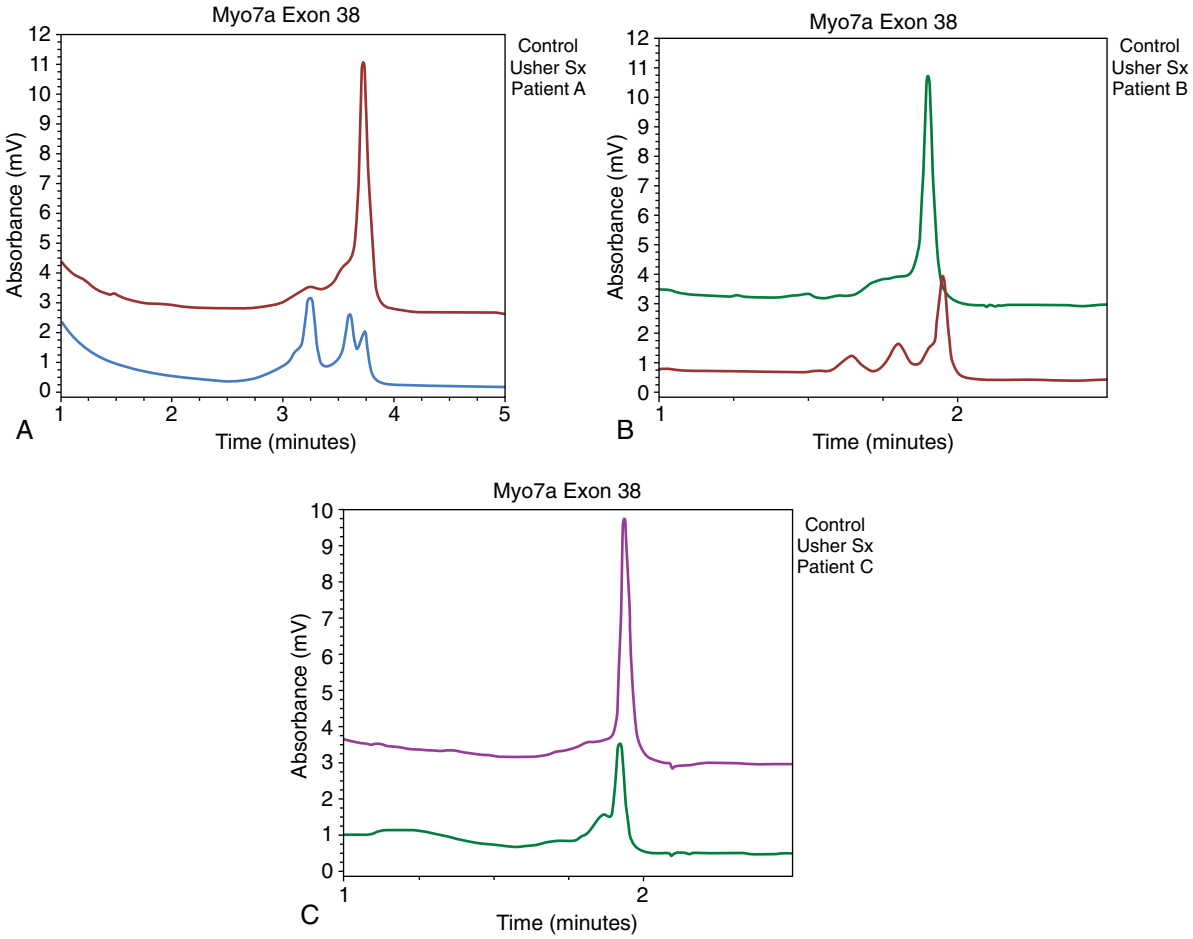

Figure 1-7. Denaturing high-performance liquid chromatography (DHPLC) using a WAVE apparatus is a common method of screening for mutations. This figure shows the results of DHPLC for three different mutations of exon 38 of the Myo7a gene, which causes Usher's syndrome type Ib. A fragment of DNA is amplified by polymerase chain reaction, heated to disassociation, and then cooled. Upon reannealing, four different double-stranded molecules are possible, two of which represent the original fragments. The other two will have double strands that differ slightly (e.g., at only one base) and that cause a slight conformational change that alters their mobility; this is observed as an additional peak or peaks when run out on a column. When a peak is observed, the exact nature of the change must be determined by sequencing.

disorders. If a woman is found to carry breast cancer liability alleles on the BRCA1 gene, is it the physician's responsibility to make sure that this patient communicates the possibility of risk to her female relatives? There is clearly a conflict here between the patient's right to privacy and the responsibility to "do good" by informing women for whom this extra diligence just might be life saving. Any genetic diagnosis carries with it the potential that a person other than the primary patient could be involved. The diagnosis of GJB2 hearing loss identifies siblings, cousins, and other relatives as potential heterozygotes who have an increased risk of having a child with profound deafness. It is not always the case that family members want the information, either. Although the issue is still argued, the general consensus is that the flow of information must come from the patient or an immediate family member, in the case of a minor.

The Utility of Molecular Genetics in Otolaryngology

The main role of molecular genetics in medical science is as a diagnostic tool. At the present time, the emphasis is on disorders that are caused by major genes. DNA testing can be used to definitively establish a diagnosis. This aids in the establishment of a prognosis, the elimination of the need for further expensive (and perhaps invasive) clinical testing, and the provision of information to the family about the likelihood of the disorder in other family members.

CHAPTER TWO

Fundamentals of Molecular Biology and Gene Therapy

Bert W. O'Malley, Jr.

Daqing Li

Hinrich Staecker

Key Points

- Gene therapy strategies involve (1) replacing defective genes with functional variants, (2) enhancing the expression of certain key genes, or (3) suppressing genes that contribute to disease.
- Methods of administering gene therapy include (1) direct injection of DNA/RNA, (2) use of specialized nonviral vectors such as nanoparticles, or (3) administration of a viral vector.
- More than 600 clinical trials have demonstrated the effectiveness of gene therapy in the treatment of a wide range of inherited and acquired diseases.
- Gene therapy has shown significant potential within otolaryngology for the treatment of head and neck cancers, to facilitate regrowth of hair cells within otology, and for tissue engineering in reconstructive and plastic surgery.
- Gene therapy continues to evolve with the introduction of new techniques such as RNA interference, which will revolutionize the treatment of disease in the 21st century.

Molecular biology is a relatively young scientific field, arising in the 1970s after the discovery of methods to study and manipulate DNA. The rapid development of these techniques enabled actual clinical application by the 1980s and 1990s. Many diagnostic laboratory tests routinely used in clinical medicine, as well as methods used to develop and mass-produce pharmaceuticals, make use of molecular biology techniques.

The growing field of molecular biology has also led to the development of novel therapeutic strategies for disease. A new understanding of genes and the products of their expression has allowed the emergence of a rising field heralded as "gene therapy." This rapidly expanding field is founded on the ability to introduce genetic material into the body to modulate the expression of genes and to thereby treat disease or alter an ongoing pathologic process.

This chapter reviews basic molecular terminology and introduces the concept of gene and molecular therapy. Emphasis is placed on the rationale, methods, and progress to date for clinical application of these exciting therapies.

Fundamentals of Molecular Biology

The basic premise of molecular biology is to study cell function and regulation at the level of the genome. With this understanding comes insight into human disease because aberrances in cell function or regulation are the basis for most diseases. The following section reviews fundamental terminology and concepts on how information travels from the genetic code to the functional protein level. Included is a brief discussion on cell cycling, which is an important concept in tumor molecular biology.

Gene Expression

The information for conducting all aspects of cellular function is contained within molecules of DNA located in the nucleus. The actual length of a human DNA strand is 1.8 M; however, it is coiled around nuclear proteins called *histones,* which structure the folds and loops of DNA to allow compression into the microscopic size of the cell's nucleus. Each strand of DNA contains thousands of genes, which are specific subunit sequences that are coded for the information required to synthesize a protein. One molecule of double-stranded DNA and its genes make up each of a cell's 46 total chromosomes. Although every cell in the human body contains the same DNA, the expression of individual genes is not the same. Gene expression varies depending on the cell's function. These differences in gene expression result in the multiple cell and tissue phenotypes that constitute the human body as a whole.

The process by which a gene codes for a specific protein begins with transcription, which is the formation of a single-stranded RNA molecule, which complements a single strand of the DNA subunit (Fig. 2-1). This RNA molecule is subsequently modified to become the messenger, which brings the genetic information or directions from the nucleus to the cell's cytoplasm where the actual synthesis of the functional protein occurs. After reaching the cytoplasm, the process of translation begins (see Fig. 2-1). During translation, the message from

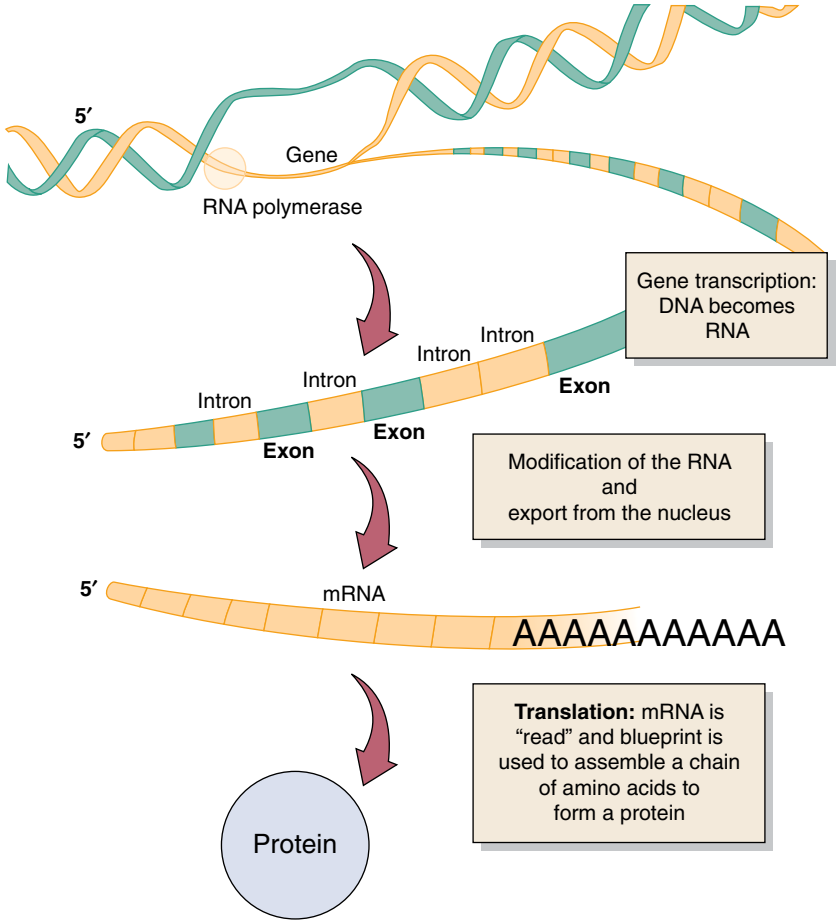

Figure 2-1. The basic steps involved in gene expression. Genes are copied within the nucleus by RNA polymerase, resulting in production of a complementary RNA strand. This is processed to produce mRNA. The mRNA exits the nucleus and undergoes "translation" by ribosomes to form a protein product.

the RNA molecule directs the construction of a protein from its basic subunit, the amino acid. Once a protein is formed, it may require further modification or control steps to enable its designated function. These modifications include the addition of sugars, lipids, or phosphates to the protein backbone. These internal control steps are mediated by existing cytoplasmic enzymes, which, if defective, can also lead to defined diseases. Once a protein is formed within the cell cytoplasm, it can reside in the cell or be released to affect other tissues within the body. Depending on the original genetic program for the protein, it may serve its purpose and be rapidly degraded, or it may enter the circulation or reside in local or distant tissues for an extended period. Although stated simply here, both transcription and translation are complex processes that have many more modification and regulatory steps governed by regulatory genes and their protein products. When these delicate control mechanisms are lost, a disease state or a state of abnormal cell proliferation can ensue, as is exemplified in the development of cancer.

Cell Division

Disorders in cell function can lead either to cell death or proliferation. Abnormal stimulation of cell proliferation is the basis for the development of cancer. For a cell to divide, it must progress through the various phases of growth and reproduction that constitute what is called the *cell cycle* (Fig. 2-2). The principal components of the cell cycle are the replication nuclear DNA and its distribution among the progeny cells (i.e., daughter cells). The first phase of the cell cycle is called G1, and it is here that all the enzymes, nucleic acids, and other factors are produced that will enable DNA replication or "synthesis," which occurs in the S phase. Once the DNA is replicated, a period of cell growth and duplication of cellular proteins and structures occurs in a period called G2. After this cell growth, the actual distribution of the replicated DNA and the physical division of the parent cell into two daughter cells occur in the M phase, which takes approximately 1 hour. After cell division, the cell cycle process can begin again, or the cell may enter a state of rest called G0.

The signal to divide can come from either internal factors or exogenous growth factors, which bind to cell surface receptors and stimulate a cascade of events, which lead to division. Important internal control mechanisms exist at the genetic level, which help regulate cell cycling. The "negative regulatory" genes that code for proteins inhibiting abnormal cell proliferation are called *tumor suppressor genes*. A mutation or loss of a tumor suppressor gene is a basic step in the development of many human cancers. Cell cycling can also be abnormally induced by cellular oncogenes, which naturally exist within cells but are typically kept dormant either by tumor suppressor genes or other regulatory mechanisms. Loss of negative regulation from tumor suppressor genes or amplification or mutation of the actual oncogene has also been associated with cancer formation.

Continued molecular research will provide further understanding of cell cycle regulation and may lead to novel therapies for treating human cancer. A discussion of basic molecular biology techniques, which have provided the means to understand gene expression, regulation, and cell cycling, is found in Chapter 16.

Gene Therapy

The basic principle of gene therapy is that the intrinsic expression of certain genes in body tissues can be modified to treat disease. This may involve replacing a defective gene with a functional version, enhancing

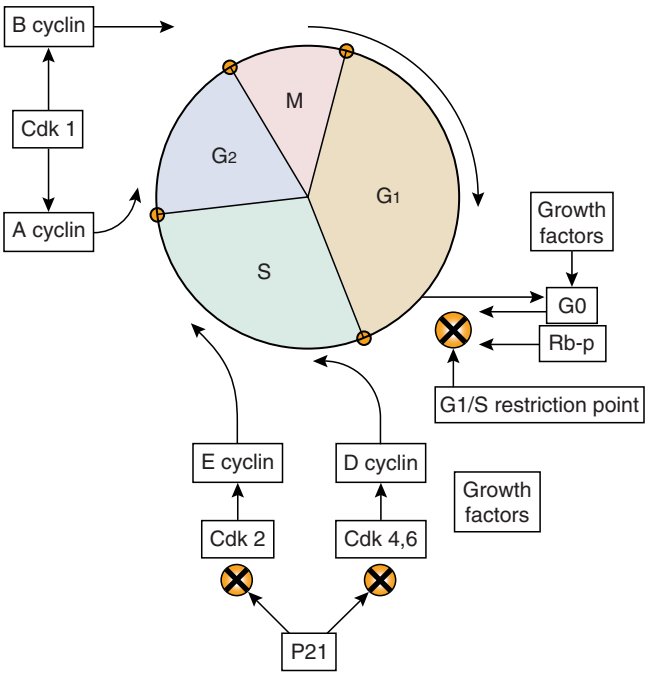

Figure 2-2. Cell cycle. The various phases of the entire cell cycle are depicted, which typically last 10 to 25 hours in animals. Only 1 hour is spent in the M phase. The longest and most variable phase is G1, which can range from 4 to 24 hours. Also depicted are regulation of the cell cycle, many elements of which are targets of gene and molecular therapy.

the baseline expression level of a gene or, contrastingly, suppressing the expression of genes that may contribute to the pathologic process. As the field of gene therapy continues its rapid advancement, it is likely that gene therapy will eventually become a standard clinical regimen available to both internists and surgeons.

Replacing Defective Genes

During the advent of gene therapy, the initial clinical targets were rare inherited diseases such as adenosine deaminase deficiency, which results in a deadly systemic immune deficiency, enzymatic deficiencies resulting in cystic fibrosis and liver disease, or coagulation pathway deficiencies resulting in various types of hemophilia. Gene therapy could be used to introduce a normal gene into the body to compensate for the low or absent function of the patient's mutant gene. For example, a proportion of children born with severe combined immunodeficiency (SCID) have a deficiency in adenosine deaminase (ADA) due to a mutation in the gene encoding this enzyme. Several clinical trials have introduced a functioning ADA gene into the bone marrow of SCID children using a viral vector, effectively reconstituting the patient's immune system.[1] Clinical trials assessing the potential for the treatment of hemophilia B through the transfer of a functioning factor IX gene, and cystic fibrosis via introduction of an intact cystic fibrosis transmembrane conductance regulator (CFTR) gene have also been completed.[2,3] These studies strongly suggest future applicability for gene therapy in the treatment of inherited diseases.

Enhancing Gene Expression

In the past decade, it has become clear that gene therapy may have its most immediate and effective role in treating more common acquired diseases, including various cancers, arthritis, and atherosclerosis.[4,5] In order to tackle these conditions, new approaches have been adopted that focus on increasing the expression of beneficial genes beyond normal levels. For example, in a clinical trial for the treatment of melanoma, tumor-infiltrating lymphocytes (TILs) were purified from a tumor at the time of surgical resection.[6] The TIL cells were then grown in the laboratory, and the gene for tumor necrosis factor (TNF) was introduced into the cells.[7] The genetically engineered cells were subsequently transfused into the patient and preferentially migrated to the site of residual tumor, delivering a therapeutic dose of TNF. As the molecular basis for disease is elucidated, there is likely to be increasing interest in this form of gene therapy.

Suppressing Gene Expression

Most recently, as the molecular pathways that underpin disease—particularly cancers—are unraveled, there has been excitement about the possibility of suppressing key genes known to be involved in the disease process. For example, RET, a proto-oncogene implicated in the pathogenesis of medullary thyroid carcinoma, can be inactivated by inducing expression of a mutant form of the RET gene, resulting in tumor regression.[8] This approach is dependent on the "dominant negative" effect where the mutant gene encodes a protein that retains binding ability to other key proteins that normally interact with the wild-type gene. However, the mutant protein is nonfunctional, creating a competitive inhibition of the wild-type functional variant. Dominant negative therapies are presently being translated to clinical trials in the hope of developing novel treatments, particularly within the field of oncology.

A new technique that may have immense potential for the future of gene therapy is RNA interference (RNAi), a method by which genes can be selectively "silenced." RNAi is a ubiquitous mechanism that is used by the cell to effectively "turn off" specific genes, as described a decade ago in a landmark paper.[9] In this study, injection of double-stranded RNA consisting of both sense and antisense strands into the nematode *Caenorhabditis elegans* profoundly silenced the gene with a sequence complementary to the dsRNA. The potential for RNAi in research and therapeutics was immediately recognized. In effect, any gene, including those involved in cancer, could be silenced and the effect of this loss of function on phenotype could be elucidated. The scientists who discovered RNAi were awarded the Nobel Prize in Medicine in 2006, only 8 years after publication of their initial, landmark paper.

Subsequent studies have partially determined the mechanism for RNAi (Fig. 2-3). In brief, an RNAase enzyme called Dicer cleaves dsRNA to form 21- to 23-nucleotide fragments of RNA. This short-interfering RNA (siRNA) is the actual effector molecule in RNAi.[10-12] The siRNA is integrated into the RNA-induced silencing complex (RISC), after which the sense strand of the duplex is discarded. The antisense siRNA is retained and acts as the "guide strand," directing RISC to mRNA molecules with a complementary sequence.[13] RISC cleaves the targeted mRNA, thereby silencing gene expression by blocking the translation of the mRNA sequence to protein.[10,14]

Considerable progress has been made in applying RNAi to mammalian systems. Transfection of mammalian cells with long dsRNA molecules of more than 30 nucleotides was found to induce a significant host antiviral interferon response that produced a general silencing of untargeted genes and often cell death. This hurdle has recently been overcome by chemically synthesizing 21-nucleotide siRNA molecules and using these to induce efficient, targeted gene silencing in mammalian cells without inducing an interferon response.[11] These siRNAs can be used in subnanomolar concentrations to achieve greater than 90% reduction in mRNA levels, a highly potent gene-silencing effect.[10] Recent animal experiments involving siRNAs have indicated that immune system activation is relatively uncommon, bolstering the safety profile of these novel therapies.

Unfortunately, a persisting problem associated with RNAi techniques are "off-target" effects. This refers to unintended siRNA-mediated silencing of genes that have similar nucleic acid sequences. Even small amounts of sequence homology, as few as seven base pairs, are enough to produce off-target effects. Several computer algorithms have been designed to aid in the selection of siRNAs with minimal off-target effects. It is unclear what effect, if any, off-target effects will have in human trials. In fact, early human trials of RNAi therapies for the treatment of macular degeneration and neurodegenerative diseases have not revealed any significant side effects.[12]

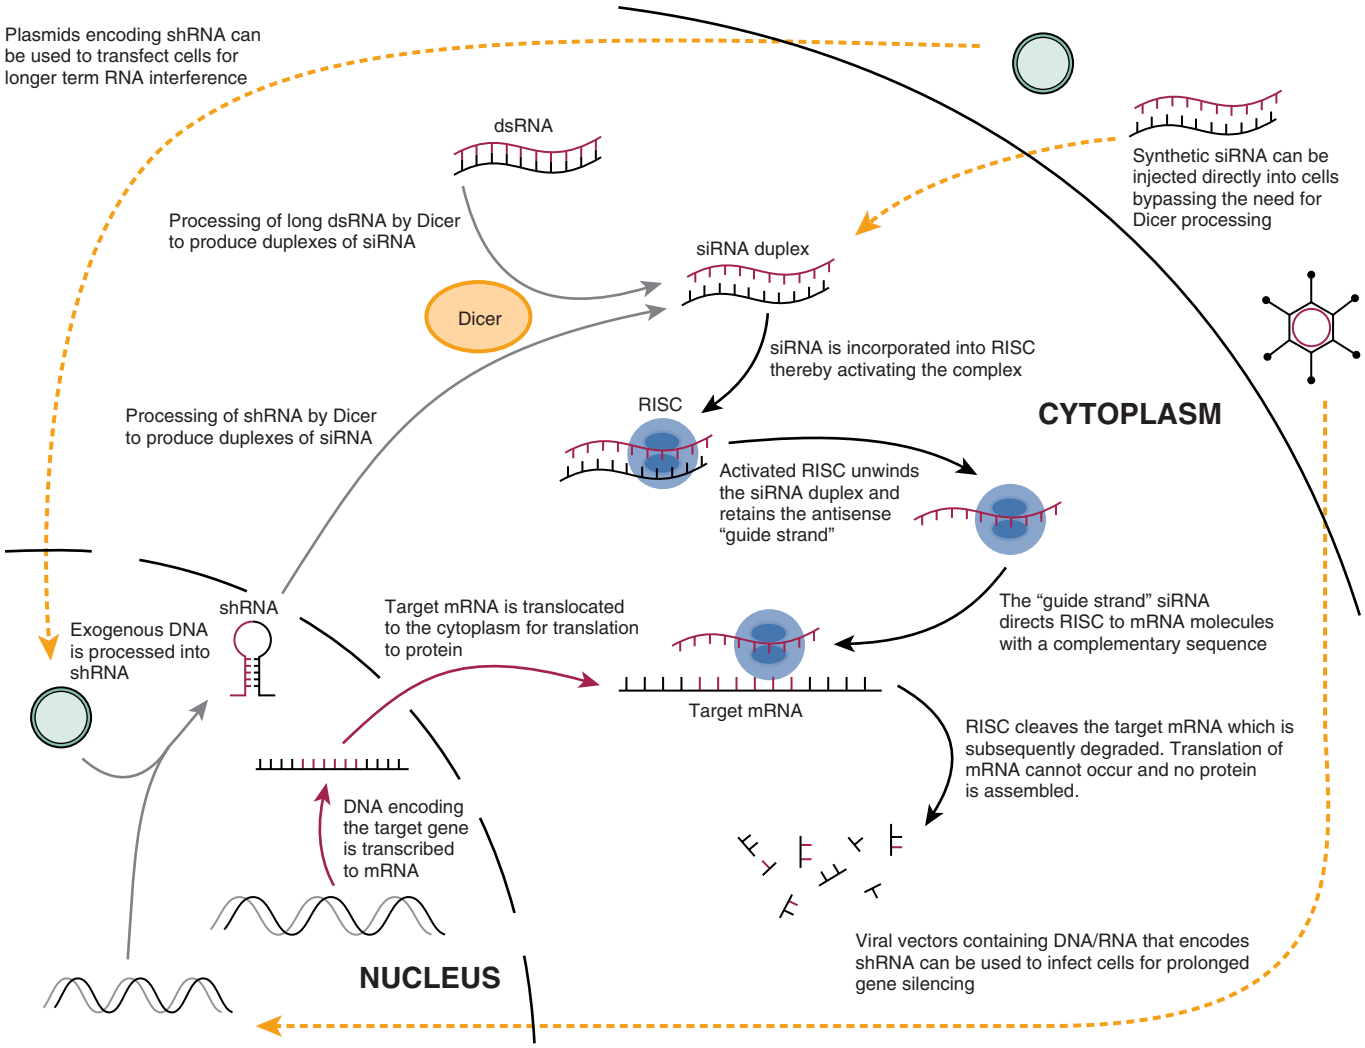

Figure 2-3. Mechanisms of RNA interference. The effector molecule for RNA interference is short-interfering RNA (siRNA). These can be derived endogenously from the production of long double-stranded RNA (dsRNA), which is then processed by Dicer to yield siRNA *(gray arrow)*. Alternatively, synthetic siRNA can be introduced into the cell by direct injection bypassing the need for Dicer *(broken arrows)*. Alternatively, plasmid or viral vectors encoding short-hairpin RNA (shRNA) can be introduced into the cell *(broken arrows)*. The shRNA is then processed by Dicer to yield siRNA *(gray arrows)*. Regardless of the route of production, the siRNA activates RISC, which then "homes in" on the mRNA sequence, which is complementary to that of the antisense siRNA "guide strand" *(black arrows)*. The mRNA is then cleaved and no gene product is produced, effectively "silencing" the gene.

Somatic versus Germ Cell Gene Therapy

Gene therapy has two possible target cell types. The first and presently used targets are the somatic cells, or those cells that constitute the organs and postnatal tissues of the body. The second potential target is the germ cells, or those cells that produce the sperm or ovum and are passed on to a person's offspring. Many different organs and cell types are targets for somatic gene therapy, including bone marrow, liver, tumor cells, muscle, skin, endothelium, thyroid, and others (Fig. 2-4). Genetic manipulation and therapy at these sites does not alter the inherited genetic material and raises few novel ethical or social issues.[15] Genetic manipulation of the sperm or ovum, however, could prevent inherited diseases by altering the genetic constitution of offspring. Although this is an appealing idea on the surface, there are serious technical and safety issues as well as profound ethical concerns involved. Currently, gene therapy is restricted to somatic cells, and genetic manipulation of human germ cells would be prohibited under existing recombinant DNA guidelines.[16]

Permanent versus Temporary Gene Therapy

A common perception is that the goal of gene therapy is to "permanently" modify the expression of the therapeutic gene in the patient. Permanent gene therapy, however, may not be necessary or optimal in a clinical setting. As a general principle, permanent gene therapy could prove more desirable when the methods required for introducing the genetic material into the patient involve significant surgical procedures or substantial risk to the patients such as in the case of organ resection, cellular transplantation, or stereotactic injection under anesthesia. To achieve permanent gene therapy, the expression of the target gene should be either enhanced or blocked indefinitely. The gene must also demonstrate appropriate regulation in response to both normal and pathologic situations, and there should be no detrimental consequences of this gene expression in later life. In considering diseases such as growth hormone deficiency or juvenile diabetes, correction by permanent gene transfer would require precise regulation of the gene products to ensure both short-term efficacy and long-term safety. This tight control and regulation of transferred genetic material is not feasible with present techniques.

For many diseases such as cancer, cystic fibrosis, arthritis, and disorders requiring surgery, "temporary" gene regulation in a patient's tumor, residual tumor, or other target cells could produce a selected beneficial therapy over a limited period of time. For example, the treatment of a tumor or area of residual tumor after surgery may only require

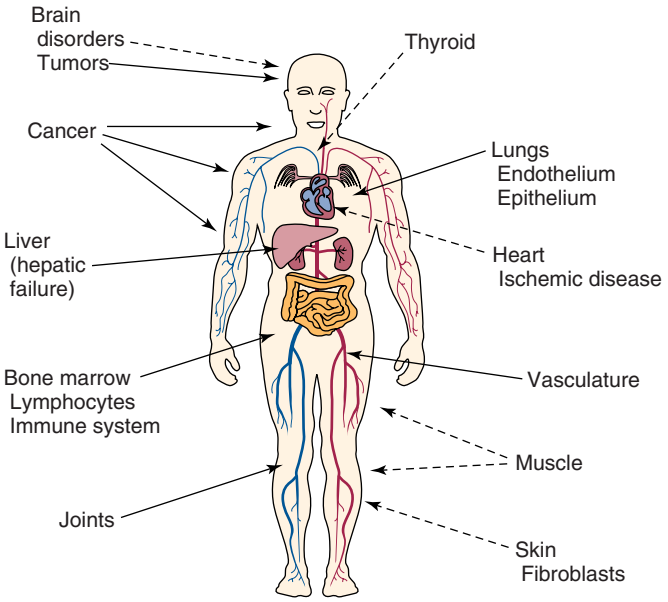

Figure 2-4. Somatic targets for gene therapy. Many different cell types are potential targets for gene therapy. *Solid arrows* represent tissue targets presently under human clinical trial investigation, and *dashed arrows* represent targets under investigation in animal models. Current gene therapy laboratory and clinical investigation explicitly excludes manipulation of germ cells (sperm and ovum), which may pass genes to future generations.

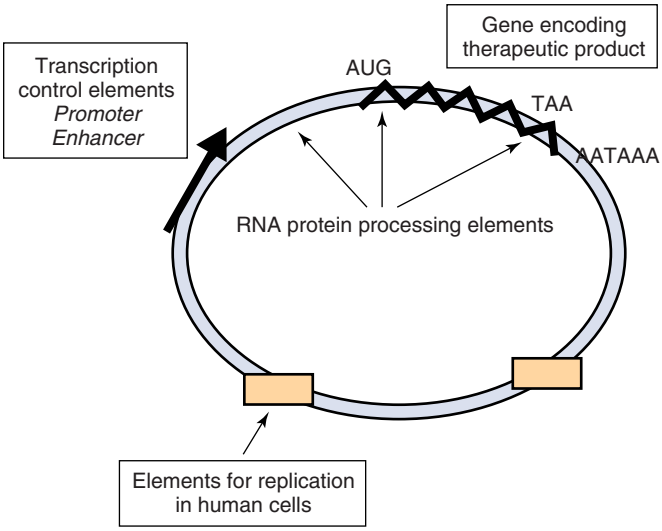

Figure 2-5. Schematic structure of a plasmid DNA vector. Plasmid DNA vectors are circular molecules of DNA encoding a therapeutic gene product. DNA vectors contain special elements required to achieve expression of the gene product at therapeutic levels. Promoter and enhancer regions regulate the transcription of plasmid DNA into RNA, and specific processing elements regulate the translation of RNA into protein. A DNA vector may be complexed with protein, lipids, or synthetic organic compounds that enhance vector uptake or provide cell uptake specificity.

a one-time, limited expression of a gene that either produces a substance directly toxic to the cancer cell or a cytokine or other factor that can initiate an antitumor immune response. Instead of permanent gene therapy, repeat gene transfer over a period of time could also prove effective, as in the case of radiation therapy or possible chemotherapy regimens. With respect to surgical procedures, the use of gene therapy to enhance wound healing or tissue regeneration after an injury might only require gene expression for a period of days or weeks. Another new frontier on the near horizon is minimally invasive or noninvasive routes for gene delivery, such as intramuscular, intravenous, oral, or even aerosol administration. This novel future application could allow the establishment of steady-state gene product levels, which parallels present medical regimens and enables the physician to adjust the dose and schedule of administration to the patient's needs.

Methods of Delivering Gene Therapy

A major focus in the field of gene therapy is the development of vehicles for introducing genetic material into selected target cells. Two general gene therapy delivery methods can be distinguished: (1) direct administration of genetic material, which involves the injection of DNA or RNA into cells in order to modify gene expression, and (2) viral-mediated gene transfer, which involves packaging a therapeutic gene into a defective virus particle and using the natural process of viral infection to introduce the genetic material. The purpose of viral-mediated gene transfer is to exploit the efficient and often complex mechanisms that viruses have evolved to introduce their viral genes into human cells during infections.

The gene that is delivered to a target cell is not itself therapeutic. Rather, it is the product encoded by the gene, which is responsible for the resulting therapeutic effect. The gene product is typically a protein, which has a specific function such as a hormone or cytokine, but could also be a bioactive RNA molecule such as a gene-silencing siRNA that alters the regulation of pathologic processes. Thus, although gene therapy commonly focuses on methods for delivering genes to cells, it is the ability to achieve expression of the gene product at therapeutic levels that ultimately determines the effectiveness and efficacy of therapy.

Direct Injection of Genetic Material

DNA-Mediated Transfer of Therapeutic Genes

The process of DNA-mediated gene transfer is called *transfection*, and the vehicle through which genetic material is transferred into a cell is called a *vector*. Functional DNA vectors are circular molecules of DNA called *plasmids* that contain various additional genetic elements required to achieve expression of the gene product at therapeutic levels (Fig. 2-5). Included in these are the special elements (promoter and enhancer) that direct gene expression and elements that determine the processing and persistence of genetic material within the cell. Plasmid vectors can be used to effectively deliver therapeutic genes to target cells. Plasmids have also been used to prolong the transient, 3- to 7-day gene-silencing effect associated with the transfection of naked siRNAs.

The delivery of DNA vectors into cells is possible via a variety of techniques. One classic method is to simply microinject plasmids directly into the cell nucleus.[17] This technique is both time-consuming and inefficient for achieving large numbers of transfected cells. Although this method is common in the laboratory with in vitro studies, its technical limitations prohibit effective application to living animal models or human subjects. A more efficient process, which also is limited to in vitro application, is the process of electroporation, in which cultured cells are exposed to DNA in the presence of a strong electrical pulse.[18] The electrical pulse creates pores in the cell membrane, which allows electrophoresis of plasmid DNA into the cell.

It is possible to effectively introduce genes into muscle[19] or thyroid[20] simply by injecting DNA into these tissues in vivo, where the process of endocytosis enables cellular uptake. Gene transfer into other organs requires special methods to enhance the uptake of DNA into the specific target cells. A common alternative method is the use of cationic lipids, which encase DNA vectors and fuse with the target cell membrane[21] to enhance intracellular gene uptake. This process has been termed *lipofection*. Another method is to couple the DNA vector to proteins that bind to specific receptors on the target cell leading to uptake of the DNA by receptor-mediated endocytosis.[22,23] A novel approach to DNA vector delivery involves the use of the "gene gun," which uses electrical currents to project microscopic gold beads coated with plasmid DNA into target tissues and organs.[24]

An important point to understand is that DNA-mediated gene transfer typically results in only transient residence of the therapeutic genes in the targeted cell. DNA vectors, which are introduced into cells, are degraded and eliminated from the cell over time. Different cell types eliminate the introduced genetic material at different rates. In muscle, for example, DNA vectors may persist in cells for many months and continue to express gene products.[19] In contrast, DNA vectors injected into the thyroid have a shorter half-life and the gene product is eliminated after 2 days.[20] Vectors introduced into the liver are eliminated with a half-life of approximately 1 to 2 hours and expression is significantly reduced after 6 to 24 hours.[25]

Although permanent incorporation of genes into cells occurs rarely after DNA-mediated gene transfer in cultured cells (less than $1:10^5$ cells), this phenomenon has not been observed in vivo. DNA vectors are therefore considered "safe" because they do not incorporate into the recipient cell's chromosome in vivo and thus should not induce the theoretical risks associated with altering the cell's genome. Moreover, they have not demonstrated significant toxicity to recipient tissues and have not induced any systemic immune response. DNA vectors can thus be delivered repeatedly, which overcomes the potential limitation of transient therapeutic gene expression. The transient nature of gene expression does have an advantage in certain clinical scenarios because the therapeutic gene can be administered by conventional oral, intramuscular, or intravenous routes to provide its beneficial effect over a predictable and extended period. In contrast to conventional medications with short half-lives, DNA-mediated gene therapy could lead to prolonged expression of a gene product at continuous levels, eliminating the need for continuous infusions or enhancing compliance by minimizing the frequency of injections.

Direct Delivery of RNA for Gene Silencing

RNA can also be introduced into cells, opening the door to potential therapeutic implementation of gene silencing. Intravenous administration of siRNA targeting the VEGF gene, for example, has been shown to significantly reduce tumor volume and intratumoral VEGF levels.[26] Unfortunately, the gene-silencing effect of synthetic siRNAs lasts only minutes to a few days before they are degraded. Chemical modification of the RNA can improve stability. The plasma half-life of an unmodified siRNA in a mouse model was 0.03 hour, the half-life of a chemically modified siRNA was 0.8 hour, and the half-life of a lipid-conjugated, modified duplex was 6.5 hours.[27]

Despite the improved stability of modified siRNA, plasma clearance is still rapid and any potential therapeutic benefit will require using chemically modified RNA in combination with some kind of delivery system.[10] Liposomes have been successfully used to deliver siRNA in vivo, and significantly improve both the duration and level of gene suppression compared to nonvector delivery methods. More recently, nanotechnology has been used to design compounds consisting of a cationic polymer that binds the RNA cargo, a neutral "stealth" coating to hide the particle from immune surveillance and a targeting ligand. This type of nanoparticle has been used to selectively target neuroblastoma tumors in nude mice with anti-VEGF receptor siRNA, resulting in a dramatic antitumor effect.[28] Electroporation and "gene gun" techniques have also been used to effectively deliver siRNA in vivo.[10]

The most common method used to date for the delivery of siRNA is termed *hydrodynamic delivery.* This approach involves injecting a large volume of an RNA-containing solution as a rapid intravenous bolus. The hydrostatic pressure generated transiently disrupts the vascular endothelium and achieves siRNA delivery to tissues. To date, hydrodynamic delivery has been successfully used to deliver siRNA to skeletal muscle in rats, dogs, and rhesus macaques.[29] Localized delivery can be achieved by application of a tourniquet to isolate a limb before intravenous injection. The potential for this approach in humans is under investigation and will likely transition to clinical trials soon.[10]

The need for sustained gene silencing has led to the development of novel DNA plasmid expression vectors that direct the synthesis of short RNA over a prolonged period (see Fig. 2-3). The encoded short RNA sequence is transcribed and processed into the effector gene-silencing RNA molecule. One method involves genetically engineering a plasmid to encode a short-hairpin RNA (shRNA). A shRNA molecule consists of a special double-stranded RNA molecule that includes a sharp hairpin turn and is processed in the cell to yield a 21-nucleotide RNA construct capable of gene silencing. Use of DNA plasmid vectors can prolong in vivo mammalian gene silencing for up to several weeks.[12] They are, however, limited by their inability to transfect nondividing cells.[11] This limitation can be overcome, however, through the use of viral vectors to deliver siRNA, which is discussed in the next section.

Viral-Mediated Gene Transfer

The majority of research to date has focused on developing methods for using viruses as vectors. Viral-mediated gene transfer involves the construction of synthetic virus particles that lack pathogenic functions, are incapable of replication, contain a therapeutic gene within the viral genome, and can deliver this gene to cells by the process of infection. Certain viruses have the property of permanently integrating their genes into the chromosomes of the infected cell; therefore select forms of viral-mediated gene transfer can lead to permanent gene therapy. Furthermore, viral-mediated gene transfer has significant advantages over plasmid-based delivery of siRNA to target tissues, in that constructs encoding siRNA can be introduced to both dividing and nondividing cells including neurons, blood, and bone marrow. By altering the type of viral vector used, siRNA expression can be designed to be transient in, for example, cancer therapy or permanent in the case of genetic diseases.

Retroviruses

The original prototypes for viral-mediated gene transfer are retroviral vectors derived from the Moloney murine leukemia virus.[30,31] Retroviral vectors were chosen as vehicles because of several useful properties. First, "defective" virus particles can be constructed that contain therapeutic genes and are capable of infecting cells, but which contain no viral genes and express no pathogenic viral gene products. A general scheme for constructing a defective retroviral particle is illustrated in Figure 2-6. Second, retroviral vectors are capable of permanently integrating the therapeutic genes they carry into the chromosomes of the target cell. Because of this property, retroviral vectors are well suited for treating diseases that require permanent gene expression. Third, modifications can be made in retroviral vectors and in the cell lines producing vectors that result in enhanced safety features.

A major limitation for this strategy is that retroviruses will only integrate into actively dividing cells and the efficiency of retroviral infection is relatively low. It is therefore difficult to generate the large numbers of transduced cells that are required for effective gene expression. This shortcoming has been addressed to some extent with the development of lentiviral vectors, which are related to retroviruses but are capable of inserting into the genome of nondividing cells. Perhaps the most serious problem, however, has been the difficulty in achieving stable, regulated gene expression from retroviral vectors in cells despite the permanent genomic integration. Cells are apparently able to shut off expression from retroviral vectors under certain conditions that have not been clearly defined.

Previous experience in animal models[32,33] and initial experiences in clinical trials suggest that these vectors are, generally, safe. However, there have been serious complications in clinical trials using retroviral vectors to treat X-linked severe combined immunodeficiency. Although gene therapy reconstituted the immune system and produced excellent clinical outcomes in most children, several cases of T-cell leukemia were reported 2.5 to 5 years after therapy.[34] This has been directly attributed to the insertional oncogenesis that can occur when the retroviral vector permanently inserts into the host genome and activates nearby cellular proto-oncogenes. The powerful promoters used to drive expression of the therapeutic gene may also activate nearby genes.[35] Consequently, newer generation retroviral vectors are in development that use weaker promoters to minimize trans-activation of genes. Special "insulator" sequences can also be used to block the transcriptional elements of the vector from interacting with cellular genes. Another option is to include "suicide" genes in the vector that will initiate cell death in overproliferating cells.[36] These methods have shown early promise but have yet to be used in a clinical trial.

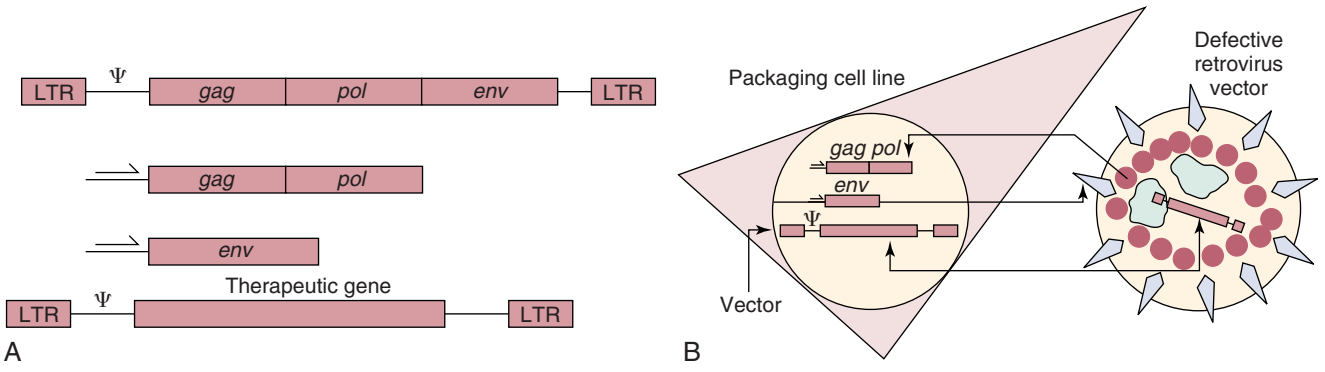

Figure 2-6. Construction of a replication-defective retroviral vector. **A,** The Moloney leukemia virus genome encodes three polyproteins—*gag*, *pol*, and *env*—which together constitute a retroviral particle. The *gag* and *pol* genes encode the inner core of the retrovirus as well as enzymes required for processing the retroviral gene after infection of the target cell. The *env* gene forms the outer envelope of the virus and recognizes a specific receptor on target cells. Defective retroviral vectors are made using several recombinant genes: one that expresses the *gag-pol* polyprotein, one that encodes the *env* protein, and one that contains the therapeutic gene in conjunction with two LTR (promoter and enhancer) sequences and the psi (packaging) sequence. **B,** A packaging cell line expresses *gag*, *pol*, and *env* from the constructs shown in **A**. When a vector containing the therapeutic gene with the LTR and psi sequences is introduced into this cell, a nonpathogenic viral particle will be assembled from the *gag*, *pol*, and *env* proteins that is capable of carrying the therapeutic sequence into cells by the process of infection. *(Reprinted from O'Malley BW Jr, Ledley FD. Somatic gene therapy. Methods for the present and future.* Arch Otolaryngol Head Neck Surg. *1993;119:1100. Copyright 1993, American Medical Association. Used with permission.)*

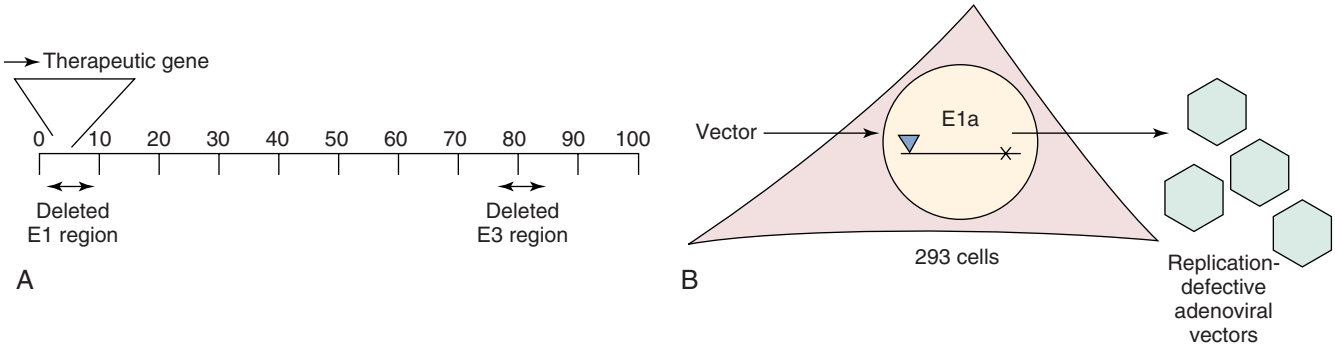

Figure 2-7. Construction of a replication-defective adenoviral vector. **A,** Adenoviral vectors are constructed using a deleted adenoviral genome that lacks the E3 gene as well as the E1 gene that is required for producing a proliferating adenovirus particle. Recombinant genes are inserted into the site of the E1 gene. **B,** Adenoviral particles are produced in the 293 cell line that is able to express E1 and is thus capable of assembling a viral particle containing only the recombinant viral genome with the therapeutic gene. *(Reprinted from O'Malley BW Jr, Ledley FD. Somatic gene therapy. Methods for the present and future.* Arch Otolaryngol Head Neck Surg. *1993;119:1100. Copyright 1993, American Medical Association. Used with permission.)*

Adenoviruses

A recent focus of gene therapy has been the development of adenovirus vectors as powerful and effective vehicles for gene transfer.[37] An overview for the construction of a replication-defective adenoviral vector is shown in Figure 2-7. Adenoviral vectors differ from retroviral vectors in that they remain episomal; that is, they do not integrate their genes into the target cell's chromosome. Compared with retroviral vectors, adenoviral vectors demonstrate the significant advantage of infecting a wide variety of both dividing and nondividing cells in vitro and in vivo with a high level of efficiency.[38-40] Using adenoviral gene transfer, expression of the therapeutic gene is possible for a period of several weeks to months. More recently, adenoviral vectors have been designed to encode and transiently express shRNA, which may be particularly useful in therapeutic strategies against cancers where long-term RNAi is not necessarily desirable.[12]

First-generation adenoviral vectors contained a deletion of portions of their E1a and E3 regions with the former acting as a "master switch" regulating the expression of other viral genes that are critical for viral replication. Consequently, all first-generation adenoviral vectors are replication-deficient. However, despite these modifications, several of the remaining viral genes are still expressed, markedly increasing immunogenicity.[4] This was highlighted during a clinical trial using a first-generation recombinant adenoviral vector that induced a severe systemic inflammatory response that resulted in the death of one patient with partial ornithine transcarbamylase deficiency.[41] The significant limitations imposed by the risk of a severe inflammatory response, as well as the transient gene expression induced by first-generation adenoviral vectors, have been addressed to some extent with further manipulation of the adenovirus genetic backbone. These newer second-generation adenoviruses have E1a, E2a, E3, and E4 region deletions, leaving very few intact viral genes, thereby greatly reducing inflammatory responses. These newer vectors can also remain in the target cell for months.[4,42] The latest generation adenoviral vectors are termed "gutless" and contain no viral genes at all, lowering immunogenicity even further.

The most recent efforts have focused on engineering adenoviral particles to specifically target cell receptors that are highly expressed on the surface of target tissues. This would reduce the risk of a host immune response by increasing the efficiency of gene transfer and reducing the required dose of adenovirus. Multiple studies have demonstrated that this can enhance delivery of therapeutic genes to target cells such as tumors.[43-46] Clinical data are pending and will need to be evaluated in order to determine whether targeted adenoviruses can potentially circumvent the adverse effects associated with untargeted vectors.

Overall, there has been considerable experience with the use of adenovirus vectors in both animal models and over the course of approximately 200 human clinical trials in the United States alone. This research suggests that there is a high margin of safety associated with the use of these vectors.[38-40,47]

Adeno-associated Virus

Recent work has focused on the utility of adeno-associated virus (AAV) in gene therapy. AAV, like retrovirus, permanently integrates into the chromosomes of the target cell but, unlike retrovirus, can stably infect nondividing cells for prolonged periods.[48] Furthermore, AAV vectors integrate in a predictable location within the infected cell and may be safer than retroviral vectors because they do not induce insertional mutagenesis or an innate immune response. Early human trials have used AAV vectors encoding factor IX to boost the levels of the coagulation factor in patients with hemophilia B.[3] These early AAV serotype 2 vectors have the main limitation of only being capable of infecting certain cell types. Newer generation AAV serotype 1 vectors are more than 1000-fold more efficient at infecting a range of cell types.[49] Ligands to cell surface receptors can also be integrated into the capsid of AAV to produce targeted vectors.[4] A disadvantage of AAV is that a wild-type "helper virus" is required to help produce the therapeutic recombinant vector. The "safe" recombinant vector must then be purified from the potentially cytotoxic helper virus before amplification. Further investigation is required to define the role and safety of AAV in clinical application. A summary of viral vector characteristics and gene transfer principles is shown in Table 2-1 and Figures 2-7 and 2-8.

Strategies for Administering Gene Therapy

Two general strategies exist for administering gene therapy (Fig. 2-9). The first and earliest conceived strategy is ex vivo gene therapy, in which tissue from a patient is removed by a surgical biopsy, cells are isolated and grown in culture, genes are inserted into these cells (typically using retroviral vectors), and the cells are then reimplanted in the body by autologous transplantation. The second is in vivo gene therapy, in which DNA or viral vectors (predominantly adenoviral vectors to date) are administered directly to patients.

Ex Vivo Gene Therapy

The initial clinical trials of gene transfer and gene therapy used the ex vivo strategy to deliver genes to lymphocytes, hepatocytes, tumor cells, fibroblasts, or bone marrow stem cells.[50,51] The intent of ex vivo gene therapy is to create a population of cells within the body, which permanently express a therapeutic function. Thus ex vivo strategies for gene therapy commonly make use of retroviral vectors because they integrate into the target cells and theoretically result in permanent therapeutic gene expression.

The initial attraction of ex vivo gene therapy stemmed from the concept that gene transfer could be performed in the laboratory under controlled conditions without exposing the patient directly to a viral or DNA vector. Ex vivo strategies, however, require methods for cellular transplantation to return the genetically manipulated cells back into the patient. Whereas bone marrow transplantation, lymphocyte transfusion, and skin grafting are accepted clinical procedures, there is little precedent for the transplantation of cells into solid organs. At present, this approach continues to be a difficult field of surgical research. Methods have been described for transplanting hepatocytes,[52] thyroid follicular cells,[53] myoblasts,[54] or fibroblasts,[55] although the effectiveness of these methods has not yet been established in clinical practice. In the above models, the number of cells that can be transplanted into the body may limit the amount of the therapeutic gene product that can be expressed by ex vivo methods.[52]

In Vivo Gene Therapy

A major recent focus in gene therapy is the application of in vivo strategies for gene therapy in which genes are administered directly to patients using viral or DNA vectors. Investigations in animal models with retroviral vectors have demonstrated that it is possible to infect dividing cells in the liver, endothelium, lung, or tumors in vivo.[50,51] Studies using adenoviral vectors have demonstrated infection of both

Table 2-1

Viral Vectors Currently Used for Gene Therapy

	Adenovirus	Retrovirus	Lentivirus	Adeno-associated Virus	Herpesvirus
Infectivity	Broad, high efficiency	Dividing cells only, high efficiency	Broad	Nondividing cells, minimal innate immunity	Nondividing, high efficiency
Integration	Episomal	Nonspecific chromosomal	Nonspecific chromosomal	Specific chromosomal	Episomal
Viral titer	High	Low	Low	Low	Low
Max. insert size	Intermediate (~8 kb)	Intermediate (~10 kb)	Intermediate (~10 kb)	Small (~5 kb)	Large (~36 kb)
Risks	Innate immune response	Insertional mutagenesis with secondary malignancy	Insertional mutagenesis with secondary malignancy	Wild-type virus contamination, adaptive immune response	Potential innate and adaptive immune response
Viral production	Helper-free	Helper-free	Helper-free	Helper virus	Helper virus and helper-free vector
No. of U.S. clinical trials	194	>600	6	32	13
Examples of disease applications	CF, colon cancer, ovarian cancer, mesothelioma	ADA-SCID, X-linked SCID, CGD, familial hyperlipidemia	HIV, Mucopolysaccharidosis, AIDS lymphoma	CF, hemophilia B, Canavan disease, AAT deficiency	Brain tumors, colon cancer

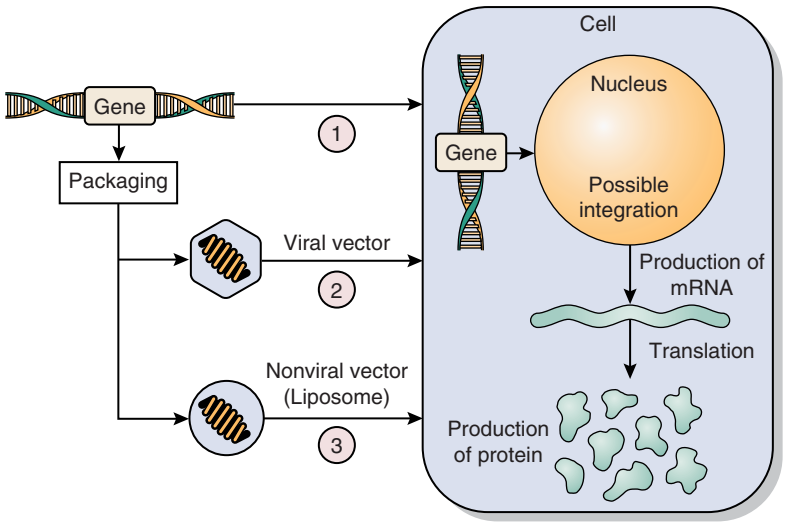

Figure 2-8. Transfer of genes can be achieved through several different delivery mechanisms. Gene transfer was originally described in muscle using naked DNA injected directly into muscle (1). This generally is considered a low-efficiency method of gene transfer but may be very useful for the development of DNA vaccination strategies. Packaging into viral vectors (2) allows for the most efficient gene transfer but is associated with safety concerns. Nonviral vector technology (3) involves coated or condensing the gene construct to allow easy passage into the cell. It is less efficient than viral vector–mediated gene transfer but is considered safer. The final common pathway for all gene delivery is production of a protein resulting in a change in cell phenotype. Alternate gene therapy strategies being developed use inhibitory RNA to decrease the expression of certain genes.

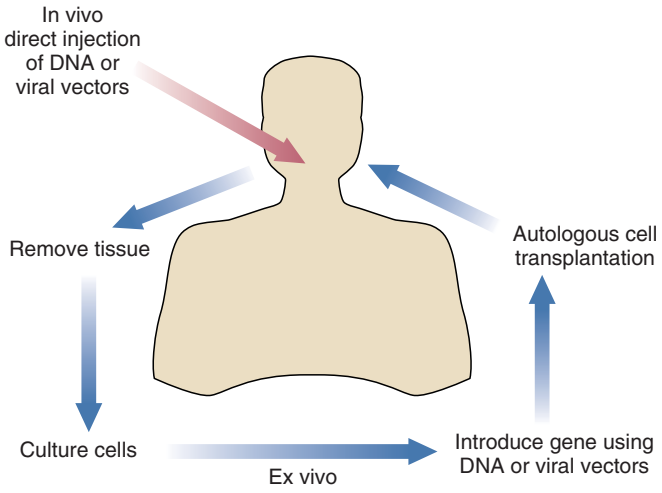

Figure 2-9. Strategies for ex vivo and in vivo gene therapy. In vivo strategies for gene therapy involve the direct administration of DNA or viral vectors to the patient by conventional routes of injection *(red arrow).* Ex vivo strategies involve removing tissue from the patient, growing cells in culture, introducing genes into these cells in the laboratory, and then returning the genetically modified cells to the patient by autologous transplantation *(blue arrows). (Reprinted from O'Malley BW Jr, Ledley FD. Somatic gene therapy. Methods for the present and future.* Arch Otolaryngol Head Neck Surg. *1993;119:1100. Copyright 1993, American Medical Association. Used with permission.)*

dividing and nondividing cells in the pulmonary epithelium,[56] liver,[57] muscle,[58] a variety of tumors,[39,40] and other tissues in vivo. Other studies have demonstrated the feasibility of delivering DNA vectors to organs including muscle,[19] thyroid,[20] liver,[23] and joints[59] in vivo.

Whereas the goal of ex vivo gene therapy is to permanently introduce a recombinant gene into a patient's cells, the primary goal of in vivo strategies can vary depending on the tissue and disease for which the treatment has been designed. In vivo gene therapy can be performed with single treatments for certain tumors,[39,40] administered intermittently in response to acute disease or given long-term to establish steady-state levels of the therapeutic gene product. The in vivo strategy correlates with conventional regimens of medical therapy; however, the gene therapy could provide prolonged or improved effects. Furthermore, the in vivo strategy facilitates the combination of conventional medical treatments or surgical procedures with gene therapy to potentially provide synergistic effects. It is the development of in vivo and relatively noninvasive methods for gene delivery that may allow the widespread application of gene therapy to the routine problems of medicine and surgery.

Therapeutic Levels of Gene Expression

Effective gene therapy requires not only the delivery of genes to the appropriate target cell within the body but the expression of the therapeutic gene product at appropriate levels. It is the ability to achieve adequate gene expression that will determine the efficacy and therapeutic index of gene therapy. There are several ways to achieve appropriate expression of a therapeutic gene product.

Specific genetic elements called *promoters* and *enhancers* that normally control the rate of therapeutic product expression can be incorporated into the gene transfer vehicles. These elements can also control the level of gene expression, restrict it to specific cell types, and provide regulated gene expression in response to endocrine or pharmacologic factors. For example, gene therapy for diabetes will certainly require the incorporation of genetic elements that provide normal regulation of insulin levels by glucose.

Promoter and enhancer elements derived from different genes can be combined to provide an improved effect. In this way, vectors can be designed to produce gene products at high levels from a cell that normally produces only low levels or to constitute expression of a gene product from a cell that does not normally produce that particular gene product. For example, clotting factors or peptide hormones can be expressed from muscle cells after gene transfer using vehicles that incorporate the promoter and enhancer elements from muscle-specific genes such as skeletal actin or myosin. In considering cancer gene therapy, highly efficient viral promoters can be mixed and matched with a variety of gene-delivery vehicles that will result in high levels of expression of therapeutic antitumor genes directly from the targeted cancer cells.

Another important regulatory mechanism resides in the natural actions of a cell, tissue, or organ. As is the case with conventional pharmaceuticals, the basic principles of drug distribution, metabolism, and elimination within the cells and tissues of the body will provide additional means for regulating the level of the gene product.

Why Gene Therapy?

An important universal question asks what advantages gene therapy has over the present accepted medical and surgical treatments that would warrant clinical investigation and application in routine patient care. In response to this basic question are several reasons why gene therapy might become a first-line treatment in clinical practice.

New Therapeutic Approach

With the rapid evolution of molecular biology over the past decade, an increasing number of basic biologic phenomena and pathologic conditions are now understood in terms of the events that take place on a molecular level between genes and their gene products. According to both experimental animal models and early human clinical trials, it is now possible to alter processes such as immunity, growth, development, regeneration, and malignancy on a molecular level using gene transfer. Furthermore, the new field of RNA interference provides a potent method of completely silencing specific genes. This will become an increasingly important area of study as the molecular pathways and the genes that govern these pathways are elucidated. Therapeutic gene transfer provides a novel approach to diseases that are not satisfactorily managed using conventional pharmacologic or surgical intervention. As a general example, using gene therapy to reconstitute deficient functions resulting from failing organs or tissues may provide an alternative to allogeneic transplantation of bone marrow, solid organs, or individual cells.

Site-Specific Gene Expression

Using the techniques and principles of gene transfer, therapeutic products can be released from specific cell types in precise locations within the body. This concept of site-specific gene expression provides a valuable advantage for gene therapy. Therapeutic proteins such as cytokines or growth factors can be expressed in precise locations, rather than administering similar products via a systemic route. The highest concentration of the therapeutic product will therefore be focused at the desired site of action. For example, gene transfer can be used to express products specifically in the epidermal or dermal layers of the skin without affecting underlying connective tissue, nerves, muscles, or vessels. Such spatial specificity will minimize untoward consequences or toxicity in organs or other vital structures outside of the site being treated.

Improved Efficacy and Safety

Gene therapy establishes the expression of normal, human proteins acting in a directed therapeutic fashion within the body. Based on this concept, gene therapy may prove to be more efficacious and safer than the application of proteins purified from microorganisms, animals, or human populations, which carry the attendant risk of transmitting pathogens or inciting allergic reactions. Moreover, gene therapy can be used to achieve regulated, physiologic expression of gene products, which may further improve efficacy. By altering the dose or schedule of gene administration to a patient, it will be possible to optimize the level, effect, and safety of the gene product.

Improved Routes of Administration and Compliance

Most standard medications have short half-lives and need to be administered by frequent oral dosing, injections, or even constant infusions to achieve an optimal therapeutic effect. Gene therapy, however, provides continuous endogenous expression of natural protein products and requires less frequent administration (of the gene), ranging from one time to weekly or monthly treatments, depending on the disease target and gene transfer strategy. As is known to all clinicians, decreasing the frequency of administration improves acceptance and compliance with therapeutic regimens.

Preventive Medicine and a Reduction in Health Care Costs

As molecular and genetic research continues to identify factors that predispose individuals to diseases such as atherosclerosis, cancer, diabetes, infections, or degenerative disorders, the application of gene therapy may allow a physician to alter the expression of these factors in a preventive manner. Of particular importance is the ability to deliver therapy over a long period in clinically asymptomatic or minimally symptomatic patients who have inherited or acquired progressive diseases—a combination of circumstances that is traditionally associated with poor compliance. For example, treating a diabetic patient with gene therapy early in the stages of the disease may prevent morbidity later in life that occurs even with conventional exogenous insulin therapy. Also, combining the advances in molecular diagnostics of cancer may allow replacement of lost or defective critical tumor-suppressor genes in normal or premalignant tissues, thereby preventing the progression of the defective tissue into cancer.

Because gene therapy can establish continuous release of a therapeutic product with one-time treatment or infrequent dosing, its use for prevention is more practical and affordable than conventional therapies. The practice of preventive gene therapy to diminish morbidity and early mortality and the use of more affordable treatment regimens will ultimately reduce the rapidly growing cost of health care.

Applications of Somatic Gene Therapy in Otolaryngology

Gene therapy is relatively new to the field of otolaryngology–head and neck surgery. Its applications are broad and important, and advances in overlapping medical and surgical fields can be applied to the diseases and clinical scenarios common to otolaryngologists.

Inherited Disease

A variety of inherited diseases are associated with head and neck pathology such as sinus disease in cystic fibrosis; hearing loss in Usher's, Alport's, or Pendred's syndrome; and goiter in certain forms of congenital hypothyroidism. In some of these diseases it might be possible to place a normal gene in appropriate cells to carry out the function of the inherited, mutant gene. For example, the first clinical trial of gene therapy for cystic fibrosis involved the introduction of a normal CFTR gene into the nasal mucosa using adenoviral vectors.[60] The intention of this study was to assess expression of the CFTR gene in the respiratory epithelium and to determine any toxic or inflammatory adverse effects. This trial provided a foundation for future studies in which the CFTR gene would be replaced throughout the respiratory tract using viral or DNA vectors.[61]

Head and Neck Oncology

Many of the initial clinical trials of somatic gene therapy are focused on the treatment of cancer. Gene therapy for head and neck oncology patients remains a focal point for this emerging strategy. The original head and neck tumor target was melanoma, but squamous cell carcinoma quickly became the target of choice for human clinical trials. Various approaches for treating cancer by gene therapy have been proposed (Fig. 2-10) and are applicable to common head and neck tumors.

Genetic Modification of Tumor-Infiltrating Lymphocytes

Although the first clinical trial of gene therapy involved only the introduction of marker genes into TIL cells, which infiltrate solid tumors such as melanoma, this trial founded the principle, feasibility, and safety of gene transfer into human patients. The original interest in TIL cells stems from prior studies demonstrating that adoptive transfer of TIL cells coupled with the administration of interleukin-2 (IL-2) could cause significant tumor regression in some patients with malignant melanoma.[62] TIL cells, however, are relatively inefficient in destroying tumors despite their ability to selectively infiltrate tumor sites.

Gene therapy is therefore an ideal strategy to increase the antitumor potential of TIL cells by providing concurrent expression of stimulatory proteins such as cytokines. One clinical trial for cancer patients used autologous cancer cells modified with a gene that produces IL-2,

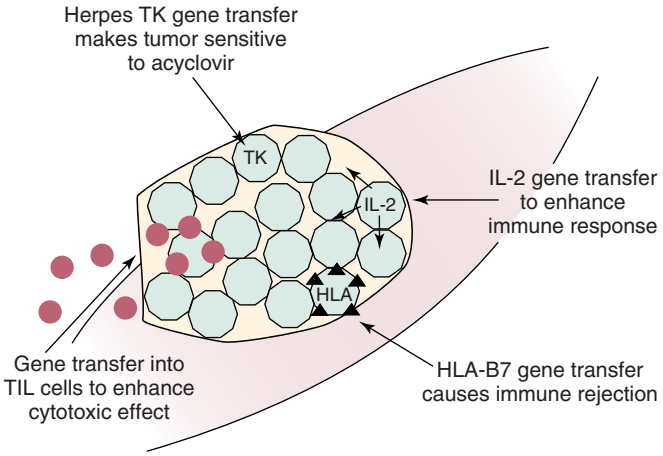

Figure 2-10. Strategies for gene therapy of cancer. Several different strategies have been described for treating cancers by gene therapy. These include expression of cytokines such as interleukin-2 within tumor cells to enhance the immune response against tumor-specific antigens; introduction of a foreign transplantation antigen such as HLA-B7 to induce immune rejection; introduction of cytokines into tumor-infiltrating lymphocytes (TIL cells) to enhance their cytopathic effect; and introducing genes such as herpes TK to make tumor cells sensitive to drugs such as acyclovir or ganciclovir. *(Reprinted from O'Malley BW Jr, Ledley FD. Somatic gene therapy. Methods for the present and future.* Arch Otolaryngol Head Neck Surg *1993;119:1191. Copyright 1993, American Medical Association. Used with permission.)*

a cytokine that increases the immunogenicity of cancer cells and suppresses tumor growth.[63] This strategy involved transfer of the gene for IL-2 directly into a patient's tumor, which resulted in the local formation of tumor-specific cytolytic TIL cells. An excisional biopsy of a draining lymph node allowed harvesting of sensitized TIL cells that were multiplied in culture and then transfused back into the patient. The TIL cells, now sensitized to the specific tumor, could then be infused into the patient and would home in on any cancer tissue or cells to enact a cytolytic response. This protocol focuses on patients with primary or metastatic cancer for which standard therapy has proved ineffective.

Direct In Vivo Stimulation of an Antitumor Immune Response

This method of cancer therapy involves introducing genes for various cytokines directly into tumor cells to increase the natural immune response to tumor-specific antigens. The human body has natural cellular and humoral immune effectors that inhibit or prevent tumor cell growth. Examples of such effectors include major histocompatibility complex (MHC)–restricted cytotoxic T cells, natural killer cells, and lymphokine-activated killer cells. The majority of human malignancies, however, arise in immunocompetent individuals, which implies that tumor cells escape the body's natural immune defenses. Tumors are also known to lack or demonstrate deficiencies in the expression of class I MHC antigens, which prevents recognition and attack by cytotoxic T cells.[64]

In animal models, the transfer of the gene for foreign class I MHC histocompatibility leukocyte antigen (HLA)-B7 into colon carcinoma, melanoma, and sarcoma cell lines has resulted in cytolytic activity from splenic lymphocytes.[65] In this immunologic gene therapy strategy, the gene for HLA-B7 expression is transferred into a cutaneous melanoma lesion of patients who have primary or recurrent tumors or distant metastases that have not responded to conventional therapy.[65] Expression of the HLA-B7 antigen on the melanoma cells is expected to lead to rejection of the primary tumor and metastases by the immune system. B7 gene therapy using nonviral vectors has been approved for a multitumor phase I clinical trial that includes head and neck squamous cell carcinoma.

In a head and neck cancer animal model, the use of adenoviral-mediated delivery of the cytokine IL-2 in combination with a cytotoxic gene has demonstrated synergistic effects on tumor regression.[66] The proposed mechanism is the stimulation of a cytotoxic T-cell immune response magnified by released tumor antigens and cellular debris created by the cytotoxic gene. Recent work has focused on the antitumor cytokine, tumor necrosis factor alpha (TNF-α) which binds to cellular receptors to trigger apoptosis. This apoptotic effect is selective for cancer cells, leaving normal cells unharmed. Despite this inherent selectivity, attempts at systemically administering TNF-α have been unsuccessful due to severe hypotension and shocklike symptoms. TNFerade is a second-generation adenoviral vector with the TNF-α gene inserted downstream of the early growth response 1 promoter, which is induced by ionizing radiation. Thus the activation of transgene expression can be triggered in target tissues through irradiation. In a phase 1 clinical trial, intratumoral injection of TNFerade was shown to have a wide therapeutic window and, coupled with radiation, is capable of inducing complete regression in a range of advanced solid tumors, including melanoma.[67]

Randomized controlled trials investigating immune modulation gene therapy are currently underway and may herald a new approach to the treatment of cancer.

Cytotoxic or Suicide Gene Therapy Strategies

Methods have been described for altering the response of tumor cells to chemotherapeutic agents. One experimental approach involves infecting tumor cells by direct injection with a retrovirus that encodes the thymidine kinase gene from herpesvirus.[68] Because retroviruses infect dividing cells, this virus selectively enters growing tumor cells, causing them to express the herpes thymidine kinase gene and making them susceptible to chemotherapy with ganciclovir or acyclovir. Because these drugs are relatively nontoxic to the immune system, this treatment not only eliminates the fraction of cells that are infected with the virus, but also allows for a more general immune response against tumor-specific antigens.

Based on the low efficiency of retrovirus application in animal model and human application, highly efficient adenovirus vectors have been created, which are capable of transferring the thymidine kinase gene directly to tumor cells.[40] This system has been effective in animal models and received approval from the U.S. Food and Drug Administration for a phase I clinical trial in 1996, which was not completed because of insufficient funding.

Modifying Oncogenes and Tumor Suppressor Genes

The discovery of oncogenes and tumor suppressor genes that are involved in the transformation of normal cells into tumor cells has stimulated new approaches for molecular therapy. Oncogenes are naturally present in cells and have proposed functions involving growth and differentiation until a mutation or over-expression activates them to oncogenic potential. Tumor suppressor genes are also naturally occurring, and their expression prevents unrestrained cell proliferation. A deletion or mutation that results in loss of tumor suppressor gene function will therefore allow uncontrolled cell growth. Mutations in the tumor suppressor genes *p53* and *p16* have been detected in a variety of human tumors and a majority of head and neck cancers.[69] (Refer to Chapter 14 for a discussion of tumor suppressor genes and their relation to head and neck cancer.)

Most gene therapy clinical trials for head and neck cancer have used adenoviruses to restore normal p53 function. This work is based on several studies from the early to mid-1990s illustrating the efficacy and safety of the Ad5CMV-p53 vector in vitro and in vivo for the treatment of head and neck cancer.[70-72] Using nude mouse models, Ad5CMV-p53 induced apoptosis and regression of squamous cell carcinoma without adverse effects. The consistent efficacy of p53 gene transfer in a variety of animal tumor models led to the development of the p53-containing adenoviral vector INGN201 (Advexin). This has since been followed by the approval of Gendicine, a similar adenoviral-based p53 gene therapy agent designed and approved for use in China.

The efficacy of Ad5CMV-p53 based therapy in human trials remains controversial. Several clinical trials have been conducted to date

in patients with ovarian, lung, bladder, esophageal, and breast cancers. Clinical efficacy and safety was demonstrated in several of these studies with improved locoregional control of disease.[73-76] However, other trials have shown no difference in clinical outcome between Ad5CMV-p53 monotherapy and conventional treatments.[77] For example, a recent multicenter p53 gene therapy trial for ovarian cancers was halted due to lack of clinical benefit.[78] In contrast, there is growing evidence from phase I and II trials for a significant benefit of adenovirus-mediated p53 gene therapy in head and neck cancers with improved locoregional disease control and a transient survival advantage.[79,80] Most recently, clinical trials have added gene therapy to conventional treatments in the hope of enhancing clinical response. Preliminary results from phase II and III trials consisting of 135 patients with advanced head and neck squamous cell carcinoma that combined p53 intratumoral gene therapy with radiation demonstrated complete tumor regression in 64% of patients and partial regression in 32%, with self-limiting fever as the only noted adverse effect.[81,82]

In order to improve the overall efficacy of adenoviral-mediated gene therapy in clinical trials, several technical issues will need to be overcome. Methods of ensuring transfer of tumor suppressor genes into a majority of tumor cells will need to be developed. This may involve retargeting viral particles as briefly discussed earlier in this chapter. Furthermore, the expression of the suppressor gene is transient, and the tumor regression in these studies has not been permanent. The development of more advanced viral vectors capable of prolonged gene expression may help circumvent this obstacle. The therapeutic potential for a targeted viral vector with sustained gene expression is considerable, but robust clinical data will be needed before gene therapy can transition from an experimental to a routine treatment.

Conditionally Replicating Adenovirus Therapy

Until recently, all viral vectors used in gene therapy strategies were replication-incompetent. Although the use of replication-incompetent or "nonpathogenic" viruses was based on safety precautions, the strategy does not take advantage of the powerful ability of viruses. That is, viruses have the ability to easily infect target cells, replicate, and release viral particles, thereby killing target cells and spreading to surrounding target cells to continue this process. Continued research and investigation in the fields of molecular biology and the genetics of cancer have led to a greater understanding of the principles of viral replication and the genetics of carcinogenesis. This greater understanding has allowed the development of replication-selective oncolytic viruses for use as novel anticancer therapies.

Conditionally replicating viruses have been engineered to selectively infect and replicate in targeted tumor cells that have inherent genetic defects such as loss of p53 gene expression. Tumor cells that lack p53 expression allow select viral replication that kills the host tumor cell, and then subsequent spread and infection of surrounding tumor cells results in further tumor kill. This modification of classic suicide gene therapy into suicide viral therapy may prove to be a key advance in overcoming limitations of gene transfer efficiency in the presently available replication-incompetent adenoviral vectors.

The first replication-selective viral vector to move from preclinical studies to human cancer clinical trials was the Onyx-015 adenovirus.[83,84] The key alteration that made this adenovirus replication selective was the deletion of the gene that codes for the p53-binding protein, E1B-55kDa. Typically, the adenovirus achieves replication through a process by which the E1B-55kDa protein binds a host cell's p53. The Onyx-015 adenovirus with its deletion of the E1B gene will not express the E1B-55kDa p53-binding protein on infection of a target cell. The lack of E1B-55kDa expression will inhibit viral replication. However, in target cells that lack normal p53 expression, Onyx-015 will maintain its ability to replicate, lyse a target cell, and spread to nearby cells. Because the majority of cancers have a loss of normal p53 function, cancer cells are the ideal target for an E1B-deleted replication-selective adenovirus therapy.

The safety of Onyx-15 for human use has been demonstrated over the course of 15 phase I or II clinical trials involving 258 patients including 99 head and neck cancer cases. Viral replication has been shown to be largely isolated to cancer cells, but this does not appear to translate to a significant clinical benefit when Onyx-015 is used as a monotherapy. Indeed, in two phase II clinical trials for recurrent head and neck cancer, a response rate of only 14% was reported.[85,86] The benefit of Onyx-015 may lie in combination therapy with chemotherapeutic agents such as cisplatin or 5-fluorouracil where significant tumor regression was induced.[87,88] Recent work has also explored the use of conditionally replicating adenoviruses to deliver shRNAs to cancer cells, providing an avenue for the selective silencing of genes involved in carcinogenesis coupled with direct lysis of infected cells.[89]

There are many other evolving strategies for oncolytic viral vector therapy, and it is not the purpose of this chapter to discuss the present state of this novel therapy in detail. However, it is important to mention replication-selective oncolytic viral therapy because it may be thought of as a type of gene-dependent suicide therapy.

Antiangiogenesis

An approach with future potential in cancer gene therapy involves introducing genes that inhibit angiogenesis in the vicinity of a tumor.[90] A decrease or regression of the tumor's important vascular supply by the action of antiangiogenesis factors has been shown to cause significant tumor regression in mouse melanoma models. Continued development and investigation of inhibitors of growth and angiogenesis coupled with the packaging of these factors into vectors for gene transfer in vivo may provide alternative or adjuvant therapies for both benign vascular and malignant tumors of the head and neck.

Plastic and Reconstructive Surgery

Great potential for gene therapy exists in the area of plastic and reconstructive surgery. The principal concept of gene therapy as applied to this field will be the expression of growth-regulating factors to enhance repair or regeneration of damaged tissues and to induce local proliferation to fill surgical defects. By introducing genes into cells within a surgical site, local expression of growth factors can be constituted at levels that maximize the therapeutic response. The use of gene transfer to release growth factors, as opposed to simply injecting suspensions of purified factors, will enable regulated expression of the product over a programmed period with restriction of the product to specific targeted layers of tissue. The combination of this property with the incorporation of proper regulatory elements could minimize associated toxicities or unwanted proliferation of nearby tissues.

Reconstructive Tissue Flaps and Wound Healing

A common problem encountered in the use of local or regional flaps is distal flap necrosis with atrophy or even partial loss.[91] Timely angiogenesis and neovascularization is essential for the survival of these tissues as well as healing of the surgical wound. This process of angiogenesis is stimulated by various growth factors such as basic fibroblast growth factor (bFGF) and heparin binding growth factor.[92] Using gene transfer techniques, a gene encoding an angiogenesis factor could be introduced into cells within a reconstructed tissue, recipient site, or primary wound defect. Subsequent to this gene therapy, an accelerated and magnified vascular response resulting from local expression of angiogenic factors could promote healing with improved tissue survival. The use of gene therapy may prove to be very important in free tissue flaps, where failure often occurs because of inadequate venous efflux leading to vascular engorgement and tissue destruction.

There are multiple other growth factors that influence the process of tissue repair and regeneration. Examples include transforming growth factors (e.g., TGFα, TGFa), insulin-like growth factors (e.g., IGF-I, IGF-II), platelet-derived growth factors (PDGF), nerve growth factors, and others. Indeed, inducing transgene expression of PDGF in a rat incisional wound model increased the mechanical strength of incisions by 75% to 100% for up to 2 weeks post-transfection. Other studies have shown that enhancing expression of epidermal growth factor (EGF) in partial thickness wounds increases re-epithelialization rates and shortened the time to wound closure. Multiple clinical trials are currently underway investigating the use of adenoviral vectors expressing PDGF-β for the enhancement of wound healing.[93]

Different combinations of growth factors can be used to enhance regeneration of vascular tissue, muscle, epithelium, and even nerves.[94]

IGF-1 is especially important in maintaining muscle mass and differentiation and may even be able to promote reinnervation of damaged muscle. Epidermal growth factor, bFGF, and TGFa are potent growth stimulators in dermal layers and may prove advantageous in the management of soft tissue defects caused by trauma or resulting from surgery, a particularly difficult problem for the reconstructive surgeon. For example, the gene for a therapeutic growth factor could be transferred into the surgical defect created by a tongue-jaw-neck resection for oral squamous cell cancer. The local programmed production of healing and growth factors resulting from the direct gene therapy would then stimulate the growth of muscle, fascia, blood vessels, or dermal structures. This growth response would decrease the size of the defect while providing added strength and vascularized tissue to prevent wound dehiscence or extrusion or infection of reconstruction plates. Because of the ability to increase muscle and connective tissue mass and retard atrophy, much smaller flaps could be taken that reduce the overall morbidity and cosmetic defect at the donor site.

Skin Grafting

Skin grafts are an attractive target for somatic gene therapy because of the proven feasibility of cultivating epidermal cells ex vivo and subsequently engrafting these cells successfully in patients. Furthermore, previous studies have established the feasibility of effective gene transfer into skin grafts in animal models.[95] The survival of skin grafts is dependent on adequate nutrition and oxygenation of the graft as well as removal of waste products. Until the blood supply is established, the recipient bed is responsible for the fibrous and plasma exudate through which nutrition is supplied and metabolic wastes are transferred.[96] Gene therapy aimed at increasing vascularization or providing local growth factors for the dermal or epidermal layers (depending on the thickness of the graft) could promote early graft take and lead to overall improved strength. As a protective mechanism, gene transfer of various cytokines, complements, or antimicrobial factors may prove effective in preventing infection. This particular application could prove invaluable in burn patients who require extensive skin grafting and in cases in which grafting is performed over irradiated tissues, ulcers, or prostheses, where survival is typically poor.

Repair and Regeneration of Irradiated Tissue

Morbidity associated with primary or postoperative radiation therapy is common in patients with head and neck cancer. Inflammation, fibrosis, pain, and even wound breakdown with infection are problems encountered in our patients receiving radiation therapy.[97] Despite efforts to narrow the x-ray field and block surrounding structures, there is still substantial damage to superficial and nearby tissues. Growth factors such as ECGF[98] have been shown to enhance viability and vascularity in irradiated soft tissue in animal models. Gene transfer of reparative factors such as ECGF may provide spatially precise and regulated expression of these factors within the field of radiation and may result in reduced toxicity and overall morbidity.

Applications in Laryngology

Treatment outcomes following the surgical repair of the paralyzed larynx are significantly compromised by laryngeal muscle atrophy secondary to denervation. Surgical reinnervation has not consistently improved outcomes. Reversal or prevention of laryngeal muscle atrophy may be possible using gene therapy techniques. In preclinical animal investigations, introduction of human insulin-like growth factor I (hIGF-1) into paralyzed rat laryngeal muscles induced a significant increase in muscle fiber diameter, while also decreasing motor endplate length and increasing the percentage of endplates with nerve contact.[99] In additional studies, hIGF-1 normalized myosin heavy chain composition in denervated rat laryngeal muscles.[100] This novel gene therapy with its combined neurotrophic and myotrophic effects holds potential for optimizing functional outcomes after either acute laryngeal nerve injury or for augmenting surgical reinnervation of the paralyzed larynx.

Applications in Otology/Neurotology

At present, progress with inner ear gene therapy is purely at the experimental stage.[101] Within the auditory system, several vectors have been studied and shown to successfully transfer functional ectopic genes into the mammalian auditory system. Adenoviruses have been shown to transfer functional marker genes such as β-galactosidase (β gal) and green fluorescent protein (GFP), as well as genes that alter the biology of the inner ear such as glial-derived neurotrophic factor (GDNF), to the auditory system.[102-104] Alternate vectors include herpesvirus-derived vectors[105] that have the advantage of being strongly neurotrophic and expressing the transgene for prolonged periods.[106] AAV and liposome packaged plasmids have also been effectively transferred into the cochlea.[107,108] The preservation of hearing in animals treated with infusion of adenoviral vectors into the cochlea and vestibule has recently been demonstrated.[109]

To date several studies have been conducted demonstrating the feasibility and clinical potential of gene therapy for inner ear disease. Adenoviral-mediated delivery of neurotrophin-3, brain derived neurotrophic growth factor and cilial neurotrophic factor have all been shown to promote spiral ganglion cell survival following drug-induced hearing loss in animal models.[110-112] Inner ear tissues can also be protected through the adenoviral delivery of genes for antioxidant enzymes including catalase and superoxide dismutase.[113] These findings could potentially be used to rescue hearing after the administration of ototoxic drugs or to prevent the loss of inner ear hair cells after cochlear implantation.[114]

Gene therapy could have a dramatic benefit in the restoration of hearing loss through the transfer of developmental genes into the inner ear. Studies have already demonstrated that adenoviral delivery of the gene Math1 to the inner ear of guinea pigs results in the production and innervation of hair cells.[115] Transfer of the developmental gene, Atoh1, to the guinea pig inner ear can successfully convert non-sensory cells into functional hair cells with a resulting improvement in hearing on ABR testing following an ototoxic insult.[116] These benchtop studies are laying the foundation for the development of novel therapeutics that may revolutionize the treatment of hearing loss.

For the long-term application of gene therapy for auditory disease to become established, several criteria need to be met. Otologic disease, generally, is not associated with mortality; therefore unlike gene therapy for cancer, vectors need to have low immunogenicity and cytotoxicity. Vectors have to be replication-deficient and nononcogenic, and must express their transgene for prolonged periods. Advances in vector design will make it possible to apply the rapidly growing knowledge of inner ear biology to human disease.

Therapeutic Gene Silencing and the Future of Gene Therapy

The newest frontier in gene therapy involves selectively turning off or "silencing" genes to prevent the development or progression of disease. The therapeutic potential of RNA interference and gene silencing techniques is evidenced by the tremendous number of studies that have been published in the relatively short period of time since the discovery of this molecular therapy technique. Consequently, more than 30 pharmaceutical or biotechnology companies are currently developing RNAi-based therapeutics.[10]

The first condition under evaluation with RNAi technology is age-related macular degeneration (AMD). AMD is caused by the abnormal growth of blood vessels behind the retina. New drugs consisting of modified siRNA targeting either VEGF or its receptor, VEGFR1, have been developed to block retinal angiogenesis. These drugs are administered directly into the eye as a single intravitreal injection and have been shown to stabilize and even improve visual acuity in a dose-dependent fashion with minimal toxicity. Phase II clinical trials are currently underway using various VEGF-targeting RNA interference methods for the treatment of AMD.[10]

Viral RNAs are also potential targets for gene silencing including genes encoding viral entry and replication within cells. Intranasal aerosol delivery of a plasmid-borne siRNA is able to potently inhibit respiratory syncytial virus (RSV) infection in mice, and this approach is currently in phase I clinical trials for human RSV infection.[117] Long-term suppression of HIV replication has been achieved by simultaneously targeting three key genes involved in HIV infection using a lentiviral vector encoding multiple shRNAs.[118] Clinical trials using this approach are underway.

There have been several successful preclinical attempts at using RNAi to induce cancer cell death. RNAi has successfully induced tumor suppression in murine models of pancreatic, ovarian, bladder, breast, liver, melanoma, and cervical cancer.[119,120] Furthermore, RNAi has proven effective in the prevention of tumor metastasis.[119] The targeting of cellular oncogenes that are overexpressed in cancer cells is particularly amenable to RNAi. For example, siRNA-mediated silencing of the tyrosine kinase receptor EphA2 gene, overexpressed in ovarian cancers, induces a 50% reduction of tumor size that can be further improved to a 90% volume reduction when combined with the conventional chemotherapeutic paclitaxel.[12] Oncogenes that arise as a result of chromosomal translocations can also be silenced using RNAi. The Bcr-Abl oncogene, the key mutation in chronic myeloid leukemia, can be silenced using a lentiviral vector expressing anti-Bcr/Abl shRNA. This leads to a down-regulation of Bcr-Abl protein kinase expression and a subsequent suppression of cancer cell proliferation.[121] This gene-silencing approach was also shown to markedly potentiate the action of the kinase-targeted inhibitor drug imatinib.[122]

Cancer cell resistance to chemotherapy is a major factor underlying treatment failure and disease relapse. The multidrug transporter, P-glycoprotein, encoded by the MDR1 gene, is a major system by which cancer cells prevent the intracellular accumulation of chemotherapy drugs. Gene silencing of MDR1 reversed the resistance of pancreatic and gastric cancers to the chemotherapeutic daunorubicin by 89% and 58%, respectively.[120]

The studies outlined above raise the possibility that RNAi can be used to treat cancers in which specific oncogenes have been implicated and may also be used to sensitize cancers to conventional treatment. The translation of RNAi to the clinical realm will require the development of efficient and safe delivery systems, but these agents have the potential to be the most selective, efficient agents ever designed and will likely revolutionize future therapies.

Conclusion

The founding work in molecular biology over the past 40 years has enabled clinical application in the realm of gene therapy. Presently, there are more than 600 completed or ongoing clinical trials, and this pace of progress continues. No longer is gene therapy simply a speculative approach for treating disease in the distant future. While the methods of gene therapy are still evolving, current methods are already sufficiently advanced so as to be used in trials of gene therapy for select diseases and to be incorporated into clinically efficacious pharmaceutical products. Gene therapy has great potential, not only for the treatment of inherited diseases, but also for providing new treatments for complex diseases such as cancer and for the development of novel adjuvants to standard medical or surgical interventions. Gene therapy technologies should have a significant impact on the quality of medicine, while at the same time providing the additional benefit of cost reduction. As the field rapidly advances, increasing opportunities should arise for physicians to apply these technologies in clinical trials and, eventually, clinical practice.

CHAPTER THREE

Laser Surgery: Basic Principles and Safety Considerations

C. Gaelyn Garrett

Robert H. Ossoff

Lou Reinisch

Key Points

- Laser technology has allowed for enhanced surgical treatment for a wide variety of otolaryngology indications including those in otology, laryngology, bronchoesophagology, and facial plastic surgery.
- Every surgeon should have basic knowledge of laser physics and laser-tissue interactions to minimize unnecessary tissue injury.
- The choice of surgical laser depends on several factors, including the target tissue, available modes of delivery, and desired tissue effects.
- Safe and proper laser use requires an established laser safety protocol at each institution and should include separate credentialing for each laser to be used by an individual surgeon.
- Newer lasers to otolaryngology such as the pulsed dye laser and the pulsed KTP laser have enhanced the ability to perform in-office unsedated treatment for certain laryngeal diseases.

Laser light is the brightest monochromatic (single color) light that exists today. In addition to being a standard tool in the research laboratory, the laser is currently used in communications, surveying, manufacturing, diagnostic medicine, and surgery. Supermarket bar code scanners, lecture pointers, and compact disc players bring laser technology into everyday life. The addition of lasers and the development of new lasers to the surgical armamentarium in otolaryngology offer new and exciting possibilities to improve conventional techniques and to expand the scope of otolaryngology.

This chapter reviews the principles, applications, and safety considerations associated with the use of lasers in the upper aerodigestive tract. The material presented provides a foundation for the otolaryngologist to safely and effectively apply this exciting technology in daily practice.

History of Lasers

Laser is a word derived from the acronym for *l*ight *a*mplification by the *s*timulated *e*mission of *r*adiation. Einstein[1] postulated the theoretical foundation of laser action, stimulated emission of radiation, in 1917. In his classic journal article, "Zur Quantem Theorie der Strahlung" ("The Quantum Theory of Radiation"), he discussed the interaction of atoms, ions, and molecules with electromagnetic radiation. He specifically addressed absorption and spontaneous emission of energy, and proposed a third process of interaction: stimulated emission. Einstein postulated that the spontaneous emission of electromagnetic radiation from an atomic transition has an enhanced rate in the presence of similar electromagnetic radiation. This "negative absorption" is the basis of laser energy. Many attempts were made in the following years to produce stimulated emission of electromagnetic energy, but it was not until 1954 that this was successfully accomplished. In that year, Gordon and others[2] reported their experiences with stimulated emission of radiation in the microwave range of the electromagnetic spectrum. This represented the first *maser* (*m*icrowave *a*mplification by the *s*timulated *e*mission of *r*adiation) and paved the way for the development of the first laser. In 1958, Schawlow and Townes[3] published "Infrared and Optical Masers," in which they discussed stimulated emission in the microwave range of the spectrum and described the desirability and principles of extending stimulated emission techniques to the infrared and optical ranges of the spectrum. Maiman[4] expanded on these theoretical writings and built the first laser in 1960. With synthetic ruby crystals, this laser produced electromagnetic radiation at a wavelength of 0.69 μm in the visible range of the spectrum. Although the laser energy produced by Maiman's ruby laser lasted less than 1 ms, it paved the way for explosive development and widespread application of this technology.

Commercial lasers were being sold for laboratory use within 1 year of being invented. Partially reacting to the recently discovered dangers of x-rays, scientists were concerned about the safety of lasers and how laser light might damage living tissue.

This concern over the safety of laser light prompted much of the early transition of the laser from the scientific laboratory to the medical clinic. In 1962, Zaret and others[5] published one of the first reports of laser light interacting with tissue. They measured the damage caused by lasers on rabbit retina and iris. In 1964, the argon (Ar) and neodymium:yttrium-aluminum-garnet (Nd:YAG) lasers were developed.[6] Excited by the ophthalmologists' progress in using the laser as a therapeutic tool, Goldman used his medical laser laboratory to look at the hazards of the laser and to consider the potential uses of the laser in medicine. Two important advances allowed the laser to be useful in

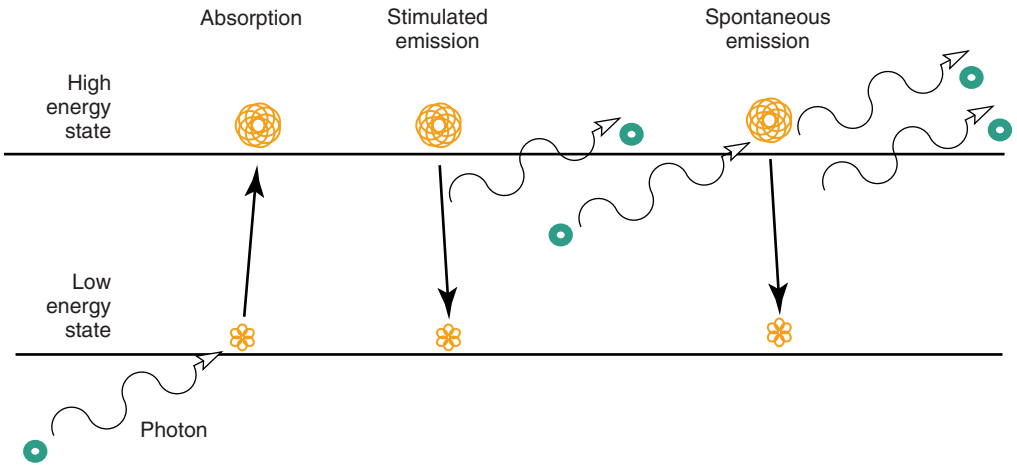

Figure 3-1. The interaction of light (a photon) with an atom. Three processes are shown: the absorption of a photon by an atom in a low-energy state, the spontaneous emission of a photon from an atom in an excited state, and the stimulated emission of a photon by a second photon of the same wavelength from an excited-state atom.

otolaryngology: (1) in 1965, the carbon dioxide (CO_2) laser was developed, and (2) in 1968, Polanyi[7] developed the articulated arm to deliver the infrared radiation from the CO_2 laser to remote targets. He combined his talents with Jako and used the articulated arm and the CO_2 laser in laryngeal surgery. Simpson and Polanyi[8] described the series of experiments and new instrumentation that made this work possible.

A laser is an electro-optical device that emits organized light (rather than the random-pattern light emitted from a light bulb) in a very narrow intense beam by a process of optical feedback and amplification. Because the explanation for this organized light involves stimulated emission, a brief review of quantum physics is necessary.

In the semiclassical picture of the atom, each proton is balanced by an electron that orbits the nucleus of the atom in one of several discrete shells or orbits. Shells correspond to specific energy levels, which are characteristic of each different atom or molecule. The smaller shells, where the electron is closer to the nucleus, have a lower energy level than the larger shells, where the electron is farther from the nucleus. Electrons of a particular atom can only orbit the nucleus at these shells or levels. Radiation of energy does not occur while the electrons remain in any of these shells.

Electrons can change their orbits, thereby changing the energy state of the atom. During excitation, an electron can make the transition from a low-energy level to a higher energy level. Excitation that comes from the electron interacting with light (a photon) is termed *absorption*. The atom always seeks its lowest energy level (i.e., the ground state). Therefore, the electron will spontaneously drop from the high-energy level back to the lowest energy level in a very short time (typically 10^{-8} sec). As the electron spontaneously drops from the higher energy level to the lower energy level, the atom must give up the energy difference. The atom emits the extra energy as a photon of light in a process termed the *spontaneous emission of radiation* (Fig. 3-1).

Einstein postulated that an atom in a high-energy level could be induced to make the transition to a lower energy state even faster than the spontaneous process if it interacted with a photon of the correct energy. This process can be imagined as a photon colliding with an excited atom, resulting in two identical photons (one incident and one produced by the decay) that leave the collision. The two photons have the same frequency and energy and travel in the same direction in the spatial and temporal phase. This process, which Einstein called stimulated emission of radiation, is the underlying principle of laser physics (see Fig. 3-1).

What Is a Laser?

All laser devices have an optical resonating chamber (cavity) with two mirrors. The space between these mirrors is filled with an active medium, such as Ar, Nd:YAG, or CO_2. An external energy source (e.g., an electric current) excites the active medium within the optical cavity. This excitation causes many atoms of the active medium to be raised to a higher energy state. A population inversion occurs when more than half of the atoms in the resonating chamber have reached a particular excited state. Spontaneous emission is taking place in all directions. Light (photons) emitted in the direction of the long axis of the laser is retained within the optical cavity by multiple reflections off the precisely aligned mirrors. One mirror is completely reflective, and the other is partially transmissive (Fig. 3-2). Stimulated emission occurs when a photon interacts with an excited atom in the optical cavity. This yields pairs of identical photons that are of equal wavelength, frequency, and energy and are in phase with each other. This process occurs at an increasing rate with each passage of the photons through the active medium.

The mirrors serve as a positive feedback mechanism for the stimulated emission of radiation by reflecting the photons back and forth. The partially transmissive mirror emits some of the radiant energy as laser light. The radiation leaving the optical cavity through the partially transmissive mirror quickly reaches equilibrium with the pumping mechanism's rate of replenishing the population of high-energy state atoms. (In the preceding discussion, the term *atom* refers to the active material. In reality, the active material can consist of molecules, ions, atoms, semiconductors, or even free electrons in an accelerator. These other systems do not require the bound electron to be excited but may instead use different forms of excitation, including molecular vibrational excitation or the kinetic energy of an accelerated electron.)

The radiant energy emitted from the optical cavity is of the same wavelength (monochromatic), is extremely intense and unidirectional (collimated), and is temporally and spatially coherent. The term *temporal coherence* refers to the waves of light oscillating in phase over a given time; whereas spatial coherence means that the photons are equal and parallel across the wavefront. These properties of monochromaticity, intensity, collimation, and coherence distinguish the organized radiant energy of a laser light source from the disorganized radiant energy of a light bulb or other light source (Fig. 3-3).

After the laser energy exits the optical cavity through the partially transmissive mirror, the radiant energy typically passes through a lens that focuses the laser beam to a very small diameter, or spot size, ranging from 0.1 to 2.0 mm. When necessary, the lens system is constructed to allow the visible helium-neon aiming laser beam and the invisible CO_2 or Nd:YAG laser beam to be focused in a coplanar manner. The optical properties of each focusing lens determine the focal length or distance from the lens to the intended target tissue for focused use.

Control of the Surgical Laser

With most surgical lasers, the physician can control three variables: (1) power (measured in watts), (2) spot size (measured in millimeters), and (3) exposure time (measured in seconds).

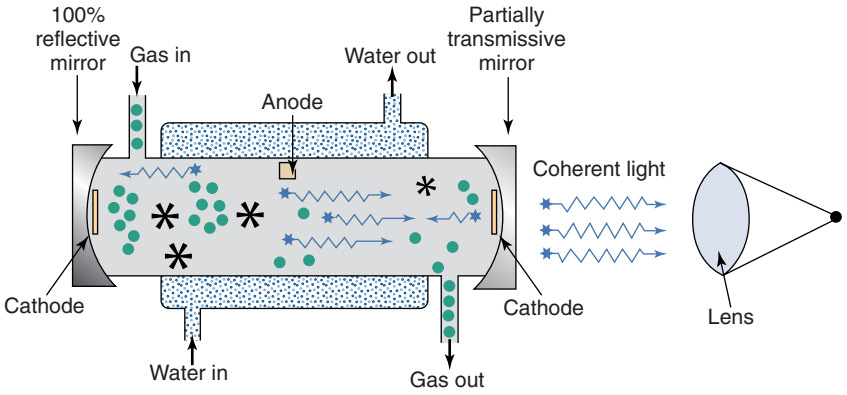

Figure 3-2. The optical resonating chamber of a carbon dioxide laser. The gas molecules are excited by an electric current. The gas is cooled by a water jacket. The two mirrors provide the optical feedback for the amplification. The emitted light is coherent, monochromatic, and collimated. The light can be focused to a small point with an external lens.

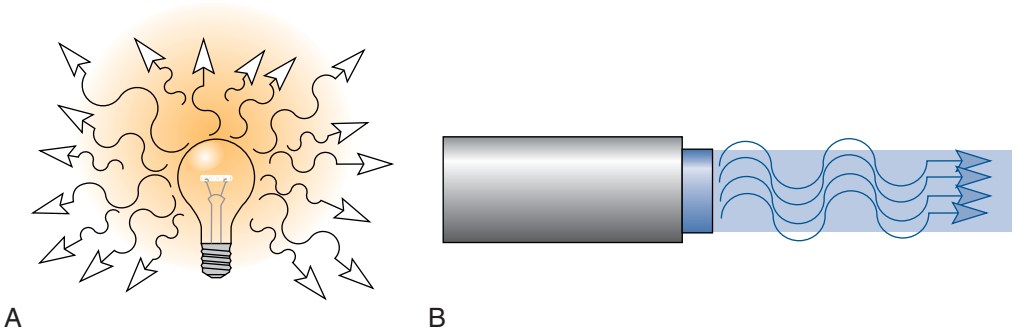

Figure 3-3. A, Light emitted from a conventional lamp. The light travels in all directions, is composed of many wavelengths, and is not coherent. **B,** Light emitted from a laser. The light travels in the same direction, it is a single wavelength, and all of the waves are in phase. The light is coherent.

Power

Of power, spot size, and exposure time, power is the least useful variable and may be kept constant with widely varying effects, depending on the spot size and the duration of exposure. For example, the relationship between power and depth of tissue injury becomes logarithmic when the power and exposure time are kept constant and the spot size is varied.

Irradiance is a more useful measure of the intensity of the beam at the focal spot than power is because it considers the surface area of the focal spot. Specifically, irradiance is expressed (in W/cm^2) as:

$$\text{Irradiance} = \text{Power in the focal spot} / \text{Area of the focal spot}$$

Spot Size

Power and spot size are considered together, and a combination is selected to produce the appropriate irradiance. If the exposure time is kept constant, the relationship between irradiance and depth of injury is linear as the spot size is varied. Irradiance is the most important operating parameter of a surgical laser at a given wavelength. Therefore surgeons should calculate the appropriate irradiance for each procedure to be performed. These calculations allow the surgeon to control, in a predictable manner, the tissue effects when changing from one focal length to another (e.g., from 400 mm for microlaryngeal surgery to 125 mm for handheld surgery). Irradiance varies directly with power and inversely with surface area. This relationship of surface area to beam diameter is important when evaluating the power density because the larger the surface area, the lower the irradiance; conversely, the smaller the surface area, the higher the irradiance. Surface area (A) is expressed as:

$$A = \pi r^2 \text{ or } A = \pi d^2/4$$

where r is the beam radius and d is the beam diameter ($d = 2r$).

Surface area and irradiance vary with the square of the beam diameter. Doubling the beam diameter (e.g., from d to 2d) increases the surface area by 4 and reduces irradiance to one fourth. Halving the beam diameter (e.g., from d to d/2) yields only one fourth of the area and increases irradiance by a factor of 4.

Current CO_2 lasers emit radiant energy with a characteristic beam intensity pattern. This beam pattern ultimately determines the depth of tissue injury and vaporization across the focal spot. Therefore the surgeon should be aware of the characteristic beam pattern of the laser. Transverse electromagnetic mode (TEM) refers to the distribution of energy across the focal spot and determines the shape of the laser's spot. The most fundamental mode is TEM_{00}, which appears circular on cross section. The power density of the beam follows a gaussian distribution. The greatest amount of energy is at the center of the beam and diminishes progressively toward the periphery. TEM_{01} and TEM_{11} are less fundamental modes that have a more complex distribution of energy across their focal spot, causing predictable variations in tissue vaporization depth. Additionally, their beams cannot be focused to as small a spot size as TEM_{00} lasers at the same working distance.[9]

Although simple ray diagrams normally show parallel light focused to a point, the actual situation is a bit more complicated. A lens focuses a gaussian beam to a beam waist of a finite size. This beam waist is the minimum spot diameter (d) and can be expressed as:

$$d \sim 2f\lambda/D$$

where f is the focal length of the lens, λ is the wavelength of light, and D is the diameter of the laser beam incident on the lens (Fig. 3-4).

The beam waist occurs over a range of distances, termed the *depth of focus*, which can be expressed as:

$$\text{Depth of focus} \sim \pi d^2/2\lambda$$

Depth of focus is realized when a camera is focused. With a camera, a range of objects is in focus, which can be set without carefully measuring the distance between the object and the lens. The preceding equations show that a long focal length lens leads to a large beam waist, which also translates as a large depth of focus.

The size of the laser beam on the tissue (spot size) can therefore be varied in two ways:

1. Because the minimum beam diameter of the focal spot increases directly with increasing the focal length of the laser-focusing lens, the surgeon can change the focal length of the lens to obtain a particular beam diameter. As the focal length decreases, a corresponding decrease occurs in the size of the focal spot. Also, the smaller the spot size is for any given power output, the greater the corresponding power density.
2. The surgeon can also vary the spot size by working in or out of focus. The minimum beam diameter and highest power concentration occur at the focal plane, where much of the precise cutting and vaporization is carried out (Fig. 3-5A). As the distance from the focal plane increases, the laser beam diverges or becomes unfocused (see Fig. 3-5B). The cross-sectional area of the spot increases and thus lowers the power density for a given output.

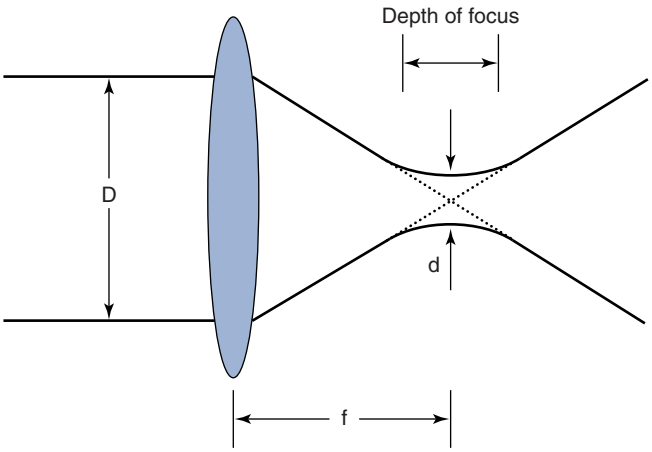

Figure 3-4. The beam waist of parallel light focused by a lens. The focal length of the lens is *f*. The incident beam is transverse electromagnetic mode (TEM_{00}) and has a diameter incident on the lens of 2D. The beam waist has a diameter of 2d.

The size of the focal spot depends on the focal length of the laser lens and whether the surgeon is working in or out of focus.

Figure 3-6 shows these concepts using arbitrary ratios accurate for a current model TEM_{00} CO_2 laser. The laser lens setting (focal length) and working distance (focused/unfocused) combinations determine the size of the focal spot. The height of the various cylinders represents the amount of tissue (depth and width) vaporized after a 1-sec exposure at the three focal lengths.

Exposure Time

The surgeon can vary the amount of energy delivered to the target tissue by varying the exposure time. *Fluence* refers to the amount of time (measured in seconds) that a laser beam irradiates a unit area of tissue at a constant irradiance. Fluence is a measure, then, of the total amount of laser energy per unit area of exposed target tissue and is expressed (J/cm^2) as:

$$\text{Fluence} = \text{Power density} \times \text{Time}$$

Fluence varies directly with the length of the exposure time, which can be varied by working in the pulsed mode (duration, 0.05 to 0.5 sec) or in the continuous mode.

Tissue Effects

When electromagnetic energy (incident radiation) interacts with tissue, the tissue reflects, absorbs, transmits, and scatters portions of the light. The surgical interaction of this radiant energy with tissue is caused only by that portion of light that is absorbed (i.e., the incident radiation minus the sum of the reflected and transmitted portions).

The actual tissue effects produced by the radiant energy of a laser vary with the wavelength of the laser. Each type of laser exhibits dif-

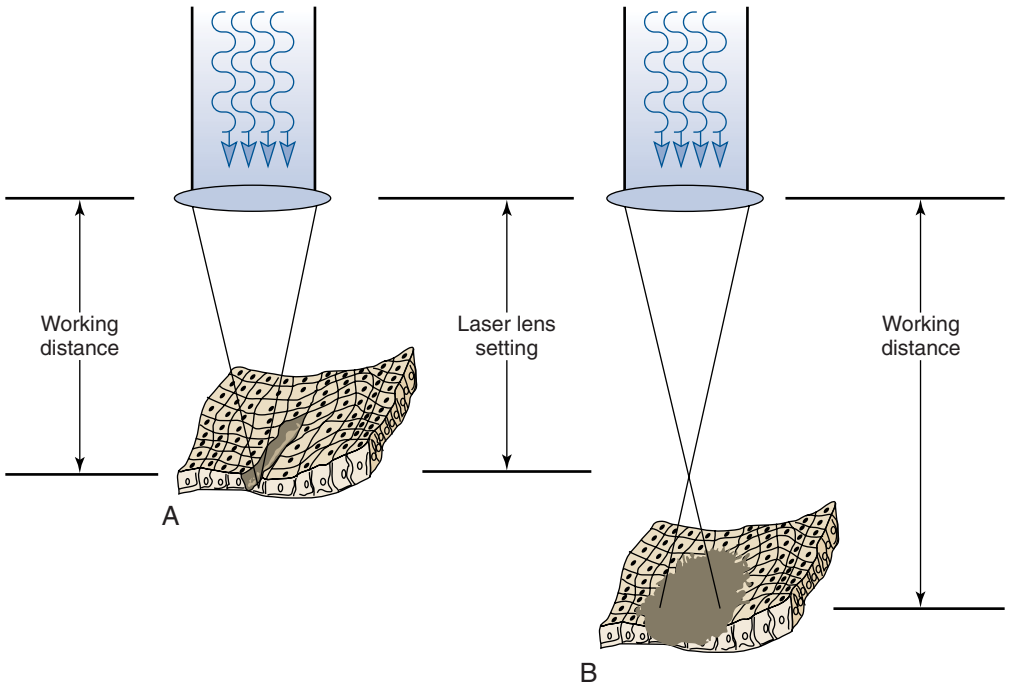

Figure 3-5. A, Laser-tissue interaction when the tissue is the focal distance away from the lens. Note the minimum beam diameter in the focal plane. **B,** Laser-tissue interaction when the tissue is not in the focal plane of the lens. The laser covers a much larger area on the tissue surface.

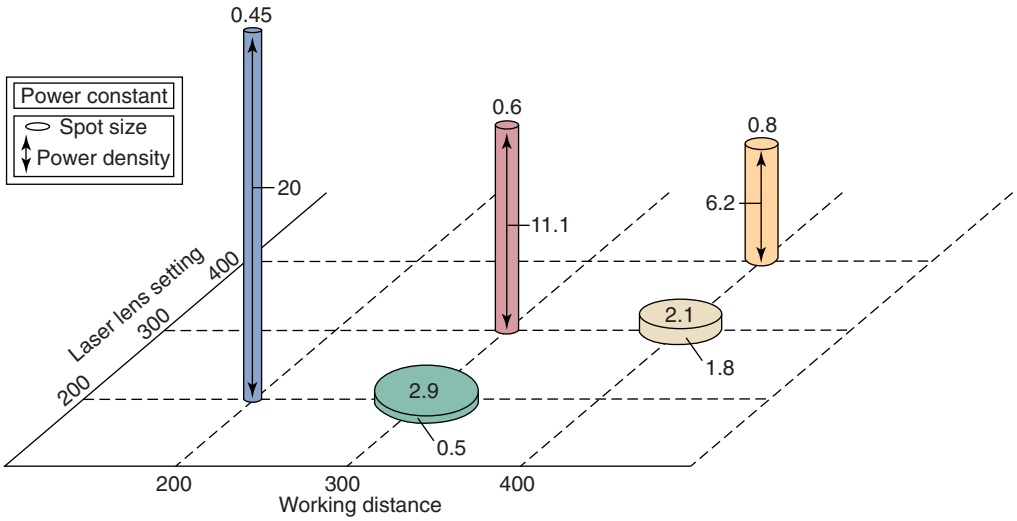

Figure 3-6. Power density versus spot size. The ratios are arbitrary for a current model carbon dioxide laser. The cylinder height represents the amount of tissue vaporized after a 1-second exposure at the three designated focal lengths.

ferent characteristic biologic effects on tissue and is therefore useful for different applications. However, certain similarities exist regarding the nature of laser light interaction with biologic tissue. The lasers used in medicine and surgery today can be ultraviolet, meaning the interactions are a complex mixture of heating and photodissociation of chemical bonds. The more commonly used lasers emit light in the visible or the infrared region of the electromagnetic spectrum, and their primary form of interaction with biologic tissue leads to heating. Therefore, if the radiant energy of a laser is to exert its effect on the target tissue, it must be absorbed by the target tissue and be converted to heat (Fig. 3-7). Scattering tends to spread the laser energy over a larger surface area of tissue, but it limits the penetration depth (Fig. 3-8). The shorter the wavelength of light, the more it is scattered by the tissue. If the radiant energy is reflected from or transmitted through the tissue (Figs. 3-7, 3-9, and 3-10), no effect will occur. To select the most appropriate laser system for a particular application, the surgeon should thoroughly understand these characteristics regarding the interaction of laser light with biologic tissue.[10]

The CO_2 laser creates a characteristic wound (Fig. 3-11). When the target absorbs a specific amount of radiant energy to increase its temperature to between 60° C and 65° C, protein denaturation occurs. Blanching of the tissue surface is readily visible, and the deep structural

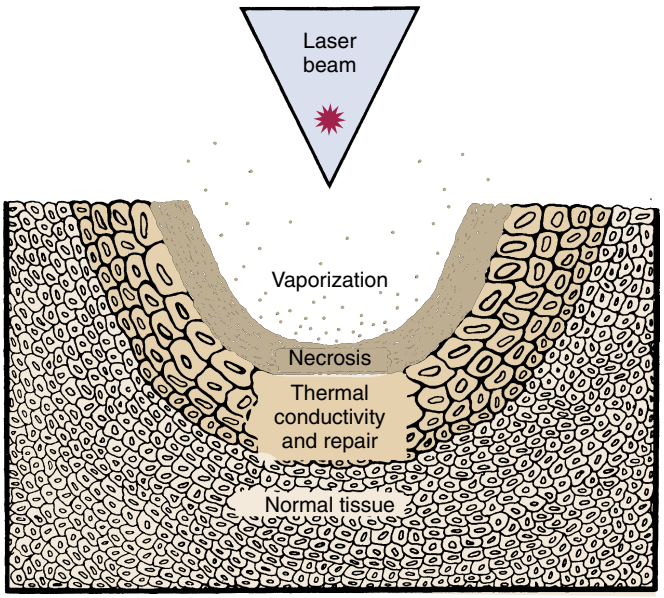

Figure 3-11. The wound created by the carbon dioxide laser, showing the representative zones of injury.

integrity of the tissue is disturbed. When the absorbed laser light heats the tissue to approximately 100° C, vaporization of intracellular water occurs, causing vacuole formation, craters, and tissue shrinkage. Carbonization, disintegration, smoke, and gas generation with destruction of the laser-radiated tissue occurs at several hundred degrees centigrade. In the center of the wound is an area of tissue vaporization, where just a few flakes of carbon debris are noted. Immediately adjacent to this area is a zone of thermal necrosis (about 100 µm wide). Next is an area of thermal conductivity and repair (usually 300 to 500 µm wide). Small vessels, nerves, and lymphatics are sealed in the zone of thermal necrosis. The minimal operative trauma combined with the vascular seal probably account for the absence of postoperative edema characteristic of laser wounds.

Comparison animal studies have been performed on the histologic properties of healing and the tensile strength of the healing wound after laser- and scalpel-produced incisions. Several studies noted impaired wound healing with the CO_2 laser incision when compared with the scalpel-produced incision.[11-15] Other studies of the healing properties of laser-induced incisions concluded that laser incisions have equivalent or better healing results than surgical knife wounds.[16-18] Buell and Schuller[19] compared the rate of tissue repair after CO_2 laser and scalpel incisions on hogs. In this study, the tensile strength of the laser incisions was less than that of similar scalpel incisions during the first 3 weeks after surgery. After this time, the tensile strength of both wounds rapidly increased at a similar rate.

Regardless of which studies accurately depict the effects of the CO_2 laser on wound healing, the incidental, collateral thermal damage is indisputable. To minimize lateral thermal damage from thermal diffusion, the tissue should be ablated with a short laser pulse.

To understand how a pulsed laser reduces thermal diffusion, consider the analogy of filling a large bucket with a hole in the bottom. If a narrow stream of water is used to fill the bucket, the filling process will take a long time and a considerable amount of water will leak out of the hole during the filling process. Instead, if the bucket is filled in one quick dump from an even larger bucket, the water will have little time to leak out of the hole during the filling process.

This analogy can also be used to understand the ablation process. In ablation, the water represents laser energy and the filled bucket represents sufficient energy deposited in the tissue to cause ablation. The hole in the bottom of the bucket represents the thermal diffusion of heat away from the ablation site while the energy is being deposited. A low-intensity, continuous laser beam is similar to the narrow stream of water. The short-pulsed, high-peak power laser is similar to the larger bucket in that it quickly dumps energy into the ablation site.

Laser Types and Applications

Several types of lasers are commonly used in otolaryngology. They include the argon laser, argon tunable dye laser, Nd:YAG laser, KTP laser, pulsed dye laser (PDL), flash lamp pumped dye laser, and CO_2 laser. Other types are in various stages of evaluation for clinical applicability, such as the thulium:YAG laser. The potential clinical applications of these surgical lasers are mainly determined by wavelength and the specific tissue-absorptive characteristics. Therefore the surgeon should consider the properties of each wavelength when choosing a particular laser to achieve the surgical objective with minimal morbidity and maximal efficiency (Table 3-1). Clinical applications are also limited by the available modes of delivery for the various lasers. It is also important to know that the applications listed can, in many cases, be addressed with nonlaser techniques as well or arguably better.

Argon (Ar) Laser

Ar lasers produce blue-green light in the visible range of the electromagnetic spectrum, with primary wavelengths of 0.488 and 0.514 µm. The radiant energy of an Ar laser may be strongly absorbed, scattered, or reflected depending on the specific biologic tissues with which it interacts. Its extinction length (i.e., the thickness of water necessary to absorb 90% of the incident radiation) in pure water is about 80 m. Therefore the radiant energy from an Ar laser is readily transmitted through clear aqueous tissues (e.g., cornea, lens, and vitreous humor) and is absorbed and reflected to varying degrees by tissues white in color (e.g., skin, fat, and bone). Light from an Ar laser is absorbed by hemoglobin and pigmented tissues. A localized thermal reaction occurs within the target tissue, causing protein coagulation. The clinician uses this selective absorption of light from an Ar laser to photocoagulate pigmented lesions, such as port-wine stains, hemangiomas, and telangiectasis. The heat produced destroys the epidermis and upper dermis. Therefore the surgeon should minimize the amount of laser energy delivered to the vascular cutaneous lesion to decrease the tendency of scarring in the overlying skin.

When the beam of the Ar laser is focused on a small focal spot, its power density increases sufficiently to vaporize the target tissue. This characteristic allows otologists to perform stapedotomy in patients with otosclerosis.[20] Bone, being a white tissue, reflects most of the incident radiation from an Ar laser. Therefore to perform an Ar laser stapedotomy, it is necessary to place a drop of blood on the stapes to initiate absorption.

Argon Tunable Dye Laser

The Ar tunable dye laser works on the principle of the Ar laser. The Ar tunable dye laser makes a high-intensity beam that is focused on dye continuously circulating in a second laser optically coupled with the Ar laser. The Ar laser beam energizes the dye, causing it to emit laser energy at a longer wavelength than the pump beam. By varying the type of dye and using a tuning system, different wavelengths can be obtained. The laser energy from this dye laser can be transmitted through flexible fiberoptics and delivered through endoscopic systems or inserted directly into tumors. The major clinical use of this laser is with selective photodynamic therapy (PDT) for malignant tumors after the intravenous injection of the photosensitizer, hematoporphyrin derivative.[21]

After intravenous injection, the hematoporphyrin derivative disseminates to all of the cells of the body, rapidly moving out of normal tissue but remaining longer in neoplastic tissue. After a few days, a differential in concentration exists between the tumor cells and the normal cells. When the tumor is exposed to red light (630 nm), the dye absorbs the light, causing a photochemical reaction. Toxic oxygen radicals such as singlet oxygen are produced within the exposed cells, causing selective tissue destruction and cell death. Because healthy tissues contain less photosensitizer, a much less severe reaction or no reaction occurs. Long-term tumor control has been achieved using PDT for recurrent nasopharyngeal cancer.[22] The overall potential and the place of maximum value of this form of management remain to be established.

Table 3-1

Laser Choices for Various Lesions

Laser	Second-Choice Laser	Anatomic Site	Lesion	Reason
Argon		Ear	Lysis of middle ear adhesions	Optical fiber delivery, hemoglobin absorption
Argon pumped dye laser			Photodynamic therapy	Can tune the laser to maximum absorption of photosensitizer
CO_2		Glottis	Nodules	Microspot, precision; nonlaser better
CO_2, in-office PDL or KTP		Glottis	Polyps	Microspot, precision; nonlaser better
CO_2, in-office PDL or KTP		Glottis	Reinke's edema	Microspot, precision, microflap technique preferred
CO_2		Glottis	T1 midfold squamous cell carcinoma with no anterior commissure involvement	Excisional biopsy
CO_2	KTP	Larynx	Laryngoceles, saccular cysts	Coagulation, hands-off technique
CO_2		Larynx	Laryngomalacia	Aryepiglottic fold division, precision, coagulation
CO_2		Larynx	Stenoses (glottic, posterior, and subglottic)	Radial excision and dilation
CO_2		Lingual tonsils	Recurrent tonsillitis, hypertrophy	Minimal edema with complete vaporization
CO_2		Oral cavity	Carcinoma (verrucous, superficial T1)	Less pain and edema, covers a large area
CO_2		Oral cavity	Premalignant (leukoplakia, erythroplakia)	Vaporization, excision, can cover a large area
CO_2	KTP	Glottis	Bilateral vocal cord paralysis	Laser arytenoidectomy, coagulation
CO_2, in-office PDL or KTP		Larynx	Recurrent respiratory papilloma	Lesion excision/ablation with CO_2 vs. angiolysis with in-office lasers
CO_2	KTP	Larynx	Suprahyoid supraglottic T1 squamous cell carcinoma	Excision with frozen section control
CO_2	KTP	Oral cavity	Tongue T1 and limited T2 cancer	Less pain and edema, precision, coagulation
CO_2	KTP or Argon	Ear	Stapedotomy	Minimal trauma
CO_2	KTP or Nd:YAG	Oral cavity	Lymphangioma	Minimal edema, coagulation
CO_2	KTP or Nd:YAG	Oropharynx	T1 and T2 squamous cell carcinoma	Precision, coagulation, less edema, contact tip with Nd:YAG
CO_2	Nd:YAG	Nose	Turbinate hypertrophy	Coagulation, less scabbing and scarring
CO_2	Nd:YAG	Subglottis	Hemangioma	Defocused beam, shrinkage, coagulation
Flash lamp pumped dye laser			Port-wine stains	Selective photothermolysis
KTP		Nose	Polyps, concha bullosa	Debulking for visualization, coagulation
KTP	CO_2	Larynx	Obstructing squamous cell carcinoma	Debulking airway, staging, coagulation
KTP	CO_2	Oropharynx	Sleep apnea (uvulopalato-pharyngoplasty)	Coagulation
KTP	CO_2	Palatine tonsils	Recurrent tonsillitis, obstructive apnea	Coagulation? Less postoperative pain
KTP	Nd:YAG	Nose	Epistaxis	Fiber delivery, coagulation, hands-off technique
Nd:YAG	KTP	Nose	Hereditary hemorrhagic telangiectasias	Coagulation, hands-off technique
Nd:YAG	KTP or CO_2	Trachea	Obstructing malignant lesions	Debulking, coagulation, fiber delivery

CO_2, carbon dioxide; KTP, potassium-titanyl-phosphate; Nd:YAG, neodymium:yttrium-aluminum-garnet; PDL, pulsed dye laser.

Neodymium:Yttrium-Aluminum-Garnet (Nd:YAG) Laser

Nd:YAG lasers produce light with a wavelength of 1.064 µm in the near infrared (invisible) range of the electromagnetic spectrum. Pure water weakly absorbs the radiant energy of the Nd:YAG laser. The extinction length is about 40 mm. Therefore its radiant energy can be transmitted through clear liquids, facilitating its use in the eye or other water-filled cavities (e.g., the urinary bladder). Absorption of light from this laser is slightly color dependent, with increased absorption in darkly pigmented tissues and charred debris. In biologic tissue, strong scattering, both forward and backward, determines the effective extinction length, which is usually 2 to 4 mm. Backward scattering can account for up to 40% of the total amount of scattering. The zone of damage produced by the incident beam of a Nd:YAG laser produces a homogeneous zone of thermal coagulation and necrosis that may extend up to 4 mm deep and lateral from the surface, making precise control impossible.

The primary applications for the Nd:YAG laser in otolaryngology include ablation or palliation of obstructing tracheobronchial lesions, palliation of obstructing esophageal lesions, photocoagulation of vascular lesions of the head and neck, and photocoagulation of lymphatic malformations. The contact Nd:YAG laser is reportedly useful in the removal of malignant tumors in the oral cavity and oropharynx, where it is difficult to maintain a generous safety margin.[23] The Nd:YAG laser has several distinct advantages in the management of obstructing lesions of the tracheobronchial tree. Hemorrhage is the most frequent and dangerous complication associated with laser bronchoscopy, and its control is extremely important. Control of hemorrhage is more secure with this laser because of its deep penetration in tissue.

Nd:YAG laser application through an open, rigid bronchoscope allows for multiple distal suction capabilities simultaneous with laser application and rapid removal of tumor fragments and debris to prevent hypoxemia. Patients for Nd:YAG laser bronchoscopy should be selected after flexible fiberoptic bronchoscopic examination of the tracheobronchial tree and tracheal computed tomography. Patients in whom extrinsic compression of the airway can be shown should be excluded. The radiant energy from the Nd:YAG laser can be transmitted through flexible fiberoptic delivery systems, allowing its use with flexible endoscopes. In the management of patients with obstructing neoplasms of the tracheobronchial tree, it is considered safer to use a rigid ventilating bronchoscope rather than a flexible fiberoptic bronchoscope.[24] During this approach, the laser fiber is passed down the lumen of the rigid bronchoscope with a rod lens telescope and suction catheter. Other advantages of the use of the Nd:YAG laser with a rigid bronchoscope include ventilatory control of the compromised airway, palpation of the tumor-cartilage interface, use of the bronchoscope tip as a "cookie cutter," and use of the bronchoscope tip to compress a bleeding tumor bed for temporary hemostasis. The flexible fiberoptic bronchoscope is often used through the open rigid scope to provide pulmonary toilet and more distal laser application after the major airway is secure.

This laser is an excellent surgical instrument for tissue coagulation. Vaporization and incision also can be performed with the Nd:YAG laser. When this laser is used for these functions, however, precision is lacking and tissue damage is widespread. The major disadvantage of the Nd:YAG laser is its comparatively less predictable depth of tissue penetration. This laser is used primarily to rapidly photocoagulate tumor masses in the upper- and lower-aerodigestive tract at 40- to 50-W, using 0.5- to 1-sec exposures. Whenever possible, the laser beam is applied parallel to the wall of the tracheobronchial tree. The rigid tip of the bronchoscope is used mechanically to separate the devascularized tumor mass from the wall of the tracheobronchial tree.

Otolaryngologists may use the Nd:YAG laser with the CO_2 laser when performing bronchoscopic laser surgery. The effective coagulating properties of the Nd:YAG laser should augment the predictable vaporizing properties of the CO_2 laser when treating patients with obstructive tracheal and proximal endobronchial cancers, especially if an ulcerative or actively bleeding tumor is present.[25]

Carbon Dioxide (CO_2) Laser

CO_2 lasers produce light with a wavelength of 10.6 µm in the infrared (invisible) range of the electromagnetic spectrum. A second, built-in, coaxial helium-neon laser is necessary because its red light indicates the site where the invisible CO_2 laser beam will impact the target tissue. Thus, this laser acts as an aiming beam for the invisible CO_2 laser beam. The radiant energy produced by the CO_2 laser is strongly absorbed by pure, homogeneous water and by all biologic tissues high in water content. The extinction length of this wavelength is about 0.03 mm in water and in soft tissue. Reflection and scattering are negligible. Because absorption of the radiant energy produced by the CO_2 laser is independent of tissue color and because the thermal effects produced by this wavelength on adjacent nontarget tissues are minimal, the CO_2 laser has become extremely versatile in otolaryngology.

Until recently, light from the CO_2 laser could not be transmitted through flexible endoscopes and was limited to transmission from the optical resonating chamber to the target tissue via a series of mirrors through an articulating arm to the target tissue. In this manner, the CO_2 laser can be used free-hand for macroscopic surgery, attached to the operating microscope for microscopic surgery, and adapted to an endoscopic coupler for bronchoscopic surgery. Pattern generators coupled with a micromanipulator on the operating microscope also help with surgical precision of the CO_2 laser in laryngology. More recently, with the emphasis on in-office procedures, the CO_2 laser has been coupled with a new flexible waveguide to allow passage through the working channel of a transnasal endoscope.[26] The Omniguide (OmniGuide, Cambridge, MA) may be adapted to most CO_2 lasers, requires a continuous infusion of helium as a coolant, and has no spot beam. Localization of the beam may be identified by the mucosal disturbance created by the helium jet produced at the end of the fiber. Although application of the Omniguide in head and neck surgery has not been fully explored, use of this technology may ultimately be limited by the cost of the individual nonreusable fibers.

The CO_2 laser is an integral instrument in all aspects of otolaryngology. The numerous types of uses vary from endoscopic resection of malignant laryngeal tumors to the precision of laser stapedotomy, as well as to cosmetic skin treatment, but its most effective use is in laryngology and bronchoesophagology.

For example, surgery for recurrent respiratory papillomatosis (RRP) advanced with the use of the laser. The increased ability to preserve normal laryngeal structures while maintaining the translaryngeal airway more than offsets the initial disappointment associated with the laser's inability to cure the disease. In a published survey in 1995, the CO_2 laser was preferred for the management of RRP by 92% of the respondents.[27] However, surgical treatment of RRP has also been influenced by the introduction of microdébriders to laryngology. A survey published in 2004 indicates that many pediatric otolaryngologists prefer the powered instrumentation over laser technology in treating juvenile RRP.[28] The CO_2 laser, however, remains a popular instrument of choice by many surgeons to treat this unrelenting disease. As in all laser applications, knowledge of laser-tissue interactions will optimize safe and effective surgical outcomes. In pediatric patients, surgery for webs, subglottic stenosis, capillary hemangiomas, and other space-occupying airway lesions has been significantly improved by the precision, preservation of normal tissue, and predictably minimal amount of postoperative edema associated with the judicious use of the CO_2 laser. In adults, surgery for polyps, nodules, leukoplakia, papillomas, cysts, granulomas, and other benign laryngeal conditions can be performed with the laser. Surgeons should be cautioned, however, to be aware of the associated thermal injury that can occur to surrounding normal tissues with use of the laser even at recommended settings. A study by Garrett and Reinisch showed thermal injury beyond the laser ablation crater as much as 285 µm deep into the lamina propria of canine vocal folds.[29] Fibrosis deep into the tissue could affect the vibratory characteristics of the lamina propria.

Management of laryngotracheal stenosis is a difficult problem for the otolaryngologist. Retrospective analysis has determined that stenotic lesions appropriate for endoscopic management have two features in common[8]: (1) All lesions treated with endoscopic techniques must retain intact external cartilaginous support. (2) Lesions appropriate for endoscopic management are usually less than 1 to 2 cm in vertical length, yet favorable results have been reported for lesions up to 3 cm in length when endoscopic incision is combined with prolonged stenting.[30,31]

The addition of the CO_2 laser to endoscopic treatment of bilateral vocal fold immobility due to nerve injury or joint fixation allows the surgeon to perform laser cordotomy, medial arytenoidectomy, or total arytenoidectomy as needed. The precision associated with the CO_2 laser facilitates performance of this operation. Pattern generators are also available that create an incision of desired length, shape, and depth of penetration, aiding in the precision and efficiency of the operating microscope micromanipulator.

The transoral management of squamous cell carcinoma of the larynx using the CO_2 laser is an obvious extension of the application of this surgical instrument. The advantages of precision, increased hemostasis, and decreased intraoperative edema allow the surgeon to perform exquisitely accurate and relatively bloodless endoscopic surgery of the larynx.

Bronchoscopic indications for CO_2 laser surgery include management of recurrent respiratory papillomatosis or granulation tissue within the tracheobronchial tree, excision of selected subglottic or tracheal strictures, excision of bronchial adenomas, and reestablishment of the airway in patients with obstructing tracheal or endobronchial cancers. In the case of obstructing tracheal or endobronchial cancers, palliation or reduction of the patient's symptoms of airway obstruction or hemoptysis is the goal.

Potassium-Titanyl-Phosphate (KTP) Laser

The KTP laser emits light at 532 nm and is therefore comparable with the Ar laser. The scattering and absorption by skin pigments when using the KTP laser are nearly the same as for the Ar laser, yet the KTP laser light is more strongly absorbed by hemoglobin.

The KTP laser has uses in otologic, rhinologic, and laryngologic surgery. It can also be used for tonsillectomy and pigmented dermal lesions. In otology, it has been shown to be effective for initial stapes surgery, as well as for revision stapedectomy.[32] Thedinger has promoted the KTP laser for chronic ear surgery, specifically for removing hyperplastic infected mucosa, disarticulating mobile stapes suprastructure in a complete cholesteatoma removal, and removing previously inserted middle ear implants.[33] Handheld probes also facilitate use of the KTP laser for functional endoscopic sinus surgery and other intranasal applications and for microlaryngeal applications. The optical fiber delivery of the 532-nm laser light can be manipulated through a rigid pediatric bronchoscope as small as 3 mm, facilitating lower tracheal and endobronchial lesion treatment in infants and neonates.[34]

The KTP crystal doubles the frequency (halves the wavelength) of an Nd:YAG laser. Therefore with this laser the output between the 532-nm KTP light and the 1064-nm Nd:YAG light can usually be switched.

Most of the past and current applications of the KTP laser use a continuous-wave mode. Recently, a pulsed mode has been introduced to take advantage of thermal relaxation times of tissue, minimizing collateral thermal damage. The pulsed KTP laser is used for selective photoangiolysis of laryngeal lesions such as papilloma and dysplastic lesions.[35] It can be applied in the office setting through flexible channeled endoscopes.

585-nm Pulsed Dye Laser

The 585-nm pulsed dye laser (PDL) is used mainly as a photoangiolytic laser for laryngeal applications. The targeted chromophore for the PDL is oxyhemoglobin, which has an absorption peak of 571 nm. Consequently, the laser energy is selectively absorbed by intraluminal blood of vascular lesions such as papilloma, vascular polyps, vocal fold ectasias and varices. Numerous surgeons have found this laser useful for in-office unsedated laser laryngoscopy through a flexible channeled laryngoscope that allows passage of the thin laser fiber.[36,37] Unlike CO_2 laser ablation effects, the PDL causes involution of the lesion through disruption of the vascular supply rather than immediate removal of the lesion. Advantages of this laser include the reduced risk of collateral thermal injury compared with the CO_2 laser.

Flash Lamp Pumped Dye Laser

The management of hemangiomas and port-wine stains with lasers has benefited from the application of the flash lamp pumped dye laser. The dye was initially selected for maximum absorption by the oxyhemoglobin at 577 nm. Tan and others showed that at 585 nm, hemoglobin absorption is maximal with minimal scattering and absorption by melanin and other pigments.[38] The light pulse is about 400 µsec long to minimize thermal diffusion in the tissue. Although dark skin types show little or no selective vascular photothermolysis with the flash lamp pumped dye laser, lighter skin types show significant results. At a threshold dose, specific vascular injury is observed without disruption of the adjacent tissue in lightly pigmented skin.

Other Lasers

In an effort to have a more controlled laser effect with less damage to adjacent tissue, several lasers in the near- to mid-infrared region have been investigated, including the erbium:YAG (Er:YAG) and the holmium:YAG (Ho:YAG). The Er:YAG emits at the infrared peak of water absorption at 2.94 µm. The extinction length in water is less than 2 µm. The laser produces very clean incisions with a minimal amount of thermal damage to the adjacent tissue. The negative aspects are that (1) the wavelength is too long to be transmitted through normal optical fibers, giving a distinct advantage to lasers that produce light that can be transmitted through fibers, and (2) more important, the thermal propagation is so short there is practically no tissue coagulation and no hemostasis. The Er:YAG laser is therefore unsuitable for use in highly vascular tissue. It has been used in dental surgery for various indications. In otolaryngology, the Er:YAG laser has been used for stapes surgery and for cutaneous applications, including rhinophyma and resurfacing for wrinkles.[23,26,39]

The Ho:YAG laser operates at 2.1 µm. This wavelength can be effectively transmitted through fibers. The extinction length in water is about 0.4 µm, which suggests that this laser light should interact with tissue in a way very similar to the CO_2 laser. The Ho:YAG has been combined with fiberoptic endoscopy for sinus surgery. The hemostasis is good, and the soft bone ablation is readily controlled. Adjacent thermal damage zones varied from 130 to 220 µm in a study by Stein and others.[8] The laser is as effective in sinus surgery as conventional surgical techniques with less blood loss but increased postoperative edema.[4] The thulium:YAG laser has also been introduced as a possible alternative to the CO_2 laser because it can easily be applied through a flexible endoscope in an office setting. It has a wavelength of 2.013 µm and has water as its main target chromophore. Early clinical reports are encouraging but whether it will replace the CO_2 laser for use in laryngology is uncertain.[40]

Pulse Structure

As mentioned earlier, the surgeon has three parameters to select when using a particular laser. The intensity of the laser is the least useful. The exposure time is important in that it controls the total amount of light incident on the tissue (i.e., the radiant exposure). The pulse structure of the laser light within the given exposure time is also crucial. The pulse structure is a characteristic of the active medium and the cavity configuration. It is often fixed and cannot be changed or modified by the surgeon.

Continuous Wave Lasers

Many lasers operate in a continuous wave mode. In this mode, the laser is always on. The instantaneous intensity and the average laser intensity are essentially the same. A shutter, external to the laser cavity, usually controls the exposure time, allowing the laser to operate independently of the exposure time or the frequency of exposures. This gives the most stable operation. A surgical CO_2 or Nd:YAG laser operates in continuous wave mode at intensities of a few watts to more than 50 W.

Flash Lamp Pulsed Lasers

Certain lasers operate in a pulsed mode. Flash lamp pumped lasers can pulse from about 0.5 msec to several 100 msec. The first ruby laser operated in a pulsed mode. The flash lamp used to pump the ruby crystal had a duration of about 1 msec. The laser output of this first ruby laser clearly was irregular and unstable. When observed with a fast detector and oscilloscope, the output intensity was found not to be a 1-msec long laser pulse but rather a series of irregular spikes. Each spike

is a few microseconds long with several microseconds between the spikes. The stimulated emission in the ruby is so efficient that it quickly depletes the population inversion and the operation stops, after which the flash lamp can reestablish the population inversion and operation can resume. This process repeats until the flash lamp stops. Most of the long-pulsed lasers operate in a spiking mode.

Q-Switched Laser

The spiking of the laser output can be controlled to produce a single very short laser pulse, much shorter than the flash lamp lifetime. One technique to produce the short pulses is Q-switching, in which the laser pumping process (usually a flash lamp) builds up a large population inversion inside the laser cavity. Blocking or removing one of the mirrors prevents the laser from emitting. After a large population inversion has developed, the feedback is restored and a short intense burst of laser light depletes the accumulated population inversion, typically in 10 to 50 nsec. Q-switching can be accomplished by several different methods. The most direct and earliest method is rotating the end mirror so that the light amplification by stimulated emission can occur during the short interval when the mirror is correctly aligned. Waring blender motors were often used as fast, stable motors. However, uncertain timing, lack of reliability, and vibration (and noise) led to many problems, particularly with the alignment. Electro-optic polarization rotators and acousto-optic beam deflectors are now commonly used for Q-switching.

Cavity Dumped Lasers

Cavity dumping produces slightly shorter pulses of light. In this technique, the laser is pumped and allowed to operate between completely reflecting mirrors. The light energy is trapped in the cavity until it reaches a maximum. Then one of the mirrors is "removed" from the cavity and allows all the light to leave the cavity. The laser pulse has a physical length of twice the cavity length. Thus the duration of the laser pulse is $2\lambda/c$, where λ is the length of cavity and c is the speed of light (c is about 3×10^{10} cm/sec or 1 foot/nsec).

Mode-Locked Lasers

Mode locking produces pulses of light as short as a few picoseconds. A Q-switched laser operates in several longitudinal modes (or slightly shifted frequencies). A fast saturable dye brings all these modes into phase. The nanosecond macropulse of light is actually a train of micropulses, each of which is several picoseconds long and repeats at about 100 MHz. These pulses can be further compressed by various techniques. The shortest laser light pulses achieved in the laboratory are less than 4 wave oscillations long (about 6 fsec or 6×10^{-15} sec).

The pulsed laser dramatically changes the interaction of the light with tissue. The intensity of the laser during the pulse is extremely high (approaching 10^9 W). The high intensity and short pulse duration enable the laser light efficiently to ablate tissue before the thermal energy spreads by thermal diffusion. The pulse should be significantly shorter than the thermal diffusion time to prevent thermal diffusion from spreading damage. Typically, a tissue under laser irradiation reaches thermal equilibrium within a few milliseconds. The heat spreads over several micrometers in less than 10 μsec. Also, the transverse mode structure of the laser beam must be preserved in the short pulses to yield the small focal spot size.

Safety Considerations

Education

The laser is a precise but potentially dangerous surgical instrument that must be used with caution. Although distinct advantages are associated with the use of laser surgery in the management of certain benign and malignant diseases of the upper aerodigestive tract, these advantages must be weighed against the risks of complications. Because of these risks, the surgeon must first determine if the laser offers an advantage over conventional surgical techniques. For the surgeon to use good judgment in the selection and use of lasers in practice, prior experience in laser surgery is necessary. Therefore some type of formal laser education program should be a prerequisite to using this technology. Most hospitals now require evidence of participation in a laser use and safety course before granting laser privileges. The surgeon who has not received training in laser surgery as a resident should attend a hands-on training course in laser surgery. Such a course should include laser biophysics, tissue interactions, safety precautions, and supervised hands-on training with laboratory animals. After completing such a course, the surgeon should practice laser surgery on cadaver or animal specimens before progressing to the more simple procedures on patients.

Hospitals that offer laser surgery should appoint a laser safety officer and set up a laser safety committee consisting of the laser safety officer, physicians using the laser, anesthesiologists, operating room nurses, a hospital administrator, and a biomedical engineer. The purpose of this committee is to develop policies and procedures for the safe use of lasers within the hospital. The safety protocols established by this committee will vary with each specialty and use of the laser. In addition, the laser safety committee should (1) make recommendations regarding the appropriate credential-certifying mechanisms required for physicians and nurses to become involved with each laser; (2) develop educational policies for surgeons, anesthesiologists, and nurses working with the laser; (3) accumulate laser patient data in cases where an investigational device was used; and (4) conduct a periodic review of all laser-related complications.

Aside from a few minor eye injuries from a laser beam exposure, most serious accidental injuries related to laser use can be traced to the ignition of surgical drapes and airway tubes.[41] Because the anesthesiologist is also concerned with the airway and because potent oxidizing gases pass through the airway in close approximation to the path of the laser beam, it is necessary to develop a team approach to the anesthetic management of the patient undergoing laser surgery of the upper aerodigestive tract. It is recommended that anesthesiologists involved with laser surgery cases attend a didactic session devoted to this subject. Finally, the operating room staff must be educated with regard to laser surgery. Attendance at an inservice workshop with exposure to clinical laser biophysics and the basic workings of the laser, as well as hands-on orientation, should be the minimal requirement for nurses to participate in laser surgery.

Safety Protocol

Development of an effective laser safety protocol that stresses compliance and meticulous attention to detail by the operating room personnel (laser surgery team) is probably the most important reason this potentially dangerous surgical instrument can be used safely in treating patients with diseases of the upper aerodigestive tract.[7] Such a laser safety protocol is usually general enough to list all the major and most minor precautions necessary when laser surgery is being performed within the specialty of otolaryngology. General considerations concern provisions for protection of the eyes and skin of patients and operating room personnel and for adequate laser plume (smoke) evacuation from the operative field. Additional precautions concern the choice of anesthetic technique, the choice and protection of endotracheal tubes, and the selection of proper instruments, including bronchoscopes.

Eye Protection

Several structures of the eye are at risk. The area of injury usually depends on which structure absorbs the most radiant energy per volume of tissue. Depending on the wavelength, corneal or retinal burns, or both, are possible from acute exposure to the laser beam. The possibility for corneal or lenticular opacities (cataracts) or retinal injury exists after chronic exposure to excessive levels of laser radiation. Retinal effects occur when the laser emission wavelength occurs in the visible and near-infrared range of the electromagnetic spectrum (0.4 to 1.4 μm). When viewed directly or secondary to the reflection from a specular (mirror-like) instrument surface, laser radiation within this wavelength range would be focused to an extremely small spot on the retina, causing serious injury. This occurs because of the focusing effects of the cornea and lens. Laser radiation in the ultraviolet (<0.4 μm) or in the infrared (>1.4 μm) range of the spectrum produces effects primarily at the cornea, although certain wavelengths also may reach the lens.[42]

To reduce the risk of ocular damage during cases involving the laser, certain precautions should be followed. Protecting the eyes of the patient, surgeon, and other operating room personnel must be addressed. The actual protective device will vary according to the wavelength of the laser used. A sign should be placed outside the operating room door warning all persons entering the room to wear protective glasses because the laser is in use. In addition, extra glasses for the specific wavelength in use should be placed on a table immediately outside the room. The doors to the operating room should remain closed during laser use.

Patients undergoing CO_2 laser surgery of the upper aerodigestive tract should have a double layer of saline-moistened eye pads placed over the eyes (Fig. 3-12). All operating room personnel should wear protective eyeglasses with side protectors. Regular eyeglasses or contact lenses protect only the areas covered by the lens and do not provide protection from possible entry of the laser beam from the side. When working with the operating microscope and the CO_2 laser, the surgeon need not wear protective glasses. The optics of the microscope provide the necessary protection (Fig. 3-13). When working with the Nd:YAG laser, all operating room personnel (and the patient) must wear wavelength-specific protective eyeglasses that are usually blue-green. Although the beam direction and point of impact may appear to be confined within the endoscope, inadvertent deflection of the beam may occur because of a faulty contact, a break in the fiber, or accidental disconnection between the fiber and endoscope. Special wavelength-specific filters are available for flexible and rigid bronchoscopes. When these filters are in place, the surgeon need not wear protective eyeglasses.[43]

When working with the Ar, KTP, or dye laser, all personnel in the operating room, including the patient, should again wear wavelength-specific protective eyeglasses that are usually tinted (Fig. 3-14). When undergoing photocoagulation for selected cutaneous vascular lesions of the face, the patient usually wears protective metal eye shields rather than protective eyeglasses. Similar precautions are necessary for the visible and near-infrared wavelength lasers. The major difference is the type of eye protection that is worn.

Skin Protection

The patient's exposed skin and mucous membranes outside the surgical field should be protected by a double layer of saline-saturated surgical towels, surgical sponges, or lap pads. When microlaryngeal laser surgery is being performed, the beam might partially reflect off the proximal rim of the laryngoscope rather than go down it. Thus saline-saturated surgical towels completely drape the patient's face. Only the proximal lumen of the laryngoscope is exposed. Great care must be exercised to keep the wet draping from drying out. It should occasionally be moistened during the procedure. Teeth in the operative field also need to be protected. Saline-saturated Telfa, surgical sponges, or specially constructed metal dental impression trays can be used. Meticulous attention is paid to the protective draping procedures at the beginning of the surgery. The same attention should be paid to the continued protection of the skin and teeth during the surgical procedure.[44]

Smoke Evacuation

Two separate suction setups should be available for all laser cases in the upper aerodigestive tract. One provides for adequate smoke and steam evacuation from the operative field; whereas the second is connected to the surgical suction tip for the aspiration of blood and mucus from the operative wound. When performing laser surgery with a closed anesthetic system, the surgeon should use constant suctioning to remove laser-induced smoke from the operating room. This helps prevent inhalation by the patient, surgeon, and operating room personnel. When the anesthetic system is open or has jet ventilation systems, suctioning should be intermittent to maintain the forced inspiratory oxygen at a safe level. Laryngoscopes, bronchoscopes, operating platforms, mirrors, and anterior commissure and ventricle retractors with built-in smoke-evacuating channels facilitate the evacuation of smoke from the operative field. One report suggested that the smoke created by the interaction of the CO_2 laser with tissue may be mutagenic.[45] Filters in the suction lines should be used to prevent clogging by the black carbonaceous smoke debris created by the laser. Although papillomavirus and other viral particles have been detected in the laser plume, no cases of clinical transmission of diseases are documented.[46,47]

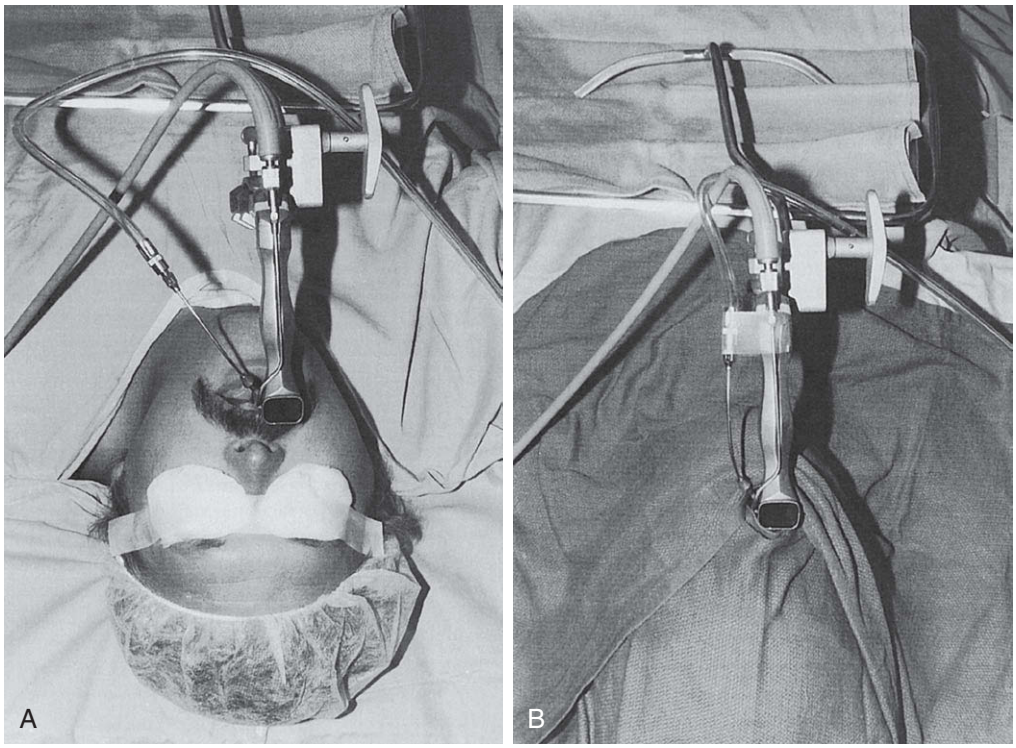

Figure 3-12. Patient undergoing carbon dioxide laser microlaryngoscopy with jet ventilation. **A,** Saline-moistened eye pads are secured with silk tape. The eyes are first taped closed with silk tape to prevent corneal abrasions from the eye pads. **B,** Saline-moistened towels are placed around the patient's head to cover all skin surfaces.

Figure 3-13. Protective eyewear is worn by the assistant surgeon during carbon dioxide laser microlaryngoscopy. The surgeon's eyes are protected by the optics of the operating microscope.

Anesthetic Considerations and Risk of Intraoperative Fire

Optimal anesthetic management of the patient undergoing laser surgery of the upper aerodigestive tract must include attention to the safety of the patient, the requirements of the surgeon, and the hazards of the equipment. Most patients undergoing upper airway laser endoscopy require general anesthesia. Any nonflammable general anesthetic is suitable. Halothane and enflurane are most often used. Because of the risk of fire associated with general endotracheal anesthesia, the inspired concentration of oxygen, a potent oxidizing gas, is critical and both surgeon and anesthesiologist must be aware of the risk involved. Mixtures of helium, nitrogen, or air plus oxygen are commonly used to maintain the forced inspiratory oxygen less than 40% and to ensure that the patient is adequately oxygenated. Nitrous oxide is also a potent oxidizing gas and should not be used in the anesthetic mixture to cut the oxygen concentration. The lowest concentration of oxygen should be used to maintain adequate oxygen saturations for the patient, and continuous dialogue between the surgeon and anesthesiologist is necessary. This is also true when performing laser surgery in the tracheobronchial tree through the rigid, ventilating bronchoscope. Although there is no flammable material in the airway, flash ignition of 100% oxygen may occur. Jet ventilation techniques during laser surgery are effective for selected patients, such as those with subglottic stenosis. Successful use of this ventilation technique requires that the anesthesiologist be experienced in this practice.

One of the most devastating complications of laser surgery of the aerodigestive tract is endotracheal tube ignition and resulting injury to the laryngotracheal mucosa. At present, a nonflammable, universally accepted endotracheal tube for all types of laser surgery of the upper aerodigestive tract does not exist. The traditional polyvinyl endotracheal tube should not be used, either wrapped or unwrapped. It offers the least resistance to penetration by the laser beam of all the endotracheal tubes that have been tested. Its fire-breakdown products are toxic, and tissue destruction associated with combustion of this tube is the most severe when compared with other tubes. Endotracheal tubes for laser surgery that are wavelength specific are now available from several manufacturers and should be used at all times unless jet ventilation techniques are used.

Protection of the endotracheal tube from direct or reflected laser beam irradiation is of primary importance. If the laser beam strikes an

Figure 3-14. Patient undergoing pulsed dye laser treatment for papillomas in the office. Both the patient and surgeon are wearing wavelength-specific protective eyewear. The laser fiber can be seen protruding from the end of the working channel on the video monitor.

unprotected endotracheal tube carrying oxygen, ignition of the tube could result in a catastrophic, intraluminal, blowtorch-type endotracheal tube fire. Protection should also be provided for the cuff of the endotracheal tube, even while using laser-specific tubes. Methylene blue–colored saline should be used to inflate the cuff. Saline-saturated cottonoids are then placed above the cuff in the subglottic larynx to further protect the cuff. These cottonoids require frequent moistening during the procedure. If the cuff deflates from an errant hit by the laser beam, the already saturated cottonoids turn blue to warn the surgeon of impending danger. The tube should then be removed and replaced with a new one. Use of the microlaryngeal operating platform offers further protection against potential danger. Inserted into the subglottic larynx above the level of the packed cottonoids, this unique instrument serves as a backstop to protect the cottonoids, endotracheal tube, and cuff from any direct or reflected laser beam irradiation. A 60-mL bulb syringe and basin of saline should be immediately available to the surgeon. In the event of tube ignition, ventilation must be stopped immediately and the tube withdrawn simultaneously as saline is flushed down the endotracheal tube. The airway must be reestablished immediately and bronchoscopy performed to assess the degree of injury. Intravenous steroids may be delivered and the patient should remain intubated; repeat bronchoscopy should be performed daily until it is established that the airway is stable.

Effectiveness of a Safety Protocol

Strong and Jako[48] and later Snow and others[49] warned of the possible complications associated with laser surgery of the upper aerodigestive tract, including the risks of endotracheal tube fires and tissue damage from reflection of the laser beam. In a survey of laser-related complications by Fried,[10] 49 of 152 otolaryngologists who used the laser reported 81 complications, including 28 incidents of endotracheal tube fires. Healy and others[50] reported a 0.2% complication rate in 4416 cases of CO_2 laser surgery in the upper aerodigestive tract. Ossoff[44] published an extensive view of laser-related complications experienced by 218 past registrants of hands-on laser surgery training courses that he directed. Seven surgeons experienced 8 complications and no endotracheal tube fires. The complication rate was 0.1% in more than 7200 laser surgical procedures. These papers have similar conclusions: (1) certain precautions are necessary when performing laser surgery of the upper aerodigestive tract, and (2) adherence to a rigid safety protocol allows laser surgery of the airway to be performed safely and with an extremely small risk of serious complications.

CHAPTER FOUR A

Surgical Robotics in Otolaryngology

David J. Terris

Key Points

- Surgical robotics have evolved from rudimentary scope holders to sophisticated and precise telerobotic systems with "wristed" technology and true three-dimensional visualization.
- Experimental robotic surgery investigation has centered on neck and thyroid, skull base, and oropharyngeal applications.
- Clinical robotic applications have so far been restricted to thyroid and oropharyngeal procedures.
- There is a burden with robotic surgery to balance increased time, expense, and technologic challenges with improvements in outcomes or other definable advantages.
- Despite a number of hurdles, it seems likely that the future will bring more indications for robotic assistance, rather than fewer.

History of Robotics

The origins of robotics may be traced to early in the twentieth century, when the Czechoslovakian Capek brothers introduced the concept of automated devices. Joseph Capek wrote the short story "Opilec" in which automats were described, and Karel Capek wrote "Rossum's Universal Robots." This introduction of the term *robot* (deriving from the Czech word *robota*, which means serf or laborer) was part of a fictional depiction of the increasing sophistication of robots, which eventually rose up against their human inventors.[1]

The next seminal spark of the collective imagination of scientists and society alike occurred with Isaac Asimov's collection of short stories in the 1940s.[2] He developed the three laws relating to robot behavior, which were recently popularized in Will Smith's "I, Robot":

1. A robot may not injure a human being or through inaction allow a human to come to harm.

2. A robot must obey orders given it by humans except when doing so conflicts with the first law.

3. A robot must protect its own existence as long as this does not conflict with the first or second law.

Other Hollywood productions stimulating public interest in robotics included the "Star Wars" series, the "Terminator" trilogy, and "Bicentennial Man," starring Robin Williams.

Simultaneous with sensational depictions of the potential for common robotic applications, gradual and stepwise breakthroughs in electronics and computers paved the way for the development and production of the first meaningful robot in 1958, dubbed "the Unimate" by General Motors. Its use in assembly lines to facilitate automobile production in 1961 was the first in what eventually became widespread application of automation in the automobile industry. Honda has been particularly innovative in its development of robotic humanoids, culminating in the ASIMO, which not only can walk but also can negotiate stairs (Fig. 4A-1).

A growing number of other applications for robotics have quickly emerged, including military uses and purposes as far-reaching as exploration of deep sea and space and as mundane as lawn care and use of home appliances. These robots can be characterized in a variety of ways: automated arms, mobile devices, mills, or telerobotic devices. With the advent of these many and varied robots, specific nomenclature has evolved to classify their actions and mechanisms.

Definitions

As the presence of robotics in the operating room becomes more pervasive, a basic knowledge of the language of robotics is desirable. The following terms represent the essential foundation of robotic lexicography[3]:

Robotic surgery—implies the use of a powered device that functions under programmable computerized control and may be used to manipulate instruments and perform surgical tasks.

Active robotics—refers to a robot that is programmed to independently perform a complete task without operator control.

Semiactive robotics—requires the input of an operator to perform defined, powered tasks.

Passive robotics—functions only at the direction of the operator, without independently powered movements (sometimes referred to as a *telemanipulator*).

Telerobotic surgery—refers to a system in which the operator controls a robot from a console containing a virtual three-dimensional visualization framework and from which robotically controlled manipulations are reproduced.

Telepresence—extension of telerobotic surgery to a remote site so that the console from which the operator issues commands is located at a distance from the robot; the robotic surgeon may therefore never have contact with the patient.

Telementoring—when coupling an experienced surgeon with a trainee at a remote location, telepresence provides the technologic framework for distance training or so-called *telementoring*.

History of Medical Robotics

While the earliest applications of robotics were in the automobile industry, the Department of Defense recognized the potential value of remotely controlled robotics, both for the military options they afforded and for the possibility of providing care to wounded soldiers on the battlefield with the surgeon safely out of harm's way. This concept of so-called virtual insertion of the surgeon into the battlefield was championed and funded by the Pentagon's Defense Advanced Research Projects Agency (DARPA). Similarly, the National Aeronautics and Space Administration (NASA) teamed up with the Ames Research Center (Mountain View, CA) and the Stanford Research Institute (Palo Alto, CA) to develop both a head-mounted virtual reality display (Fig. 4A-2A) and a data-glove (see Fig. 4A-2B), by which the user could cause and witness his own interactions within a virtual environment.

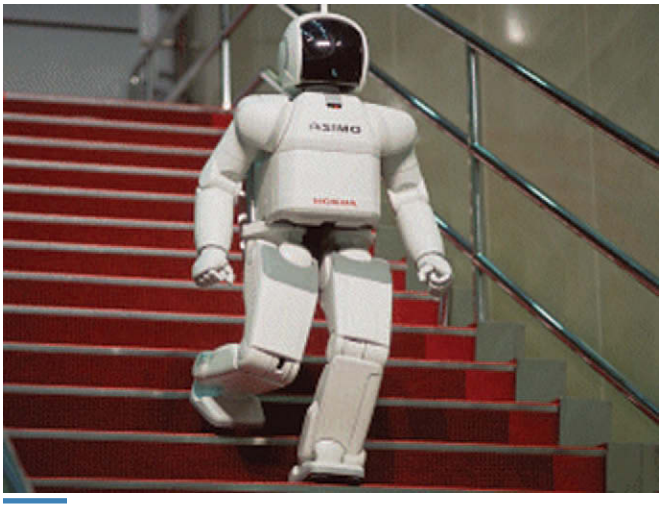

Figure 4A-1. The ASIMO from Honda is a humanoid robot that is capable not only of walking, but of negotiating stairs.

Less sophisticated technology was used to accomplish the first robot-assisted surgical procedure in 1985, a stereotactic brain biopsy.[1] In 1992, the Robodoc (a computer-guided mill used to core the femoral head) was introduced in Europe for use in hip replacement surgery, and later the Acrobot was developed for knee replacement and temporal bone surgery. These have yet to receive U.S. Food and Drug Administration approval for use in the United States, largely because of concerns regarding complication rates.

The growing interest in surgical robotic applications, along with ample funding, spawned a number of market leaders in medical robotics, including the companies Computer Motion, Inc., and Intuitive Surgical, Inc. Computer Motion developed the automated endoscopic system for optimal positioning (AESOP) system (Fig. 4A-3), which was combined with Hermes voice-activation movement technology, and has seen limited adoption in laparoscopic surgical procedures. Computer Motion was also responsible for creating the Zeus telerobotic system (Fig. 4A-4).

Computer Motion was eventually acquired by Intuitive Surgical, the Zeus was retired, and the daVinci system has become the industry standard for surgical robotics. The current leading applications include prostate surgery,[4] cardiothoracic surgery,[5] and advanced gynecologic surgery.[6] More than 50% of radical prostatectomies, for example, are performed using the daVinci system.

The first trans-Atlantic telerobotic surgery received relatively little attention because of the temporal relationship to the 9/11/01 terrorist attacks on the United States. On September 7, 2001, Jacques Marescaux was seated in New York City while he performed a laparoscopic cholecystectomy on a patient who was 3800 miles away in Strasbourg, France. Dubbed the Lindbergh Operation (in tribute to Charles Lindbergh, who was the first to accomplish a trans-Atlantic solo flight), the procedure was a collaboration between Marescaux and Michel Gagner of Mount Sinai Hospital in New York. High-speed fiberoptic connections provided by French Telecom were necessary to minimize the time-lag between surgeon commands and robotic movements, and the response-delay achieved was 155 msec. Even though sensational events like these prompt high expectations, the implementation of robotics into fields such as otolaryngology–head and neck surgery has been a much more gradual and deliberate process.

Robotic Applications in Otolaryngology

A role for this technology in otolaryngology is beginning to emerge, particularly where precision is required or visualization is limited, and there are a number of pioneering contributions. The first otolaryngo-

Figure 4A-2. The combination of a virtual reality headset **(A)** and a data-glove **(B)** allow the user to interact with his virtual environment while witnessing the activity.

logic application of robotics occurred as early as 2002 with several reports from the Terris group at the Medical College of Georgia exploring endoscopic neck procedures.[7-10] The first human application was described by McLeod and Melder[11] with a case report of excision of a vallecular cyst. Hockstein and colleagues further pursued oral and oropharyngeal applications of robotic technology with a stepwise experimental approach.[12,13] Finally, interest in robotic skull base surgery has emerged with the work of Hanna and colleagues.[14]

Experimental Origins

The first use of robotics for otolaryngologic applications was explored in a porcine model of neck surgery that included parotidectomy, submandibular gland resection, and selective neck dissection.[8] This work built on previous promising findings for totally endoscopic neck surgery (also described by Terris and collaborators[15,16]) and provided proof of principle, in that the safety and efficacy of endorobotic neck surgery was demonstrated, and quickly established that advantages in duration of surgery could be easily achieved with the addition of robotic technology.

Figure 4A-3. The AESOP (automated endoscopic system for optimal positioning) combines robotics with voice activation to accomplish precise camera positioning during endoscopic surgery.

The first investigative protocol[8] was represented by a prospective nonrandomized investigation in a porcine model in which four different types of neck surgery were accomplished using the daVinci surgical system (Intuitive Surgical Inc., Sunnyvale, CA) (Fig. 4A-5). This system employs robotics to enable microsurgery in an endoscopic environment. It consists of a surgeon's console with two control handles and a virtual three-dimensional vision projection system, and a patient side cart with three or four robotic arms, three of which manipulate operative instruments and a fourth that controls a video endoscope. The video system contains twin-mounted endoscopes, with projection of one image to one eye of the console and the other image to the other eye (Fig. 4A-6). This therefore produces true three-dimensional images at the tip of the scope. The robotic arms permit utilization of a full range of articulated instruments (Fig. 4A-7) that are used for clamping, cutting, suturing, and tissue manipulation, including electrocautery, forceps, clip appliers, and scissors. These instruments are equipped with EndoWrist technology, which provides up to 7 degrees of freedom (unlike the 4 degrees associated with conventional endoscopic instrumentation), allowing the surgeon's endoscopic movements to closely mimic those of the human wrist. The daVinci tracks the surgeon's hand movements 1300 times each second and relays the data to the instrument tips, reproducing the surgical maneuvers. While the primary surgeon controls the robotic instruments and the camera, an assistant changes and adjusts the instruments.

The procedures performed in this original investigation included one thymectomy, one partial parotidectomy, three submandibular gland resections, and three neck dissections (Fig. 4A-8). There were no complications, and no conversions to open surgery were necessary. Because of the substantial preparation required to ready the robotic system for use, careful documentation of the time that transpired during the establishment of the operative pocket and the time needed to assemble and position the robotic arms was undertaken. Despite a total setup time exceeding 30 minutes, there was still a savings in overall operative duration when comparing robotic submandibular gland resection and neck dissection to historical controls (conventional endoscopic procedures) (Fig. 4A-9).

The natural next model for systematic exploration of feasibility of robotic neck surgery was the fresh cadaver. Terris and colleagues

Figure 4A-4. The Zeus telerobotic system consists of a patient-side cart **(A)** and a console **(B)**. It was the precursor to the daVinci surgical system, which also consists of a console and a patient-side cart. It has been retired, leaving the daVinci as the only commercially available surgical robot in the United States.

Figure 4A-5. With the daVinci surgical system, the surgeon manipulates the robotic instruments of the master console, which is located within several feet of the operating table. *(Reprinted with permission from Haus BM, Kambham N, Le D, et al. Surgical robotic applications in otolaryngology.* Laryngoscope. *2003;113[7]:1139-1144.)*

described a series of 11 endorobotic submandibular gland resections that were accomplished in six fresh cadavers.[9] The port placement was similar to that which had been previously described.[17] A 14-mm incision was created approximately 9 cm lateral to the sternal notch over the clavicular head of the sternocleidomastoid muscle for the camera port, and two 10-mm incisions were created approximately 4 cm to each side of the camera port for 8-mm instrument trocars (Fig. 4A-10). The submandibular gland was accessed by approaching inferiorly in the subplatysmal plane. The facial artery and vein and submandibular duct were ligated using the robotic clip appliers. After the submandibular gland was completely mobilized, the robotic camera was repositioned into one of the 8-mm ports and the specimen was retrieved through the 14-mm trocar incision.

Because prior conventional endoscopic procedures had been accomplished by the same investigators,[17] a noncontemporaneous comparison of outcomes to historical controls was possible and showed a significant reduction in median surgical times, from 65.5 minutes to 48 minutes.

Stimulated by the promising findings in these seminal studies, Hockstein and colleagues likewise embarked on a series of experiments, first in an inanimate model (mannequin[12]) and then in cadaver studies[13] to evaluate the feasibility and potential benefit of robot-assisted oropharyngeal surgery.

In their first publication in 2005, Hockstein and colleagues used a mannequin with the same daVinci device to define the optimal configuration for exposing the oropharynx (McIvor mouthgag combined with the 30-degree three-dimensional endoscope) and relationship of the robot to the operating table and patient (Fig. 4A-11).

In a subsequent study, the same group accomplished several procedures on a single cadaver using a Dingman mouthgag for exposure. These included vocal cord strippings and arytenoidectomies (Fig. 4A-12). These exploratory investigations provided the foundation for subsequent clinical protocols.

Clinical Applications

With McLeod and Melder's[11] report on a patient with a robotically assisted vallecular cyst marsupialization in 2005, and then with the subsequent report by Lobe and colleagues[18] of a successful robotic axillary thyroidectomy later that year, the first human applications of robotic surgery in otolaryngology were realized. A number of other applications of this technology have quickly followed, and with increasing versatility of the robot combined with miniaturization, expansion

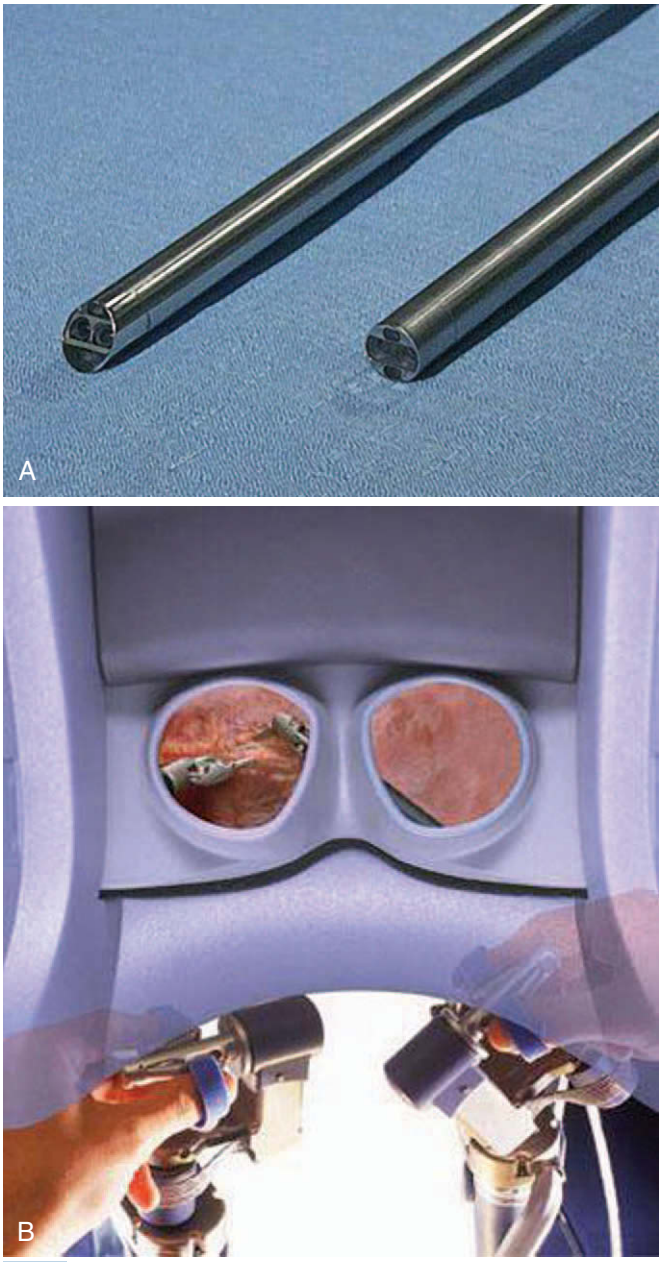

Figure 4A-6. The image obtained with the daVinci system is truly three-dimensional, in that one image of the twin-mounted endoscopes (either 30 degree or 0 degree, depicted in **A**) is projected to one eye on the console, and the other image is projected to the other eye (as seen through the console in **B**).

of the indications for its use seems likely. The only commercially available surgical robot remains the daVinci (Intuitive Surgical, Inc.). A number of challenges are posed by this technology and need to be overcome to justify its use in surgical procedures.[19]

The value-added for thyroidectomy is represented by the ability to work past the clavicle when approaching the thyroid compartment from the axilla. For oropharyngeal surgery, the possibility of working "around corners" provides improved access, particularly to the tongue base. For skull base surgery, the three-dimensional visualization combined with precise manipulation comprise the benefits worthy of additional study.

Robotic Thyroidectomy

A number of Japanese investigators described an axillary approach to the thyroid compartment[20,21] that was coincident with the development

of a central endoscopic-assisted approach.[22,23] The central approach has seen widespread adoption,[24,25] while the axillary technique has remained largely an Asian exercise in patience (3 to 4 hours are required to accomplish a simple lobectomy, and more than 6 hours are needed for a total thyroidectomy). Experimental work done by Terris[26] and Faust[27] spawned the concept of merging the robotic technology with a totally endoscopic thyroid procedure, thereby facilitating access that is necessarily cumbersome because the clavicle impedes direct access to the thyroid compartment. This culminated in the description of an axillary thyroidectomy in a patient in 2005.[18] Even though an improvement in surgical times has not yet been realized (this simple lobectomy lasted 4.5 hours), there were no untoward outcomes and further study seems warranted.

Robotic Skull Base Surgery

Because of the limited exposure and plentiful critical structures demanding skill and precision, there has been intense interest in accomplishing robotic surgery at the skull base. Much of the groundwork was established by Hanna and colleagues in a study of four human cadavers, including bilateral transantral access (Fig. 4A-13) and positioning of the robotic arms, and determination of the advantages related to suturing and reconstruction (Fig. 4A-14).

O'Malley and colleagues[28] took this approach into the human under an IRB-approved protocol in which an infratemporal fossa cyst was removed from a patient. The skull base probably represents the least studied but most fertile surgical site for robotic technology in the head and neck.

Robotic Oropharyngeal Surgery

In an extension of the experimental work done by Hockstein, the surgical robot was eventually paired with the endoscopic oropharyngeal approach pioneered by Steiner[29] and popularized by Grant and others.[30]

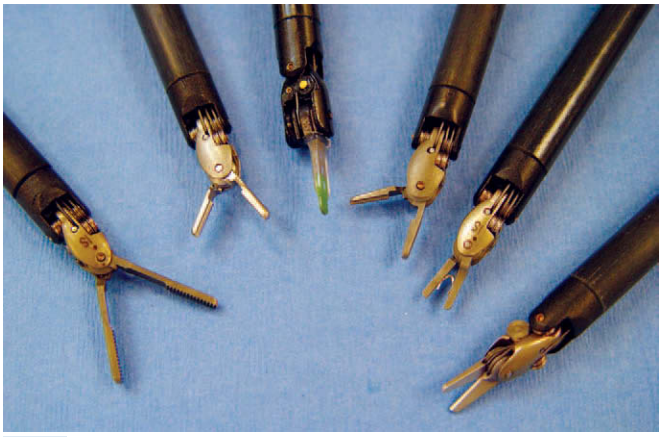

Figure 4A-7. The 8-mm operative ports are used for a variety of robotic instruments designed for clamping, cutting, suturing, and tissue manipulation, including an electrocautery device, forceps, clip appliers, and scissors. *(Reprinted with permission from Haus BM, Kambham N, Le D, et al. Three patients with small base of tongue cancers underwent transoral resection with robotic assistance with no apparent complications.[31] It remains too early to assess the oncologic outcomes from these interventions. Introducing robotic technology to accomplish a tonsillectomy has less apparent advantage.[32]

The use of robotic assistance for otolaryngologic applications certainly must still be considered experimental, and findings from each of the robotic groups cited will need to be confirmed at other institutions (or preferably in controlled multicenter trials) before regulatory approval will be granted and more widespread adoption occurs.

Future Directions

The question no longer appears to be "Will robotics find a place in surgery?" Rather, the question appears to be simply "How and in which applications will robotics be used?" Particularly in the field of otolaryngology, head, and neck surgery, inevitable advances in miniaturization and versatility will combine with improvements in visual fidelity to widen the procedural clinical applications. The challenge will be to responsibly pursue these technology-laden procedures in a logical and cautious fashion when they provide meaningful added value and not simply to satisfy the technologic appetite of the surgeon. Nevertheless, one can anticipate a number of additional procedures that may derive benefit from the addition of robotic technology, including precise and technically demanding otologic surgery, delicate voice surgery, and complex resections and reconstructions throughout the upper aerodigestive tract.

Another necessary parallel development will include specific training in robotic surgery. This will manifest in several forms, ranging from the classic weekend primer course for those technologically oriented individuals already adept at advanced endoscopic surgery,

Figure 4A-14. all the way to year-long robotic surgery fellowships as we further exploit the electronic and technologic advances that continue to accelerate.

CHAPTER FOUR B

Simulation and Haptics in Otolaryngology Training

Marvin P. Fried

Gregory J. Wiet

Babak Sadoughi

Key Points

- Surgical training must rely on standardized and well-tested methods of instruction.
- Patient risk reduction is an unquestionable priority.
- Simulation provides an ideal environment to train surgeons in realistic conditions without jeopardizing patients.
- Surgical scientific societies support surgical simulators as mandatory training media.
- Scientific validation is a critical factor of simulator development.
- Otolaryngology is a pioneering specialty in the development and implementation of surgical simulators.
- The Endoscopic Sinus Surgery Simulator (ES3) is the most sophisticated simulator available for paranasal sinus surgery.
- Validation studies have demonstrated construct validity of the ES3; further studies are underway to assess the validity of the ES3 to improve actual surgical skills in the operating room.
- A number of temporal bone surgery simulators have been developed around the world; the system designed by The Ohio State University and the Ohio Supercomputer Center, based on volume-rendering, has particularly strong realism and interactivity.
- The Ohio State Temporal Bone Simulator can also easily import imaging data sets and allow a patient-specific surgical rehearsal experience.
- The Ohio State Temporal Bone Simulator is currently being tested as a training tool through a large multi-institutional trial.
- Concurrent curriculum development is an essential part of all simulation training projects.

Surgical skills training must be predicated on standard and well-tested methods of instruction. Besides hands-on operative experience on live patients, resident training currently relies on video tapes and cadaver dissection where available. Some institutions have used cadavers to provide the first surgical experience to residents learning endoscopic sinus surgery. Stankiewicz has long been a proponent of a rigorous curriculum using cadaveric dissection before performing a first sinus surgery procedure, although the utility of such a method has never been demonstrated.[1] More frequently, direct observation of procedures in the operating room is employed, with increased responsibility as residents progress in training, ultimately becoming the major participant by their final year.

In light of the increasing scrutiny on the medical profession, diminishing patient risk is of paramount concern, particularly for surgical procedures. Medical simulator technology provides interim training media wherein proficiency can be achieved before entering the operating room. Indeed, the science of simulation, well past 50 years of implementation in other high-risk professions (e.g., aviation industry, nuclear power plants), has already demonstrated the following capabilities (Brandon Hall Research News, 2005, available at www.brandon-hall.com):

- Providing a safe environment to make mistakes
- Reducing training time, thereby creating the most efficient path for solving a specific problem
- Allowing practice of hazardous procedures, such as shutting down a nuclear reactor or flying in hazardous conditions
- Streamlining the processes that are being taught (e.g., improvements in process are often made when creating simulations)
- Facilitating greater retention
- Transferring expert thinking by "modeling" expert behavior in the learning

High-fidelity virtual reality (VR) simulators have long had an impact on improving the skill level of military and commercial pilots, and they hold similar promise for the medical field. With a validated surgical simulator, proficiency criteria can be attained before permitting the student surgeon to operate upon a patient. Based on the lessons

from aviation training over the past 3 decades, computer-assisted devices have had significant success in augmenting the education and training of surgical residents in a number of fields.[2-5] VR simulation has already played a role in the training of residents for laparoscopic, gastrointestinal, plastic, ophthalmologic, dermatologic, urologic, and some laryngologic procedures.[6-13] The efficacy of VR simulation as a teaching tool is evident, and its superiority to conventional teaching methods is increasingly accepted. Recently, it has been reported that virtual reality training impacts positively not only on resident operating room performance but also potentially on safety.[14]

During the past 15 years, medical simulation technology has gained substantial support. Validation studies have established that surgical skills trained using medical simulation significantly improved trainee performance by decreasing operating times, improving efficiency, and decreasing errors. The medical profession, academics, authoritative organizations (training, testing, licensing and certification bodies) and corporate partners have accepted the importance of simulation within the context of a quantitative assessment environment unique to simulators. The impact on patient safety is *a priori*—that is, make the corrections on a simulator, not on a patient. For instance, the American College of Surgeons is interested in promoting surgical simulators by identifying targets for simulation; researching, writing, and implementing the plan for medical simulation training; and investigating sources of funding.[15] Simulation is expected to soon provide a full range of possible surgical conditions wherein training can occur without placing a patient at risk. Otolaryngology has been a leading field in virtual reality simulation, mainly with efforts in the specific spheres of paranasal sinus surgery and temporal bone surgery simulation.

Endoscopic Sinus Surgery

The impact of sinus disease on quality of life as well as social and work performance is significant.[16,17] In 2004, 31 million Americans, almost 14% of the population, suffered from sinus disease.[18] Every year, sinus disease sufferers account for 12.5 million visits to office-based physicians and 1.1 million hospital outpatient visits per year.[19] The overall direct expenditures attributable to sinusitis in 1996 were estimated at $5.8 billion, of which $1.8 billion (31%) was incurred to treat children 12 years of age or younger.[20] Because of the limitations of large-scale evaluations, these figures likely underestimate true direct costs.[21] The indirect costs of sinusitis are staggering too: the number of total restricted activity days due to sinusitis rose from approximately 50 million per year between 1986 and 1988 to 73 million per year between 1990 and 1992.[18]

In 2004, Lynn-Macrae and colleagues queried a computerized legal database to retrospectively analyze state and federal civil litigation involving injuries resulting from endoscopic sinus surgery (ESS) between 1990 and 2003. They observed that 76% of ESS-related malpractice suits were prompted by alleged negligent technique, with an average verdict award of $751,275.[22]

Surgery is used when medications fail or when complications of the sinus disease ensue. ESS was first introduced in the 1970s and has since been established as the standard of care for operative treatment of the sinuses and nasal cavity.[23-26] ESS involves the introduction of delicate surgical instruments through the nares to perform exacting maneuvers for a wide range of surgical interventions involving the paranasal sinuses and the cranial base. Although the concept of ESS is straightforward, skillfully performing the procedure can be challenging.[27] The relevant anatomy is highly complex and compact, with the added concern of the vicinity of such important structures as the brain, orbital contents, and carotid artery.[1,28] With very little room for error, the surgeon must navigate and manipulate instrumentation using dominant and nondominant hands simultaneously, while coordinating movements indirectly with the aid of a television monitor. Precise hand-eye coordination is an obvious prerequisite. The ESS technique provides the surgeon with excellent visualization, supplemented by an array of instruments that permit access to the depths of the sinuses and to the cranial base. The use of a computer-based image-guidance system (IGS) adds to these capabilities by providing unprecedented navigational support to reach the area of interest while delineating the surrounding anatomy that is not at pathologic risk. The applications of endoscopic procedures have expanded widely as safety and efficacy have been documented.[29-31]

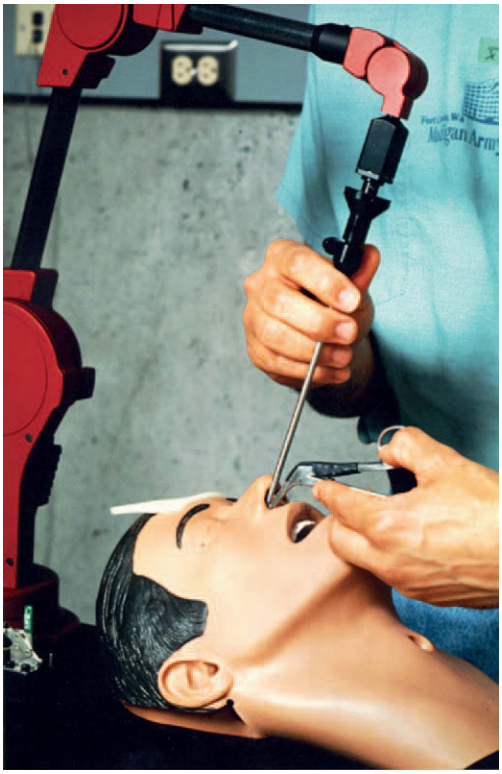

Figure 4B-1. The Madigan/Lockheed Martin Endoscopic Sinus Surgery Simulator (ES3).

However, the potential complications of ESS may be very serious in less than well-trained hands, and simulation may well reduce the complication rates of ESS. While designing a curriculum for ESS, emphasis is therefore placed on the quality and quantity of training that a surgical trainee must have before performing independently.

Endoscopic Sinus Surgery Simulator

The technical acumen required for basic ESS procedures is not achieved, for the most part, until the later half of a resident's training. With the increase in the complexity of microdissection equipment and the growing demand to broaden the indications of ESS,[32] there is a real need to make residents more familiar with the technical skills of ESS at an earlier stage in training. As technology matures, the need for simulators to teach surgery has become apparent.[33] Again otolaryngology took a leadership role in this venture with the conception in 1996 by Department of Defense contractor Lockheed Martin Corporation of the Endoscopic Sinus Surgery Simulator (ES3) (Fig. 4B-1). The system employs virtual anatomy and instruments, visual and haptic (force) feedback, voice commands, phased instruction, and performance monitoring to create a virtual reality environment designed to train otolaryngology residents.[13,34-37] The simulator provides spatial relationships, ability to maneuver in operating space, presentation of sinus anatomy, common surgical instruments, and basic to advanced surgical technologies. The ES3 development team conducted evaluation studies[13,34-37] that have been followed by a series of formal scientific validation studies by multi-institutional academic and corporate consortia.

The ES3 consortium organization, led by the Albert Einstein College of Medicine's Montefiore Medical Center and funded by the Agency for Healthcare Research and Quality, provided a center for curriculum development (Yale University), centers for data collection (New York University Medical Center, New York Eye and Ear

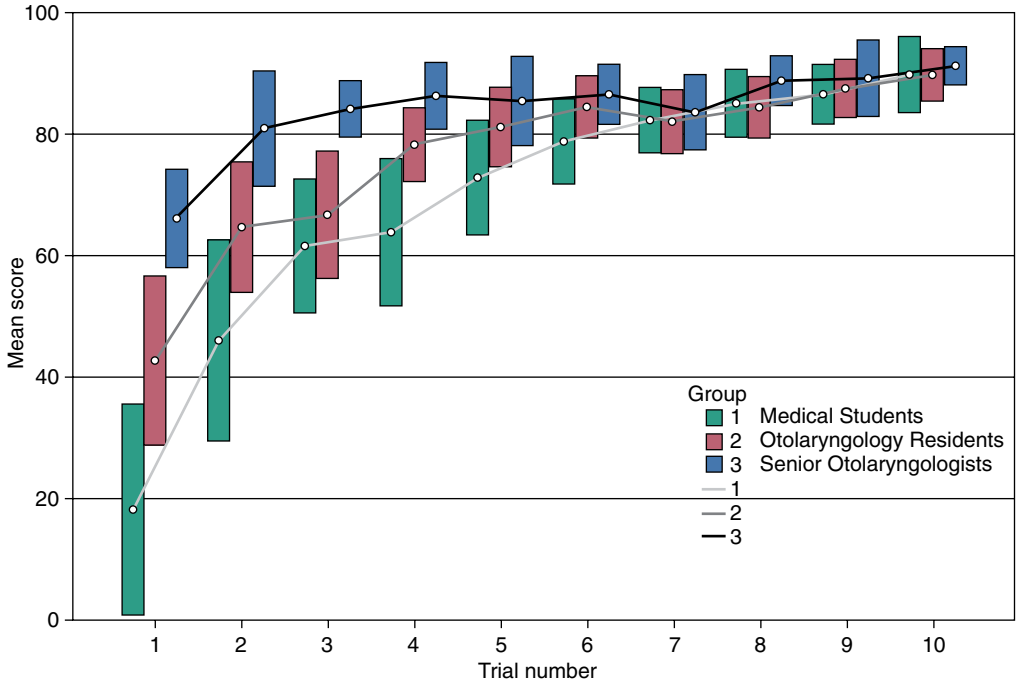

Figure 4B-2. Performance over 10 trials on the ES3 novice level by otolaryngology attendings, residents, and medical students. *(From Fried MP, Sadoughi B, Weghorst SJ, et al. Construct validity of the endoscopic sinus surgery simulator: II. Assessment of discriminant validity and expert benchmarking.* Arch Otolaryngol Head Neck Surg. *2007;133[4]:350-357.)*

Infirmary, Mount Sinai Medical Center), and a center for web database and outcomes reporting (UW-HITLab).

The development team also developed a prototype intelligent multimodal expert surgical assistant for the ES3.[38] The system, which incorporates knowledge of the endoscopic procedure into a structured rule base, interprets the user's multimodal inputs (currently voice and virtual endoscope position) and interacts with the user dynamically. While performing the simulated procedure, the user can query the system about anatomy and the specifics of the procedure, asking the system to identify features or demonstrate maneuvers. In turn the system recognizes the user's actions and can provide vocal and visual feedback, as well as warnings when the user is about to execute a dangerous maneuver. In addition to enhancing simulation for training purposes, the expert surgical assistant can also be used for guidance during actual surgical procedures. This assistance can be particularly helpful for procedures in which situation awareness is diminished due to the complexity of the anatomy or to surgical complications.

One of the initial first validation studies of the ES3 specifically addressed the system's discriminant and concurrent validity, by comparing cumulative performance levels between medical students, otolaryngology residents, and otolaryngology attendings as groups, thereby establishing attending benchmark data against which residents and medical students can be measured. The simulator performance data of 10 medical students were compared with those of 14 otolaryngology residents and 10 attending otolaryngologists. The results (Figs. 4B-2 and 4B-3) clearly demonstrated significant differences in performance among the three groups. Attending otolaryngologists perform the best at all levels, with residents close behind and medical students performing substantially subpar to residents. However, by the end of the curriculum (i.e., trial 10), all groups achieved plateau scores included within a remarkably narrow range. This illustrates the consistency and relatively low variability of performance after simulator training, allowing the instructors to set predefined performance goals tailored to the educational needs of the trainees.[39] A spinoff observation yielded by the study of medical student performance showed that, after a critical period of training had been accomplished, the performance of the trainee did not substantially diminish even after 1 month without simulator training.[40] Hence, the transfer of complex skills facilitated by the ES3 produces long-lasting and memorable performance. This has implications with regard to the use of surgical simulation as a meaningful training tool in an effort to reduce surgical errors and increase patient safety.

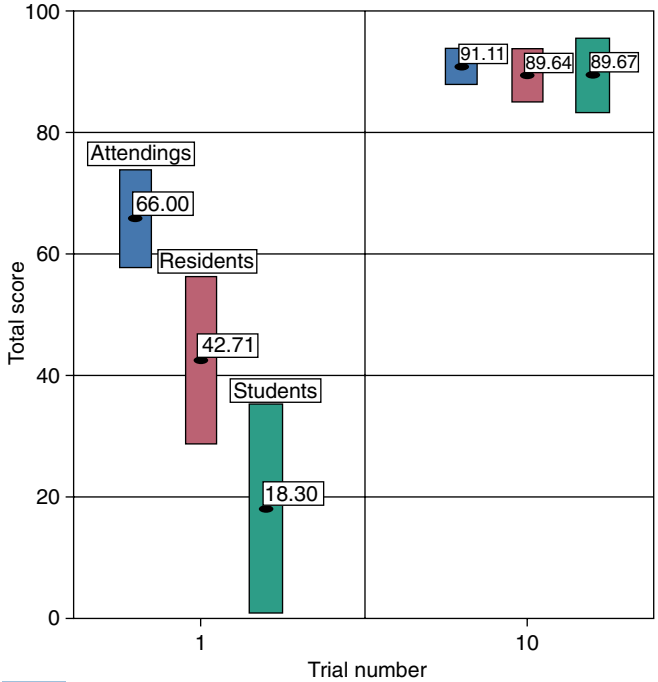

Figure 4B-3. Performance range variability between trials 1 and 10. *(From Fried MP, Sadoughi B, Weghorst SJ, et al. Construct validity of the endoscopic sinus surgery simulator: II. Assessment of discriminant validity and expert benchmarking.* Arch Otolaryngol Head Neck Surg. *2007;133[4]:350-357.)*

Table 4B-1

Pearson Correlation Coefficients between ES3 Hazard and Total Scores and Independent Tests of Visuospatial, Psychomotor, and Perceptual Abilities

	Pict Surface Orientation (PicSOr)	Cube Comparison (CC)	Card Rotation (CR)	MIST-VR Total Score	Regression Model Fit (ES3 trial score, PicSOr, CC, MIST-VR)
ES3 Hazard score	r = .5* (P <.001)	r = .29 (P <.1)	r = .27 (P <.14)	r = .36 (P <.06)	
ES3 Trial score	r = .3 (P <.2)	r = .43* (P <.01)	r = .45* (P <.01)	r = .57* (P <.001)	r = .63* (P <.01)

*Statistically significant correlations.
From Arora H, Uribe J, Ralph W, et al. Assessment of construct validity of the endoscopic sinus surgery simulator. *Arch Otolaryngol Head Neck Surg.* 2005;131:217-221.

A second validation study was designed to correlate the performance of subjects on the ES3 with their performance on other validated tests of innate ability. Indeed, ESS requires two-handed coordination of surgical instruments with an endoscope in three-dimensional space. The technique necessitates complex ambidextrous psychomotor, visuospatial, and perceptual capabilities. This second set of studies aimed to assess whether objective tests of such fundamental abilities might also predict performance on the ES3. Results assessed on 34 medical students and four otolaryngology residents showed conclusively that statistically significant correlations exist between performance on various validated tests and the ES3 (Table 4B-1).[39] This confirmed the robustness and utility of the ES3 and helped develop a multifaceted and enriched learning environment designed to reduce surgical errors and improve patient safety in the operating room.

The third study, focusing on predictive validity ("Virtual Reality to Operating Room," or "VR to OR" protocol), is probably the most significant part of the validation work of the ES3, addressing directly the question of whether training on the simulator improves the performance of otolaryngology residents in actual surgery and reduces their surgical errors. The study required the collection of resident data from 12 different institutions throughout the country. Otolaryngology residents in their junior year were included in either an experimental group (destined to receive conventional sinus surgery training as well as ES3 training) or a control group (receiving only conventional sinus surgery training). One subsequent sinus surgery procedure was used to videotape their first performance in the operating room, which was then reviewed by a masked panel of experts to rate the individual. Preliminary results of this ongoing study are still pending, but a prior similar study on the ES3 with fewer subjects has suggested substantial superiority of surgical performance by residents trained on the simulator compared to that of control residents.[41,42] The VR-to-OR study is expected to further corroborate the hypothesis with increased sample size, statistical power, and refined methodology.

The future of surgical simulation training will rely significantly on the principles learned from flight training: a "mission" will be rehearsed following clearly defined objectives, then performed, and then reviewed and analyzed in order to move toward improved performance and patient safety.

Curriculum Development

A refined state-of-the-art curriculum was developed with assistance from the Yale University School of Medicine Division of Otolaryngology to standardize training on the ES3, regardless of training level. Video information (demonstrating successful as well as erroneous operation of each training level), written background, anatomic information, and other tools were incorporated onto a compact disc. This medium greatly facilitates the trainees' compliance with the protocols and eliminates bias related to the vastly different educational starting points of the subjects.

To better understand the present state of resident training, a survey of the major centers participating in the past ES3 research was conducted. The results showed that residents often did not begin performing endoscopic sinus surgery until their last year of otolaryngologic training and that only half of the institutions that responded gave formal lectures and required a reading list before residents were allowed to perform ESS in the operating room. It was concluded that there clearly was a need to develop curriculum content that would be systematic, comprehensive, and well structured, hypothesizing that such curriculum would improve effectiveness, reduce errors, and improve safety compared to controls.

A new direction of research, based on studies suggesting the use of expert-defined criteria as benchmark levels of performance,[33] has been initiated with funding from the Department of Defense's Telemedicine and Advanced Technology Research Center. This research is expected to confirm the necessity of a paradigm shift in the core concepts of modern specialty training. Surgical residents will be trained on the ES3 until they reach a performance criterion level, objectively predefined by the performance of experienced sinus surgeons on the same simulator tasks. This will ensure that those receiving VR training meet at least the same benchmark criteria on several consecutive training trials. This is in distinction to establishing a specific number of cases as an adequate training criterion. Iterative comparison of videotaped operating room performance to that of control residents (not subject to the proficiency-based training requirement) will aim to objectively evaluate the efficacy of this educational principle.

Other ESS Simulators

The Dextroscope (www.dextroscope.com) is a software application able to create a three-dimensional model based on computerized imaging (computed tomography or magnetic resonance imaging). It allows free volume interaction with a visual model to rehearse surgical procedures. The method was shown to improve understanding of the anatomy for junior residents, but failed to impact their operating room performance.[43] The system paves the way toward patient-specific data analysis for planning, rehearsing, and debriefing of surgical procedures, but lacks haptic feedback and is not designed to emulate the operating room environment.

The Innovation Center for Computer Assisted Surgery (ICCAS) group at the Medical Faculty of the University of Leipzig, Germany, is developing the VR-FESS, in addition to designing a transsphenoidal pituitary surgery simulator. The team also envisions the elaboration of surgical *ontologies* and workflows, that is, formalized descriptions of surgical procedures allowing analysis and detailed evaluation.[44] However, no validation efforts have yet been published by this group.

A second German group has developed the Nasal Endoscopy Simulator, which consists of a graphics workstation, a tracking system for the position of the endoscope and surgical instruments, and a physical model.[45] The virtual model is based on patient-specific imaging data sets, with textures derived from endoscopic images superimposed on the virtual reality environment.[46] The initial prototype was not haptics enabled[47] and a later version was reported to be under development,[48,49] but there has not yet been report of further advancement of this work.

Japan's Surgical Institute for Advanced Industrial Science and Technology developed a Paranasal Sinuses Simulator, comprising a soft dummy with force sensors that deliver counterforce measurements for analysis and computation into a patient risk index. Preliminary studies suggest positive face and construct validity.[50] Despite not being a true virtual reality simulator, the effort is worthy, in that the force applied to instruments is a variable that may be of value for objective skills assessment by any simulator.

Even though the aforementioned undertakings bring unquestionable value to the expansion of virtual reality training for ESS, none has produced a comprehensive surgical training experience comparable to the ES3, which remains the most sophisticated and best evaluated surgical simulator for ESS.

Temporal Bone Surgery

Traditionally, temporal bone surgery has been learned through contemporary media: textbooks and atlases,[51-54] illustrations, CD-ROMS,[55,56] models[57] (www.temporal-bone.com/plastic.htm), and cadaver dissections.[58,59] Although CD-ROMs provide a cost-effective solution through the integration of photographs, illustrations, movies, computer graphics, and tomographic images, the interactivity is limited.

Harada first introduced the concept of exploiting three-dimensional volumetric reconstructions from computed tomography for emulating drilling and exposing the intricate regional anatomy of the temporal bone.[60] In that era, the computational overhead required by volume-rendering algorithms to produce realistic visual display was prohibitive. Subsequently, surface-based approaches were predominantly employed for modeling structure to exploit hardware-accelerated surface rendering techniques that had been developed for the video gaming industry. Similar techniques using reconstructions from histologic sections to derive iso-surfaces (surface-based rendering) have focused on clarifying the spatial relationships of the regional anatomy.[61-64] Stereo presentations of surface-based models acquired from the Visible Human Project (VHP-NLM 2002) were presented for transpetrosal, retrosigmoid, and middle fossa approaches to the cerebellopontine angle.[65] Even though surface-based representations of soft tissues and bone structures have been developed, these systems did not provide haptic feedback to the user and provided only schematic emulation of dissection and surgical technique. As graphics processing hardware (GPU) advanced as a function of the popularity of gaming systems, issues related to poor performance in volume-rendering were resolved. In comparison to surface-based rendering systems, pure volume-rendering systems eliminate the tasks of redrawing surfaces, and interactivity is more realistic. Furthermore, the advent of high-fidelity haptic interfaces has enabled accurate display of the sense of touch. It was these particular steps in graphics processing and haptic development that allowed the possibility of real-time, interactive surgical simulation. Currently, there are several systems in use, each of which has unique features.

First is a system developed at Stanford University in conjunction with Dr. Nikolas Blevins in the Department of Otolaryngology.[66-68] This system uses CT data, a combination of volume- and surface-based rendering for visual display, and a haptic interface consisting of a SensAble Phantom with 3 degrees of freedom haptic feedback and 6 degrees of freedom positional input. The visual interface consists of a computer screen (Fig. 4B-4). A sophisticated haptic model was developed that provides not only force feedback to the user but also sense of vibration that is bit dependent. Bone dust is synthesized using a grid-based approach that requires the user to keep the operative field clean as in real temporal bone surgery. Lastly, sound production relative to bone thickness is provided to further enhance the simulation environment.

Figure 4B-4. The Stanford University simulator demonstrating the visual and haptic user interface.

Figure 4B-5. The Stanford University simulator demonstrating use of the haptic mentoring feature with trainee and expert at linked interfaces.

The developers have used this system to demonstrate construct validity (an element of simulation validation that identifies experts from novices based on their performance in the simulation).[67] Additionally, they have demonstrated a novel approach to trainee interactivity with the system by using "haptic mentoring" (Fig. 4B-5). In this mode, the trainee can "feel" what the instructor is feeling at the same time the instructor is drilling or experience the "feel" when the instructor is off line in a rehearsal mode. Another key component to this system is the ability of the simulation environment to provide automated evaluation and feedback. In this feature, elements such as visibility testing, safe force application, and correct sequence of bone removal are tracked and visual cues are offered to the trainee to either confirm or redirect current activity. It is the automated feedback element of this system that makes it ideal for independent learning of the procedure and is the major advantage of this system. This function provides an environment as if an experienced surgeon were instructing the trainee in elements of technique during the dissection. It offers instant feedback to the trainee, an aspect of training that is critical to skills development.[69]

The system developed at The Ohio State University in conjunction with the Ohio Supercomputer Center demonstrates a strong emphasis on realism and interactivity.[70-73] In comparison to the hybrid renderer used in the Stanford system, the OSU system uses true volume rendering for visual display combined with haptic feedback. The algorithms used to provide the visual display in the OSU system are particularly realistic. Like the Stanford system, a SensAble Phantom device is used for haptic feedback. In contrast to the Stanford system, a stereo-capable display (z800, eMagin) analogous to the microscope is used (Fig. 4B-6). Moreover, the Ohio State System also has the ability to integrate new

Figure 4B-6. The Ohio State University temporal bone dissection simulator demonstrating the stereo visual display, haptic display, and rendering on background monitor. (See www.osc.edu/vtbone for more information.)

data easily. Companion software allows import of raw CT data (DICOM format), three-dimensional segmentation, and conversion of data for immediate use in the simulator. Additionally, an "intelligent tutor" is integrated into the simulation environment that allows trainees to choose and display vital anatomic structures in the context of the surgical environment. Complex time sequence recording capabilities are integrated into the simulator that continuously capture the entire volume while manipulations are performed by the user. This allows highly precise tracking of all visual information, tool position, force development, and navigation data from the user for later analysis. In the simulation environment, various types and sizes of burrs can be selected, zoom adjustments analogous to changing objectives on the microscope can be made, and panning of the microscope is available. Currently, the system provides access to 40 different bones with capability for accessing an unlimited number. It records demographic data, including past temporal bone dissection experience, general computer experience, training year, and additional information from the user for testing purposes. New developments in the system include simulation of fluid flow for irrigation and bleeding (video clip available on website). The system has been tested in a small local trial at The Ohio State University in which novice trainees (fourth year medical students and first and second year residents) were randomized to temporal bone dissection training in a cadaveric laboratory or training on a simulator.[74] Group performance was blindly rated using a validated performance measure for temporal bone dissection.[75] Cadaveric laboratory trainees performed marginally better than those trained in the simulator. The Ohio State University system has been recently upgraded and is currently being tested as a training tool in a large multi-institutional trial using a protocol similar to the local trial.

Lastly, a system for virtual temporal bone surgery was developed at the University of Hamburg-Eppendorf in Germany.[76] This system also uses volume-rendering to display the virtual temporal bone during the act of drilling. It has subsequently been developed into a commercial product, VOXEL-MAN TempoSurg simulator (Spiggle and Theis, Overath, Germany; www.uke.de/voxel-man). This system has been used in a recent validation study.[69] Novice and experienced surgeons' hand movements were videotaped while in the simulator or in the cadaveric laboratory performing temporal bone dissections. The videos were then blindly analyzed by expert raters. Raters were able to distinguish the more experienced surgeons from the novice surgeons while performing cadaveric dissections at a statistically significant level but not when using the simulator. Additionally, hand movements were tracked by electromagnetic marker and analyzed for number of movements, distance traveled, and other parameters. Using this objective hand movement measure of performance, the investigators showed that, overall, study subjects seem to score better in the simulation environment compared to the cadaveric laboratory. The significance of this finding is unclear. Currently, the VOXEL-MAN TempoSurg system is the only commercially available system on the market. Further studies using this system will be needed to demonstrate its efficacy in training and assessment.

Conclusion

Simulation allows teaching surgical technique in a complex but safe environment with no risks for patients. Repetition practice in simulation under criterion-referenced instruction can be achieved until proficiency is reached. There is strong support from the surgical governing and regulating entities to mandate the use of virtual reality simulation in surgical training curricula.

For most surgical simulation environments, it is now possible to import patient-specific data and generate high-fidelity practice environments. As technology achieves greater capabilities, the surgeon will be able to practice the procedure in simulation (preoperative assessment and presurgical planning) and identify critical areas for consideration during the operation. The pathology to be addressed will be detailed and the areas at risk such as critical anatomic structures and pathologic variants will be pre-identified.

Overall, the use of simulation technology for otolaryngologic training and assessment has grown from schematic visualizations that provided limited interactivity to fully featured systems. The task at hand for all involved in the development and application of this technology is to demonstrate improvements in outcomes for trainees and ultimately for patients. This will be a long and arduous course especially because we have few if any gold standards to measure performance and outcomes in this field. This process of validation is key to the eventual widespread acceptance and use of simulation technology in general and in otolaryngology in particular. It does, however, hold the promise of mitigating our learning curve and providing detailed performance measures that are currently unavailable with other technologies.

CHAPTER FIVE

Outcomes Research

Amy Anne Lassig

Bevan Yueh

Key Points

- Outcomes research or clinical epidemiology is the study of treatment effectiveness or the success of treatment in the nonrandomized, real-world setting. It allows researchers to gain knowledge from observational data.
- Bias and confounding can affect researchers' interpretation of study data, and an accurate assessment of baseline disease status, treatment given, and outcomes of treatment are critical to sound outcomes research.
- Many types of studies are available to evaluate treatment effectiveness and include the randomized trial, observational study, case-control study, case series, and expert opinions. The concept of *evidence-based medicine* uses the level of evidence presented in the aforementioned studies to grade diagnostic and treatment recommendations.
- Outcomes in clinical epidemiology are often difficult to quantify, and thus instruments measuring these outcomes must meet criteria of the *classical test theory* (reliability, validity, responsiveness, and burden) or the *item response theory* to be considered psychometrically valid.
- Many outcomes instruments assess health-related quality of life. These scales are generic or disease-specific, including assessment of head and neck cancer, otologic disease, rhinologic disease, pediatric disease, voice disorders, and sleep disorders.

The time when physicians chose treatment based solely on their personal notions of what was best is past. This era, although chronologically recent, is now conceptually distant. In a health care environment altered by abundant information on the Internet and continual oversight by managed care organizations, patients and insurers are now active participants in selecting treatment. Personal notions ("expert opinion") are replaced by objective evidence. And the physician's sense of what is best is being supplemented by patients' perspectives on outcomes after treatment.

Outcomes research (clinical epidemiology) is the scientific study of treatment effectiveness. The word *effectiveness* is a critical one, because it pertains to the success of treatment in populations found in actual practice in the real world, as opposed to treatment success in the controlled populations of randomized clinical trials in academic settings ("efficacy").[1,2] Success of treatment can be measured using survival, costs, and physiologic measures, but frequently health-related quality of life (QOL) is a primary consideration.

Therefore, to gain scientific insight into these types of outcomes in the observational (nonrandomized) setting, outcomes researchers need to be fluent with methodologic techniques that are borrowed from a variety of disciplines, including epidemiology, biostatistics, economics, management science, and psychometrics. A full description of the techniques in clinical epidemiology[3] is beyond the scope of this chapter. This chapter provides the basic concepts in effectiveness research and a sense of the breadth and capacity of outcomes research and clinical epidemiology.

History

In 1900, Dr. Ernest Codman proposed to study what he termed the "end results" of therapy at the Massachusetts General Hospital.[4] He asked his fellow surgeons to report the success and failure of *each* operation and developed a classification scheme by which failures could be further detailed. Over the next 2 decades, his attempts to introduce systematic study of surgical end results were scorned by the medical establishment, and his prescient efforts to study surgical outcomes gradually faded.

Over the next 50 years, the medical community accepted the randomized clinical trial (RCT) as the dominant method for evaluating treatment.[5] By the 1960s, the authority of the RCT was rarely questioned.[6] However, a landmark 1973 publication by Wennberg and Gittelsohn spurred a sudden re-evaluation of the value of observational (nonrandomized) data. These authors documented significant geographic variation in rates of surgery.[7] Tonsillectomy rates in 13 Vermont regions varied from 13 to 151 per 10,000 persons, even though there was no variation in the prevalence of tonsillitis. Even in cities with similar demographics and similar access to health care (Boston and New Haven, Conn.), rates of surgical procedures varied 10-fold. These findings raised the question of whether the higher rates of surgery represented better care or unnecessary surgery.

Researchers at the Rand Corporation sought to evaluate the appropriateness of surgical procedures. Supplementing relatively sparse data in the literature about treatment effectiveness with expert opinion conferences, these investigators argued that rates of inappropriate surgery were high.[8] However, utilization rates did not correlate with rates of inappropriateness, and therefore did not explain all of the variation in surgical rates.[9,10] To some, this suggested that the practice of medicine was anecdotal and inadequately scientific.[11] In 1988, a seminal editorial by physicians from the Health Care Financing Administration argued that a fundamental change toward study of treatment effectiveness was necessary.[12] These events subsequently led Congress to establish the Agency for Health Care Policy and Research in 1989 (since renamed the Agency for Healthcare Research and Quality, or AHRQ), which was charged with "systematically studying the relationships between health care and its outcomes."

In the past decade, outcomes research and the AHRQ has become integral to understanding treatment effectiveness and establishing health policy. Randomized trials cannot be used to answer all clinical questions, and outcomes research techniques can be used to gain considerable insights from observational data (including data from large administrative databases). With current attention on evidence-based medicine and quality of care, a basic familiarity with outcomes research is more important than ever.

Key Terms and Concepts

The fundamentals of clinical epidemiology are best understood by thinking about an episode of treatment: a patient presents at baseline with an index condition, receives treatment for that condition, and then experiences a response to treatment. Assessment of baseline state, treatment, and outcomes are all subject to bias. We begin with a brief review of bias and confounding.

Bias and Confounding

Bias occurs when "compared components are not sufficiently similar."[3] The compared components may involve any aspect of the study. For example, *selection* bias exists if, in comparing surgical resection to chemoradiation, oncologists avoid treating patients with renal or liver failure. This makes the comparison unfair because, on average, the surgical cohort will accrue more ill patients. *Treatment* bias occurs when comparing, for example, standard stapedotomy with laser stapedotomy, but one procedure is performed by an experienced surgeon, and the other is performed by resident staff.

Similar to bias, *confounding* also has the potential to distort results. However, confounding refers to specific variables. Confounding occurs when a variable thought to cause an outcome is actually not responsible, because of the unseen effects of another variable. Consider the hypothetical (and obviously faulty) case in which an investigator postulates that nicotine-stained teeth cause laryngeal cancer. Despite a strong statistical association, this relationship is not causal, because another variable—cigarette smoking—is responsible. Cigarette smoking is confounding because it is associated with both the outcome (laryngeal cancer) and the supposed baseline state (stained teeth).

Assessment of Baseline

Most physicians are aware of the confounding influences of age, gender, ethnicity, and race. However, accurate baseline assessment also means that investigators should carefully define the disease under study, account for disease severity, and consider other important variables such as comorbidity.

Definition of Disease

It would seem obvious that the first step is to establish diagnostic criteria for the disease under study. Yet this is often incomplete. Inclusion criteria should include all relevant portions of the history, the physical examination, and laboratory and radiographic data. For example, the definition of chronic sinusitis may vary by pattern of disease (e.g., persistent vs. recurrent acute infections), duration of symptoms (3 months vs. 6 months), and diagnostic criteria for sinusitis (clinical examination vs. ultrasound vs. computed tomography vs. sinus taps and cultures). All of these aspects must be delineated to place studies into proper context.

In addition, advances in diagnostic technology may introduce a bias called *stage migration.*[13] In cancer treatment, stage migration occurs when more sensitive technologies (such as CT scans in the past, and positron emission tomography scans now) may "migrate" patients with previously undetectable metastatic disease out of an early stage (improving the survival of that group), and place them into a stage with otherwise advanced disease (improving this group's survival as well).[14,15] The net effect is that there is improvement in stage-specific survival, but no change in overall survival.

Disease Severity

The severity of disease strongly influences response to treatment. This reality is second nature for oncologists, who use tumor-node-metastasis stage to select treatment and interpret survival outcomes. It is intuitively clear that the more severe the disease, the more difficult it will be (on average) to restore function. Yet this concept has not been fully integrated into the study and practice of common otolaryngologic diseases such as sinusitis and hearing loss.

Recent progress has been made in sinusitis. Kennedy identified prognostic factors for successful outcomes in patients with sinusitis and has encouraged the development of staging systems.[16] Several staging systems have been proposed, but most systems rely primarily on radiographic appearance.[17-20] Clinical measures of disease severity (symptoms, findings) are not typically included. Although the Lund-Mackay staging system is reproducible,[21] often radiographic staging systems have correlated poorly with clinical disease.[22-26] As such, the Zinreich method was created as a modification of the Lund-Mackay system, adding assessment of osteomeatal obstruction.[27] Alternatively, the Harvard staging system has been reproducible[21] and may predict response to treatment.[28] Scoring systems have also been developed for specific disorders such as acute fungal rhinosinusitis,[29] and clinical scoring systems based on endoscopic evaluation have likewise been developed.[30] The development and validation of reliable staging systems for other common disorders, as well as the integration of these systems into patient care, is a pressing challenge in otolaryngology.

Comorbidity

Comorbidity refers to the presence of concomitant disease unrelated to the "index disease" (the disease under consideration), which may affect the diagnosis, treatment, and prognosis for the patient.[31-33] Documentation of comorbidity is important, because the failure to identify comorbid conditions such as liver failure may result in inaccurately attributing poor outcomes to the index disease being studied.[34] This baseline variable is most commonly considered in oncology, because most models of comorbidity have been developed to predict survival.[32,35] The Adult Comorbidity Evaluation 27 (ACE-27) is a validated instrument for evaluating comorbidity in cancer patients and has shown the prognostic significance of comorbidity in a cancer population.[36,37] Because of its impact on costs, utilization, and QOL, comorbidity should be incorporated in studies of nononcologic diseases as well.

Assessment of Treatment

Control Groups

Reliance on case series to report results of surgical treatment is time-honored. It is also inadequate for establishing cause and effect relationships. A recent evaluation of endoscopic sinus surgery reports revealed that only 4 of 35 studies used a control group.[38] Without a control group, the investigator cannot establish that the observed effects of treatment were directly related to the treatment itself.[3]

It is also particularly crucial to recognize that the scientific rigor of the study varies with the suitability of the control group. The more fair the comparison, the more rigorous the results. Therefore a randomized cohort study in which subjects are randomly allocated to different treatments is more likely to be free of biased comparisons than observational cohort studies in which treatment decisions are made by an individual, a group of individuals, or a health care system. Within observational cohorts, there are also different levels of rigor. In a recent evaluation of critical pathways in head and neck cancer, a "positive" finding in comparison with a historical control group (a comparison group assembled in the past) was not significant when compared to a concurrent control group.[39]

Assessment of Outcomes

Efficacy

The distinction between efficacy and effectiveness, briefly discussed earlier, illustrates one of the fundamental differences between randomized trials and outcomes research. *Efficacy* refers to whether a health intervention, in a controlled environment, achieves better outcomes than does placebo. Two aspects of this definition need emphasis. First, efficacy is a comparison to placebo. As long as the intervention is better, it is efficacious. Second, controlled environments shelter patients and

physicians from problems in actual clinical settings. For example, randomized efficacy trials of medications provide continuing reminders for patients to use their medications, and nonadherent patients are dropped from further study.

Effectiveness

An efficacious treatment that retains its value under usual clinical circumstances is *effective*. Effective treatment must overcome a number of barriers not encountered in the typical trial setting. For example, disease severity and comorbidity may be worse in the community, in that healthy patients tend to be enrolled in (nononcologic) trials. Patient adherence to treatment may also be imperfect. Consider continuous positive airway pressure (CPAP) treatment for patients with obstructive sleep apnea. Although the CPAP is efficacious in the sleep laboratory, the positive pressure is ineffective if the patients do not wear the masks when they return home.[40] A different challenge is present for surgical treatments, because community physicians learning a new procedure cannot be expected to perform it as effectively as the surgeon investigator who pioneered its development.

Fundamentals of Study Design

A variety of study designs are used to gain insight into treatment effectiveness. Each has advantages and disadvantages. The principal tradeoff is complexity versus rigor, because rigorous evidence demands greater effort. An understanding of the fundamental differences in study design can help interpret the quality of evidence, which has been formalized by the evidence-based medicine (EBM) movement. EBM is the "conscientious, explicit, and judicious use of current best evidence in making decisions about the care of individual patients."[41] EBM is discussed in detail elsewhere in this textbook. The following paragraphs summarize the major categories of study designs, with reference to the EBM hierarchy of levels of evidence (Table 5-1).[41,42]

Randomized Trial

Randomized clinical trials (RCTs) represent the highest level of evidence, because the controlled, experimental nature of the RCT allows the investigator to establish a causal relationship between treatment and subsequent outcome. The random distribution of patients also allows unbiased distribution of baseline variables and minimizes the influence of confounding. Although randomized trials have generally been used to address efficacy, modifications can facilitate insight into effectiveness as well. RCTs with well-defined inclusion criteria, double-blinded treatment and assessment, low losses to follow-up, and high statistical power are considered high-quality RCTs and represent level 1 evidence. Lower quality RCTs are rated level 2 evidence.

Observational Study

In observational studies, sometimes called *cohort studies*, patients are identified at baseline *before* treatment (or "exposure" in standard epidemiology cohort studies investigating risk factors for disease), similar to randomized trials. However, these studies accrue patients who receive routine clinical care. Inclusion criteria are substantially less stringent, and treatment is assigned by the provider in the course of clinical care. Maintenance of the cohort is also straightforward, because there is no need to keep patients and providers doubly blinded.

The challenge in cohort studies is to find an appropriate control group. Rigorous prospective and retrospective cohort studies *with a suitable control group* represent high-quality studies and can represent level 2 evidence. To obtain insight into comparisons of treatment effectiveness, these studies need to use sophisticated statistical and epidemiologic methods to overcome the biases discussed in the prior section. Even with these techniques, there is the risk that unmeasured confounding variables will distort the comparison of interest. Poor-quality cohorts without control groups, or inadequate adjustment for confounding variables, are considered level 4 evidence, because they are essentially equivalent to a case series.

Case-Control Study

Case-control studies are typically used by traditional epidemiologists to identify risk factors for the development of disease. In such cases, the disease becomes the "outcome." In contrast to randomized and observational studies, which identify patients before exposure to a treatment (or a pathogen), and then follow patients forward in time to observe the outcome, case-control studies use the opposite temporal direction. This design is particularly valuable when prospective studies are not feasible, either because the disease is too rare or because the time interval between baseline and outcome is prohibitively long.

For example, a prospective study of an association between a proposed carcinogen (e.g., gastroesophageal reflux) and laryngeal cancer would require a tremendous number of patients and decades of observation. However, by identifying patients with and without laryngeal cancer, and comparing relative rates of carcinogen exposure, a case-control study can obtain a relatively quick answer.[43] Because the temporal relationship between exposure and outcome is not directly observed, no causal judgments are possible, however. These studies are considered level 3 evidence.

Case Series and Expert Opinion

Case series are the least sophisticated format. As discussed earlier, no conclusions about causal relationships between treatment and outcome

Table 5-1

Summary of Study Designs

Design	Advantages	Disadvantages	Level of Evidence
Randomized clinical trial (RCT)	Only design to prove causation Unbiased distribution of confounding	Expensive and complex Typically targets efficacy	1, if high-quality RCT 2, if low-quality RCT
Observational (cohort) study	Cheaper than RCT Clear temporal directionality from treatment to outcome	Difficult to find suitable controls Confounding	2, with control group 4, if no control group
Case-control study	Cheaper than cohort study Efficient study of rare diseases or delayed outcomes	Must rely on retrospective data Directionality between exposure and outcome unclear	3
Case series	Cheap and simple	No control group No causal link between treatment and outcome	4
Expert opinion	N/A	N/A	5

Table 5-2

Grade of Recommendation and Level of Evidence

Grade of Recommendation	Level of Evidence
A	1
B	2 or 3
C	4
D	5

can be made because of uncontrolled bias and the absence of any control group. These studies are considered level 4 evidence. If case studies are unavailable, then expert opinion is used to provide level 5 evidence.

Other Study Designs

There are numerous other important study designs in outcomes research, but a detailed discussion of these techniques is beyond the scope of this chapter. The most common approaches include decision analyses,[44,45] cost-identification and cost-effectiveness studies,[46-48] secondary analyses of administrative databases,[49-51] and meta-analyses.[52,53] Critiques of these techniques are referenced for completeness.

Grading of Evidence-Based Medicine Recommendations

EBM uses the levels of evidence described earlier to grade treatment recommendations (Table 5-2).[54] The presence of high-quality RCTs allows treatment recommendations for a particular intervention to be ranked as grade A. If no RCTs are available, but there is level 2 or 3 evidence (observational study with a control group or a case-control study), then the treatment recommendations are ranked as grade B. The presence of only a case series would result in a grade C recommendation. If only expert opinion is available, then the recommendation for the index treatment is considered grade D.

Measurement of Clinical Outcomes

Clinical studies have traditionally used outcomes such as mortality and morbidity, or other "hard" laboratory or physiologic endpoints,[55] such as blood pressure, white cell counts, or radiographs. This practice has persisted despite evidence that interobserver variability of accepted "hard" outcomes such as chest x-ray findings and histologic reports are distressingly high.[56] In addition, clinicians rely on "soft" data, such as pain relief or symptomatic improvement to determine whether patients are responding to treatment. But because it has been difficult to quantify these variables, these outcomes have until recently been largely ignored.

Psychometric Validation

An important contribution of outcomes research has been the development of questionnaires to quantify these "soft" constructs, such as symptoms, satisfaction, and QOL. Under the Classical Test Theory, a rigorous psychometric validation process is typically followed to create these questionnaires (more often termed *scales*, or *instruments*). These scales can then be administered to patients to produce a numeric score. The validation process is introduced herein; a more complete description can be found elsewhere.[57-59] The three major steps in the process are the establishment of *reliability*, *validity*, and *responsiveness*; in addition, increasing consideration is also given to *burden*.

- *Reliability*. A reliable scale reproduces the same result in precise fashion. For example, assuming there is no clinical change, a scale administered today and next week should produce the same result. This is called *test-retest reliability*. Other forms of reliability include *internal consistency* and *interobserver reliability*.[59,60]

- *Validity*. A valid scale measures what it is purported to measure. This concept is initially difficult to appreciate. Because these scales are designed to measure constructs that have not previously been measured, and because the constructs are difficult to define in the first place (what is QOL?), how does one determine what the scales are supposed to measure? The abbreviated answer is that the scales should behave in the hypothesized way. A simple example of an appropriate hypothesis is that a proposed cancer-specific QOL scale should correlate strongly with pain, tumor stage, and disfigurement, but less strongly with age and gender. For more complete discussion, several excellent references are listed.[57-61]

- *Responsiveness*. A responsive scale detects clinically important change.[62] For instance, a scale may distinguish a moderately hearing impaired individual from a deaf individual (the scale is "valid"), but can it detect a different score if the individual's hearing improves mildly after surgery? Alternatively, the minimum improvement in score that represents a clinically important change might be provided.[63,64]

- *Burden*. Burden refers to the time and energy that patients must spend to complete a scale, as well as the resources necessary for observers to score the questionnaire. A scale should not be an excessive encumbrance to a patient, caregiver, or provider using it.

More recently, item response theory (IRT) has been used to create and evaluate self-reported instruments. A full discussion of IRT is beyond the scope of this chapter. In brief, Item Response Theory uses mathematic models to draw conclusions based on the relationships between patient characteristics (latent traits) and patient responses to items on a questionnaire. A critical limitation is that IRT assumes that only one domain is measured by the scale. This may not fit assumptions for multidimensional QOL scales. However, if this assumption is valid, IRT-tested scales have several advantages. IRT allows for the contribution of each test item to be considered individually, thereby allowing the selection of a few test items that most precisely measure a continuum of a characteristic. In other words, because each test item is scaled to a different portion of the characteristic being tested, the number of questions can be reduced.[65-68] Therefore, IRT lends itself easily to adaptive computerized testing, allowing for significantly diminished testing time and reduced test burden.[65] In the future, IRT will likely be the basis to more and more new questionnaires evaluating outcomes, including QOL.

Categories of Outcomes

In informal use, the terms *health status*, *function*, and *quality of life* are frequently used interchangeably. However, these terms have important distinctions in the health services literature. *Health status* describes an individual's physical, emotional, and social capabilities and limitations, and *function* refers to how well an individual is able to perform important roles, tasks, or activities.[58] *QOL* differs because the central focus is on the *value* that individuals place on their health status and function.[58]

Because many aspects of QOL are unrelated to a patient's health status (income level, marital and family happiness), outcomes researchers typically focus on scales that measure only *health-related QOL* (HRQOL). HRQOL scales may be categorized as either *generic* or *disease-specific*. *Generic*, or general, scales are used for QOL assessment in a broad range of patients. The principal advantage of generic measures is that they facilitate comparison of results across different diseases (how does the QOL of a heart transplant patient compare to that of a cancer patient?). *Disease-specific* scales, on the other hand, are designed to assess specific patient populations. Because these scales can focus on a narrower range of topics, they tend to be more responsive to clinical change in the population under study. To benefit from the advantages of each type of scale, rigorous studies often use both a generic and a disease-specific scale to assess outcomes.

In addition to these measures, a number of other outcomes are increasingly popular. These include patient satisfaction, costs and charges,[47,48] health care utilization, and patient preferences (utilities,

willingness to pay).[47,69,70] Descriptions of these methods are referenced for completeness.

Examples of Outcomes Measures

As mentioned earlier, one of the principal contributions of outcomes research has been the development of scales to measure HRQOL and related outcomes. The following paragraphs briefly discuss several validated scales that are relevant to otolaryngology. Unless otherwise indicated, these scales are completed by the patient. The references contain details about validation data, and most also include a listing of sample questions and scoring instructions. The most widely used scales in each category are listed in Table 5-3.

Generic Scales

The best-known and most widely used outcomes instrument in the world is the Medical Outcomes Study Short Form-36, commonly called the *SF-36*.[71] This 36-item scale is designed for adults and surveys general health status. It produces scores in eight health constructs (e.g., vitality, bodily pain, limitations in physical activities), as well as two summary scores on overall physical and mental health status. Normative population scores are available, and the scale has been translated into numerous languages. Reference to instructions, numerous reference publications, and other related information can be found at the SF-36 website (www.sf36.com).

A variety of other popular, generic scales are also available. One health status measure is the Sickness Impact Profile.[72] The Quality of Well Being (QWB[73,74]) and the Health Utilities Index (HUI[75,76]) measure patient preferences, or utilities. The World Health Organization has developed a QOL scale (WHO-QOL[77]) as a measure of generic QOL as well as the International Classification of Functioning (ICF), Disability, and Health to evaluate a patient's functioning and disability.[78] The ICF has been used not only as an instrument itself but also as a standalone reference by which to evaluate other measures of QOL and functioning.[79,80]

Disease-Specific Scales

Head and Neck Cancer

In 2002, the NIH sponsored a conference to achieve consensus on the methods used to measure and report QOL of life assessment in head and neck cancer.[81] There was agreement that an adequate number of scales already exist to measure general QOL in head and neck cancer patients. The three most popular scales at this time are the European Organization for Research and Treatment of Cancer Quality of Life Questionnaire (EORTC-HN35[82]), the University of Washington Quality of Life scale (UW-QOL[83-85]), and the Functional Assessment of Cancer Therapy Head and Neck module (FACT-HN[86]). Both the EORTC and FACT instruments offer additional modules that measure general cancer QOL in addition to the head and neck cancer specific modules, but are longer than the 12-item UW-QOL scale.

A clinician-rated scale (i.e., the clinician completes the scale, rather than the patient) that has achieved widespread use is the Performance Status Scale, a three-item instrument that correlates well with many of the aforementioned cancer scales.[87] A number of other excellent, validated patient-completed scales are also available, including the Head and Neck Quality of Life (HNQOL[88]) and the Head & Neck Survey (H&NS[89]), although these scales have not been used as widely. Several validated scales that focus on QOL of patients undergoing radiation are also in use.[90,91]

A few measures focus on symptom inventory and symptom distress directly related to head and neck cancer. These include the Head and Neck Distress Scale (HNDS)[92] and the M.D. Anderson Symptom Inventory, Head and Neck Module.[93]

Table 5-3

Outcomes Measures Relevant to Otolaryngology*

Disease Category		Examples
Generic	Health status Quality of life Utility	SF-36[71] WHO-QOL[77] QWB[73]
Head and neck cancer	General Radiation-specific Clinician-rated	UWQOL,[85] FACT,[86] EORTC,[82] HNQOL[88] QOL-RTI/H&N[90] PSS[87]
Otologic	General Conductive loss Amplification Dizziness Tinnitus Cochlear implants	HHIE[99] HSS[102] APHAB,[103] EAR[162] DHI[113] THI[114] Nimigen,[106] CAMP[107]
Rhinologic	Nasal obstruction Chronic sinusitis Rhinitis	NOSE[124] SNOT-20,[115] CSS,[116] RhinoQOL[123] mRQLQ,[120] ROQ[121]
Pediatric	Tonsillectomy Otitis media Sleep apnea	TAHSI[135] OM-6[131] OSD-6,[133] OSA-18[132]
Other/symptoms	Adult sleep apnea Swallowing Voice Cosmetic	FOSQ,[150] SAQLI[151] MDADI,[158] SWAL-QOL[159] VHI,[139] VOS,[140] VRQOL[146] ROE, BOE[161]

*Refer to text for additional scales.

Several new instruments have been developed as disease-specific measures within the field of head and neck cancer. For example, to assess the impact of cutaneous malignancy on QOL, the Skin Cancer Index has been validated and found to be sensitive and responsive,[94,95] and the Patient Outcomes of Surgery—Head/Neck (POS-Head/Neck) has newly been developed to assess surgical outcomes in cutaneous malignancy.[96] In addition, an instrument has recently been developed to assess QOL after treatment of anterior skull base lesions.[97] A questionnaire has also been developed to evaluate outcomes directly related to the use of voice prostheses after total laryngectomy.[98]

Otologic Disease

The most widely used validated measure to quantify hearing-related QOL is the Hearing Handicap Inventory in the Elderly (HHIE), a 25-item scale with two subscales that measure the emotional and social impact of hearing loss.[99,100] The minimum change in score that corresponds to a clinically important difference has been established.[101] However, the scale does not distinguish between conductive or sensorineural loss. The Hearing Satisfaction Scale (HHS) is specifically designed to measure outcomes after treatment for conductive hearing loss. It therefore addresses side effects or complications of treatment, and is brief (15 items).[102]

Numerous validated measures exist to assess outcomes after hearing amplification. One popular scale is the Abbreviated Profile of Hearing Aid Benefit (APHAB).[103] This 24-item scale measures four aspects of communication ability. Values corresponding to minimally clinically important clinical change have also been established.[104] The Effectiveness of Auditory Rehabilitation (EAR) scale addresses comfort and cosmesis issues associated with hearing aids that are overlooked in many hearing aid scales. There are two brief 10-item modules: the Inner EAR addresses intrinsic issues of hearing loss such as functional, physical, emotional, and social impairment. The Outer EAR covers extrinsic factors such as the comfort, convenience, and cosmetic appearance.[105]

Effects of cochlear implantation on HRQOL have also recently begun to be measured. The Nimegen Cochlear Implant Questionnaire has been used for this purpose,[106] and the University of Washington Clinical Assessment of Musical Perception (CAMP) has been developed to assess perception of music in cochlear implant recipients.[107]

Individuals interested in pursuing research on hearing amplification should also be aware of a number of other validated scales; only a partial listing is referenced here.[108-112] In addition to these scales, there are several excellent, validated scales that assess other aspects of otologic disease including dizziness[113] and tinnitus.[114]

Rhinologic Disease

The ability to assess outcomes in chronic rhinosinusitis has dramatically improved with the development of disease-specific scales. The two most widely used scales are the Sinonasal Outcome Test (SNOT-20[115]) and the Chronic Sinusitis Survey (CSS[116]). The SNOT-20 has 20 items, has been extensively validated, and is a shortened version of the 31 item Rhinosinusitis Outcome Measure.[117] It is responsive to clinical change and has established scores that reflect minimally clinically important differences. The CSS is a shorter scale consisting of two components. The severity-based component has four items, and the duration-based component asks about duration of both symptoms and medication use. In addition to the SNOT and CSS, there are also a number of other excellent validated sinusitis scales.[118,119] Some of these scales focus on rhinitis specifically, including the Mini Rhinoconjunctivitis QOL Questionnaire,[120] the Rhinitis Outcome Questionnaire[121] and the Nocturnal Rhinoconjunctivitis Questionnaire,[122] whereas others focus on rhinosinusitis specifically. The Rhinosinusitis Quality of Life survey (RhinoQOL) has been validated for both acute and chronic sinusitis.[123] Additional new rhinologic scales continue to be developed.

In 2003, the American Academy of Otolaryngology-Head and Neck Surgery Foundation commissioned the National Center for the Promotion of Research in Otolaryngology (NC-PRO) to develop and validate a disease-specific instrument for patients with nasal obstruction for a national outcomes study. The Nasal Obstruction Symptom Evaluation (NOSE) scale is a five-item instrument that is valid, reliable, and responsive.[124]

Pediatric Diseases

An important difference between measuring outcomes in adults and children is that younger children may be unable to complete the scales by themselves. In these cases, the instruments need to be completed by proxy, typically a parent or other caregiver. This difference in perspective should be kept in mind when interpreting the results of pediatric studies. A good generic scale, similar to the SF-36 in adults, is the Child Health Questionnaire (CHQ[125]). This is also a widely used instrument that has been extensively validated and translated into numerous languages. It is a health status measure designed for children 5 years of age and older, and can be completed directly by children 10 and older. Other generic QOL assessments for children include the Pediatric Quality of Life Inventory (PedsQL) and the Child Health and Illness Profile—Child Edition (CHIP-CE).[126,127] The Glasgow Children's Benefit Inventory is a validated measure that evaluates the benefit a child receives from an intervention and is a general measure that was developed with otolaryngologic disease in mind.[128] The Caregiver Impact Questionnaire has been used to evaluate the impact of disease on the child's caregivers.[129,130]

There are a number of excellent, validated disease-specific scales for children. A number of instruments have been developed to assess the impact of otitis media. The most widely used OM-6 is a brief, six-item scale useful for the evaluation of otitis media–related QOL in children.[131] It has been shown to be reliable, valid, and responsive, and has been widely adopted. Two scales are pertinent to children with obstructive sleep disorders, the OSA-18,[132] which has been found to be valid, reliable, and responsive, and the OSD-6.[133,134] A scale has also recently been developed for studying tonsil and adenoid health in children.[135] Voice-related QOL has also been evaluated in children via the Pediatric Voice Outcomes Survey and the Pediatric Voice-Related Quality-of-Life survey (PVQOL).[136-138]

Voice

Several instruments have been developed to assess outcomes in voice.[139,140] The Voice Handicap Index is one of the most widely used instruments and has been well studied. It evaluates the psychosocial impact of dysphonia and has been validated by both Classical Test Theory[108,141] and Item Response Theory.[142] The Voice Symptom Scale (VoiSS),[143,144] the Vocal Performance Questionnaire, and the Voice Related Quality of Life Instrument have all also been well studied and well used.[145,146] These instruments provide independent useful data that complement clinician performed perceptual evaluation.[147,148] In addition, the Singing Voice Handicap Index has been created and found to be valid and reliable for assessing vocal problems specific to singers.[149]

Sleep

Several validated scales are in use to assess HRQOL in adults with obstructive sleep apnea. The most widely used are the 30-item Functional Outcomes of Sleep Questionnaire (FOSQ[150]) and the 50-item Calgary Sleep Apnea Quality of Life Index (SAQLI[151,152]). In addition, the Quebec Sleep Questionnaire (QSQ) was recently validated as an additional OSA instrument.[153] Clinicians interested in a more brief instrument may wish to consider the Symptoms of Nocturnal Obstruction and Respiratory Events (SNORE-25[154]). The eight-item Epworth Sleepiness Scale (ESS) is commonly used to assess the degree of daytime sleepiness,[155] Although perhaps one of the most useful tools available, a recent study found that it was not clinically reproducible,[156] and a number of studies have shown wide variability in correlation between the ESS and objective measures of sleep apnea severity. Because sleepiness and fatigue can be difficult to differentiate on QOL instruments and in clinical practice, recently the Empirical Sleepiness and Fatigue Scales were created (utilizing a number of items from the ESS). These scales were found to have internal consistency and good test-retest reliability and will likely aid in the evaluation of patients with OSA who are more likely to endorse sleepiness variables.[157]

Symptom Scales

Two scales specific to swallowing are available. The M.D. Anderson Dysphagia Inventory (MDADI[158]) is a brief, 20-item scale intended to

measure dysphagia in head and neck cancer patients. The SWAL-QOL is longer (44 items), but validated for use in a more general population.[159] An instrument known as the Quality of Life in Reflux and Dyspepsia (QOLRAD) has also been developed which assesses QOL in patients with laryngopharyngeal reflux.[160] Finally, several instruments have been developed to assess outcomes in facial plastic surgery.[161]

Summary and Future Directions

Outcomes research is the scientific analysis of treatment effectiveness. In the past 2 decades, it has contributed substantially to the national debate on health resource allocation. Outcomes research provides insight into the value of otolaryngology treatments and methods for quantifying important outcomes that were previously too "soft" to measure. Better appreciation for outcomes research will improve the level of evidence about important treatments and operations.

The impact of outcomes research is beginning to extend into deliberations about quality of care as the health care system moves to establish standards for patient safety. The Leapfrog Group, a coalition of the largest public and private organizations that provide health care benefits for its employees, uses its collective purchasing power to ensure that its employees have access to, and more informed choices about, quality health care. Policy makers will increasingly look to outcomes research for insight into how to measure quality and safety, in addition to effectiveness.

It is imperative that clinicians be familiar with these basic principles. Otolaryngologists should participate in local and national outcomes research efforts to improve the evidence supporting successful otolaryngology interventions and to provide informed physician perspective in a health care environment that is increasingly driven by third-party participants.

CHAPTER SIX

Interpreting Medical Data

Richard M. Rosenfeld

Key Points

- Learning how to interpret medical data will make you a better clinician, researcher, and teacher.
- Interpreting data begins by assessing the investigation that produced it; low-quality, biased data are of limited value, regardless of how appealing the results may seem.
- The presence or absence of a *control group* has a profound influence on data interpretation. An uncontrolled study is purely descriptive and cannot assess effectiveness or efficacy.
- Statistical tests often make assumptions about the underlying data. Unless these assumptions are met, the test is invalid.
- Uncertainty is present in all data, because of the inherent variability in biologic systems and in our ability to assess them in a reproducible fashion. Results should be reported with 95% confidence intervals, which incorporate uncertainty by providing a range of values considered plausible for the population.
- All statistical tests measure error. The *P* value is the likelihood of a type I error (false-positive conclusion), which occurs if a true null hypothesis is mistakenly rejected. Conversely, a type II error (false-negative conclusion) occurs when a real difference is missed, and is related to statistical power and sample size.
- A study has internal validity when the data are analyzed and interpreted properly, but external validity (generalizability) requires that the study sample be representative of the larger population to which it is intended to apply.
- Confidence and common sense are needed to balance statistical significance with clinical importance.
- A single study is rarely definitive. Science is a cumulative process that requires a large body of consistent and reproducible evidence before conclusions can be formed.
- Effective data interpretation facilitates moving from observations to generalizations with predictable degrees of certainty and uncertainty.

In every chapter of this text, whether it relates to clinical medicine or basic science, the authors draw on their own experience and the experience of others to form systematic conclusions. Experience yields data, and interpreting data is the heart and soul of the cumulative process called science. Learning how to interpret medical data will make you a better clinician, researcher, and teacher.

Effective data interpretation is a habit: a combination of knowledge, skill, and desire.[1] By applying the seven habits (Table 6-1) outlined in this chapter, any otolaryngologist—regardless of his or her level of statistical knowledge or lack thereof—can interpret data. The numerous tables that accompany the text are designed as stand-alone reminders, and often contain keywords with definitions endorsed by the International Epidemiological Association.[2]

This chapter also discusses the practice of data interpretation, including specific hypothesis tests, sample size determination, and common statistical deceptions encountered in the otolaryngology literature. You do not have to be a numerical wizard to understand data; all you need are patience, persistence, and a few good habits that will help settle the dust following the clash of statistics with the human mind.

The Seven Habits of Highly Effective Data Users

The seven habits that follow are the key to understanding data.[3] They embody fundamental principles of epidemiology and biostatistics that are developed in a logical and sequential fashion. Table 6-1 gives an overview of the seven habits, as well as the corresponding principles and keywords that comprise them.

Habit 1: Check Quality Before Quantity

Bias is a four-letter word that is easy to ignore but difficult to avoid.[4] Data collected specifically for research (Table 6-2) are likely to be unbiased—they reflect the true value of the attribute being measured. In contrast, data collected during routine clinical care will vary in quality depending on the specific methodology applied.

Experimental studies, such as randomized trials, often yield high-quality data because they are performed under carefully controlled conditions. In *observational* studies, however, the investigator is simply a bystander who records the natural course of health events during clinical care. Although more reflective of "real life" than a contrived experiment, observational studies are more prone to bias. Comparing randomized trials with outcomes studies highlights the difference between experimental and observational research (Table 6-3).

The presence or absence of a *control group* has a profound influence on data interpretation. An uncontrolled study, no matter how elegant, is purely descriptive.[5] Nonetheless, authors of case series often delight in unjustified musings on efficacy, effectiveness, association, and causality. A case series is of greatest value when dealing with uncommon disorders or interventions, or with circumstances in which randomized trials would be unethical or impractical. The best case series include a consecutive sample of subjects, describe the sample fully, include details

Table 6-1

The Seven Habits of Highly Effective Data Users

Habit	Underlying Principles	Keywords
1. Check quality before quantity.	All data are not created equal; fancy statistics cannot salvage biased data from a poorly designed and executed study.	Bias, accuracy, research design, confounding, causality
2. Describe before you analyze.	Special data require special tests; improper analysis of small samples or data with an asymmetric distribution gives deceptive results.	Measurement scale, frequency distribution, descriptive statistics
3. Accept the uncertainty of all data.	All observations have some degree of random error; interpretation requires estimating the associated level of precision or confidence.	Precision, random error, confidence intervals
4. Measure error with the right statistical test.	Uncertainty in observation implies certainty of error; positive results must be qualified by the chance of being wrong; negative results by the chance of having missed a true difference	Statistical test, type I error, *P* value, type II error, power
5. Put clinical importance before statistical significance.	Statistical tests measure error, not importance; an appropriate measure of clinical importance must be checked.	Effect size, statistical significance, clinical importance
6. Seek the sample source.	Results from one data set do not necessarily apply to another; findings can be generalized only for a random and representative sample.	Population, sample, selection criteria, external validity
7. View science as a cumulative process.	A single study is rarely definitive; data must be interpreted relative to past efforts, and by their implications for future efforts.	Research integration, level of evidence, meta-analysis

Table 6-2

Effect of Study Design on Data Interpretation

Aspect of Study Design	Effect on Data Interpretation
How were the data originally collected?	
Specifically for research	Interpretation facilitated by quality data collected according to an a priori protocol
During routine clinical care	Interpretation limited by consistency, accuracy, availability, and completeness of the source records
Is the study experimental or observational?	
Experimental study with conditions under direct control of the investigator	Low potential for systematic error (bias); bias can be reduced further by randomization and masking (blinding)
Observational study without intervention other than to record, classify, analyze	High potential for bias in sample selection, treatment assignment, measurement of exposures, and outcomes
Is there a comparison or control group?	
Comparative or controlled study with two or more groups	Permits analytic statements concerning efficacy, effectiveness, and association
No comparison group present	Permits descriptive statements only, because of improvements from natural history and placebo effect
What is the direction of study inquiry?	
Subjects identified before an outcome or disease; future events recorded	Prospective design measures incidence (new events) and causality (if comparison group included)
Subjects identified after an outcome or disease; past histories examined	Retrospective design measures prevalence (existing events) and causality (if comparison group included)
Subjects identified at a single time point, regardless of outcome or disease	Cross-sectional design measures prevalence (existing events) and association (if comparison group included)

Table 6-3

Comparison of Randomized Controlled Trials and Outcomes Studies

Characteristic	Randomized Controlled Trial	Outcomes Study
Level of investigator control	Experimental	Observational
Treatment allocation	Random assignment	Routine clinical care
Patient selection criteria	Restrictive	Broad
Typical setting	Hospital or university based	Community based
End point definitions	Objective health status	Subjective quality of life
End point assessment	Masked (blinded)	Unmasked
Statistical analysis	Comparison of groups	Multivariate regression
Potential for bias	Low	Very high
Generalizability	Potentially low	Potentially high

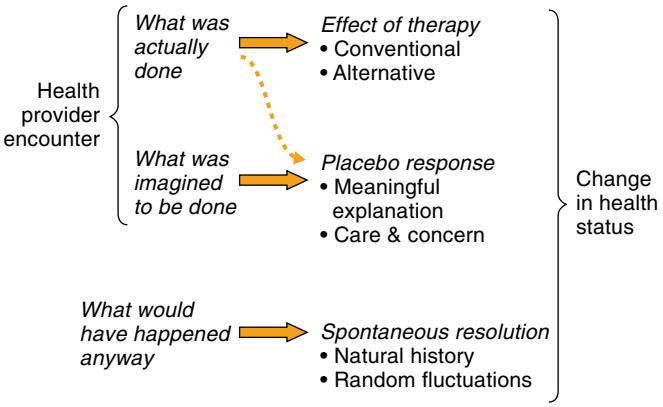

Figure 6-1. Model depicting change in health status after a healing encounter. Dashed arrow shows that a placebo response may occur from symbolic significance of the specific therapy given or from interpersonal aspects of the encounter.

of interventions and adjunctive treatments, account for all participants enrolled (including withdrawals and dropouts), and ensure that follow-up duration is adequate to overcome random disease fluctuations.[6]

Without a control or comparison group, treatment effects cannot be distinguished from other causes of clinical change (Table 6-4). Some of these causes are seen in Figure 6-1, which depicts change in health status after a healing encounter as a complex interaction of three primary factors[7-8]:

1. *What was actually done*. Specific effects of therapy, including medications, surgery, physical manipulations, and alternative or integrative approaches.

2. *What was imagined to be done*. Placebo response, defined as a change in health status resulting from the symbolic significance attributed by the patient (or proxy) to the encounter itself. A placebo response is most likely to occur when the patient receives a meaningful and personalized explanation, feels care and concern expressed by the healer, and achieves control and mastery over the illness (or believes that the healer can control the illness).[9]

3. *What would have happened anyway*. Spontaneous resolution, including natural history, random fluctuations in disease status, and regression to a mean symptom state.

The placebo response differs from the traditional definition of placebo as an inactive medical substance. Whereas a placebo can elicit a placebo response, the latter can occur without the former. A placebo response results from the psychological or symbolic importance attributed by the patient to any nonspecific event in a healing environment. These events include touch, words, gestures, local ambience, and social interactions.[10] Many of these factors are encompassed in the term *caring effects*,[11] which have been central to medical practice in all cultures throughout history. Caring and placebo effects are so important that they have been deliberately used to achieve positive outcomes in clinical practice.[12]

When data from a comparison or control group are available, inferential statistics may be used to test hypotheses and measure associations. Causality may also be assessed when the study has a time span component, either retrospective or prospective (see Table 6-2). Prospective studies measure *incidence* (new events) whereas retrospective studies measure *prevalence* (existing events). Unlike time span studies, cross-sectional inquiries measure association not causality. Examples include surveys, screening programs, and evaluation of diagnostic tests. Experimentally planned interventions are ideal for assessing cause-effect relationships, because observational studies are prone to innate distortions or biases caused by individual judgments and other selective decisions.[13]

Another clue to data quality is study type,[14] but this cannot replace the four questions in Table 6-2. Note the variability in data quality for the study types listed in Table 6-5, particularly the observational designs. Randomization balances baseline prognostic factors (known and unknown) among groups, including severity of illness and the presence of comorbid conditions. Because these factors also influence a clinician's decision to offer treatment, nonrandomized studies are prone to allocation (susceptibility) bias (see Table 6-3) and false-positive results.[15] For example, when the survival of surgically treated cancer patients is compared with the survival of nonsurgical controls (e.g., radiation or chemotherapy), without randomization, the surgical group will generally have a more favorable prognosis independent of therapy, because the customary criteria for operability (special anatomic conditions and no major comorbidity) also predispose to favorable results.

The relationship between data quality and interpretation is illustrated in Table 6-6 using hypothetical studies to determine whether tonsillectomy causes baldness. Note how a case series (examples 1 and

Table 6-4

Explanations Other Than "Efficacy" for Outcomes in Treatment Studies

Explanation	Definition	Solution
Bias	Systematic variation of measurements from their true values; may be intentional or unintentional	Accurate, protocol-driven data collection
Chance	Random variation without apparent relation to other measurements or variables; example: luck	Control or comparison group
Natural history	Course of a disease from onset to resolution; may include relapse, remission, and spontaneous recovery	Control or comparison group
Regression to the mean	Symptom improvement independent of therapy as sick patients return to a mean level after seeking care	Control or comparison group
Placebo effect	Beneficial effect caused by the expectation that the regimen will have an effect; example: power of suggestion	Control or comparison group with placebo
Halo effect	Beneficial effect caused by treatment novelty or by the provider's manner, attention, and caring	Control or comparison group treated similarly
Hawthorne effect	Beneficial effect caused by the participant's knowledge of being evaluated and observed in a study	Control or comparison group treated similarly
Confounding	Distortion of an effect by other prognostic factors or variables for which adjustments have not been made	Randomization or multivariate analysis
Allocation (susceptibility) bias	Beneficial effect caused by allocating subjects with less severe disease or better prognosis to treatment group	Randomization or comorbidity analysis
Ascertainment (detection) bias	Favoring the treatment group during outcome analysis; example: rounding up for treated subjects, down for controls	Masked (blinded) outcome assessment

Table 6-5

Relationship of Study Type to Study Methodology

Study Type	How Were the Data Originally Collected?	Is There a Control or Comparison Group?	What Is the Direction of Study Inquiry?
Experimental Studies			
Basic science study	Research	Yes or no	Prospective or cross-sectional
Clinical trial	Research	Yes or no	Prospective or cross-sectional
Randomized trial	Research	Yes	Prospective
Observational Studies			
Cohort study	Clinical care or research	Yes or no	Prospective
Historical cohort study	Clinical care	Yes	Prospective
Outcomes research	Clinical care or research	Yes or no	Prospective
Case-control study	Clinical care	Yes	Retrospective
Case series	Clinical care	Yes or no	Retrospective or prospective
Survey study	Clinical care or research	Yes or no	Cross-sectional
Diagnostic test study	Clinical care or research	Yes or no	Cross-sectional

2) can have either a prospective or retrospective direction of inquiry depending on how subjects are identified; contrary to common usage, all cases series are not "retrospective reviews." Only the controlled studies (examples 3 through 7) can measure associations, and only the controlled studies with a time span component (examples 4 through 7) can assess causality. The nonrandomized studies (examples 3 through 6), however, require adjustment for potential confounding variables—baseline prognostic factors that may be associated with both tonsillectomy and baldness and therefore influence results. As noted previously, adequate randomization ensures balanced allocation of prognostic factors among groups, thereby avoiding the issue of confounding.

Habit 2: Describe Before You Analyze

Statistical tests often make assumptions about the underlying data. Unless these assumptions are met, the test will be invalid. Describing

Table 6-6

Determining If Tonsillectomy Causes Baldness: Study Design vs. Interpretation

Study Design*	Study Execution	Interpretation
1. Case series, retrospective	A group of bald subjects are questioned as to whether or not they ever had tonsillectomy.	Measures prevalence of tonsillectomy in bald subjects; cannot assess association or causality
2. Case series, prospective	A group of subjects who had or who are about to have tonsillectomy are examined later for baldness.	Measures incidence of baldness after tonsillectomy; cannot assess association or causality
3. Cross-sectional study	A group of subjects are examined for baldness and for presence or absence of tonsils at the same time.	Measures prevalence of baldness and tonsillectomy and their association; cannot assess causality
4. Case-control study	A group of bald subjects and a group of nonbald subjects are questioned about prior tonsillectomy.	Measures prevalence of baldness and association with tonsillectomy; limited ability to assess causality
5. Historical cohort study	A group of subjects who had prior tonsillectomy and a comparison group with intact tonsils are examined later for baldness.	Measures incidence of baldness and association with tonsillectomy; can assess causality when adjusted for confounding variables
6. Cohort study (longitudinal)	A group of nonbald subjects about to have tonsillectomy and a nonbald comparison group with intact tonsils are examined later for baldness.	Measures incidence of baldness and association with tonsillectomy; can assess causality when adjusted for confounding variables
7. Randomized controlled trial	A group of nonbald subjects with intact tonsils are randomly assigned to tonsillectomy or observation and examined later for baldness.	Measures incidence of baldness and association with tonsillectomy; can assess causality despite baseline confounding variables

*Studies are listed in order of increasing ability to establish causal relationship.

Table 6-7

Measurement Scales for Describing and Analyzing Data

Scale	Definition	Examples
Dichotomous	Classification into either of two mutually exclusive categories	Breastfeeding (yes/no), sex (male/female)
Nominal	Classification into unordered qualitative categories	Race, religion, country of origin
Ordinal	Classification into ordered qualitative categories, but with no natural (numerical) distance between their possible values	Hearing loss (none, mild, moderate), patient satisfaction (low, medium, high), age group
Numerical	Measurements with a continuous scale, or a large number of discrete ordered values	Temperature, age in years, hearing level in decibels
Numerical (censored)	Measurements on subjects lost to follow-up, or in whom a specified event has not yet occurred at the end of a study	Survival rate, recurrence rate, or any time-to-event outcome in a prospective study

before you analyze avoids trying to unlock the mysteries of square data with a round key.

Describing data begins by defining the *measurement scale* that best suits the observations. Categorical (qualitative) observations fall into one or more categories and include dichotomous, nominal, and ordinal scales (Table 6-7). Numerical (quantitative) observations are measured on a continuous scale and are further classified by the underlying *frequency distribution* (plot of observed values vs. the frequency of each value). Numerical data with a symmetric (normal) distribution are symmetrically placed around a central crest or trough (bell-shaped curve). Numerical data with an asymmetric distribution are skewed (shifted) to one side of the center, have a sloping "exponential" shape that resembles a forward or backward J, or contain some unusually high or low outlier values.

Depending on the measurement scale, data may be summarized using one or more of the descriptive statistics in Table 6-8. Note that when summarizing numerical data, the descriptive method varies according to the underlying distribution. Numerical data with a symmetric distribution are best summarized with the mean and standard deviation (SD), because 68% of the observations fall within the mean ± 1 SD and 95% fall within the mean ± 2 SD. In contrast, asymmetric numerical data are best summarized with the median, because even a single outlier can strongly influence the mean. If a series of five patients are followed after sinus surgery for 10, 12, 15, 16, and 48 months, the mean duration of follow-up is 20 months, but the median is only 15 months. In this case a single outlier, 48 months, distorts the mean.

Although the mean is appropriate only for numerical data with a symmetric distribution, it is often applied regardless of the underlying

Table 6-8

Descriptive Statistics

Descriptive Measure	Definition	When to Use It
Central Tendency		
Mean	Arithmetic average	Numerical data that are symmetric
Median	Middle observation; half the values are smaller and half are larger	Ordinal data; numerical data with an asymmetric distribution
Mode	Most frequent value	Nominal data; bimodal distribution
Dispersion		
Range	Largest value minus smallest value	Emphasizes extreme values
Standard deviation	Spread of data about their mean	Numerical data that are symmetric
Percentile	Percentage of values that are equal to or below that number	Ordinal data; numerical data with an asymmetric distribution
Interquartile range	Difference between the 25th percentile and 75th percentile	Ordinal data; numerical data with an asymmetric distribution
Outcome		
Survival rate	Proportion of subjects surviving, or with some other outcome, after a time interval (e.g., 1 year, 5 years)	Numerical (censored) data in a prospective study
Odds ratio	Odds of a disease or outcome in subjects with a risk factor divided by odds in controls	Dichotomous data in a retrospective or prospective controlled study
Relative risk	Incidence of a disease or outcome in subjects with a risk factor divided by incidence in controls	Dichotomous data in a prospective controlled study
Rate difference*	Event rate in treatment group minus event rate in control group	Compares success or failure rates in clinical trial groups
Correlation coefficient	Degree to which two variables have a linear relationship	Numerical or ordinal data

*Also called the absolute risk reduction.

symmetry. An easy way to determine whether the mean or median is appropriate for numerical data is to calculate both; if they differ significantly, the median should be used. Another way is to examine the SD; when it is very large (e.g., larger than the mean value with which it is associated), the data often have an asymmetric distribution and should be described by the median and interquartile range. When in doubt, the median should always be used over the mean.[16]

A special form of numerical data is called *censored* (see Table 6-7). Data are censored when three conditions apply: (1) the direction of study inquiry is prospective, (2) the outcome of interest is time-related, and (3) some subjects die, are lost, or have not yet had the outcome of interest when the study ends. Interpreting censored data is called *survival analysis*, because of its use in cancer studies where survival is the outcome of interest. Survival analysis permits full use of censored observations by including them in the analysis up to the time the censoring occurred. If censored observations are instead excluded from analysis (e.g., exclude all patients with less than 3 years of follow-up in a cancer study), the resulting survival rates will be biased and sample size will be unnecessarily reduced.

A *survival curve* starts with 100% of the study sample alive and shows the percentage still surviving at successive times for as long as information is available. The curve may be applied not only to survival as such, but also to the persistence of freedom from a disease or complication or some other end point. For example, one could estimate the 3-year, 5-year, or 10-year rates for cholesteatoma recurrence or the future "survival" of tonsils (e.g., no need for tonsillectomy) in a cohort of children after adenoidectomy alone. Several statistical methods are available for analyzing survival data. The Kaplan-Meier (product-limit) method records events by exact dates and is suitable for small and large samples. Conversely, the life table (actuarial) method records events by time interval (e.g., every month, every year) and is most commonly used for large samples in epidemiologic studies.

The odds ratio, relative risk, and rate difference (see Table 6-7) are useful ways of comparing two groups of dichotomous data.[17] A retrospective (case-control) study of tonsillectomy and baldness might report an *odds ratio* of 1.6, indicating that bald subjects were 1.6 times more likely to have had tonsillectomy than were nonbald controls. In contrast, a prospective study would report results using *relative risk*. A relative risk of 1.6 means that baldness was 1.6 times more likely to develop in tonsillectomy subjects than in nonsurgical controls. Finally, a *rate difference* of 30% in a prospective trial or experiment reflects the increase in baldness caused by tonsillectomy, above and beyond what occurred in controls. No association exists between groups when the rate difference equals zero, or the odds ratio or relative risk equals one (unity).

Two groups of ordinal or numerical data are compared with a *correlation coefficient* (see Table 6-8). A coefficient (r) from 0 to 0.25 indicates little or no relationship, from 0.25 to 0.49 a fair relationship, from 0.50 to 0.74 a moderate to good relationship, and greater than 0.75 a good to excellent relationship. A perfect linear relationship would yield a coefficient of 1.00. When one variable varies directly with the other, the coefficient is positive; a negative coefficient implies an inverse association. Sometimes the correlation coefficient is squared (r^2) to form the *coefficient of determination*, which estimates the percentage of variability in one measure that is predicted by the other.

Habit 3: Accept the Uncertainty of All Data

Uncertainty is present in all data, because of the inherent variability in biologic systems and in our ability to assess them in a reproducible fashion.[18] If hearing in 20 healthy volunteers was measured on five different days, how likely would it be to get the same mean result each time? It is very unlikely, because audiometry has a variable behavioral component that depends on the subject's response to a stimulus and the examiner's perception of that response. Similarly, if hearing was measured in five groups of 20 healthy volunteers each, how likely would it be to get the same mean hearing level in each group? Again unlikely, because of variations between individuals. A range of similar results would be obtained, but rarely the exact same result on repetitive trials.

Uncertainty must be dealt with when interpreting data, unless the results are meant to apply only to the particular group of patients, animals, cell cultures, and DNA strands, in which the observations were initially made. Recognizing this uncertainty, each of the descriptive measures in Table 6-8 is called a *point estimate*, specific to the data that generated it. In medicine, however, one seeks to pass from observations to generalizations, from point estimates to estimates about other populations. When this process occurs with calculated degrees of uncertainty, it is called *inference*.

The following is a brief example of clinical inference. After treating five vertiginous patients with vitamin C, you remark to a colleague that four had excellent relief of their vertigo. She asks, "How confident are you of your results?"

"Quite confident," you reply. "There were five patients, four got better, and that's 80%."

"Maybe I wasn't clear," she interjects, "how confident are you that 80% of vertiginous patients you see in the next few weeks will respond favorably, or that 80% of similar patients in my practice will do well with vitamin C? In other words, can you *infer* anything about the real effect of vitamin C on vertigo from only five patients?"

Hesitatingly you retort, "I'm pretty confident about that number 80%, but maybe I'll have to see a few more patients to be sure."

The real issue, of course, is that a sample of only five patients offers low *precision* (repeatability). How likely is it that the same results would be found if five new patients were studied? Actually, one can state with 95% confidence that four out of five successes in a single trial is consistent with a range of results from 28% to 99% in future trials. This *95% confidence interval* may be calculated manually or with a statistical program; it reveals the range values considered plausible for the population. A point estimate summarizes findings for the sample, but extrapolation to the large population introduces error and uncertainty, which makes a range of plausible values more appropriate.

Precision may be increased (uncertainty may be decreased) by using a more reproducible measure, by increasing the number of observations (sample size), or by decreasing the variability among the observations. The most common method is to increase the sample size, because the variability inherent in the subjects studied can rarely be reduced. Even a huge sample of perhaps 50,000 subjects still has some degree of uncertainty, but the 95% confidence interval will be quite small. Realizing that uncertainty can never completely be avoided, statistics are used to estimate precision. Thus when data are described using the summary measures listed in Table 6-8, a corresponding 95% confidence interval should accompany each point estimate.

Precision differs from accuracy. *Precision* relates to random error and measures repeatability; *accuracy* relates to systematic error (bias) and measures nearness to the truth. A precise otologist may always perform a superb mastoidectomy, but an accurate otologist performs it on the right patient. A precise surgeon cuts on the exact center of the line, but an accurate surgeon first checks the line to be sure it is in the right place. Succinctly put, precision is doing things right and accuracy is doing the right thing. Precise data include a large enough sample of carefully measured observations to yield repeatable estimates; accurate data are measured in an unbiased manner and reflect what is truly purported to be measured. When we interpret data, we must estimate both precision and accuracy.

To summarize habits 1, 2, and 3: "Check quality before quantity" determines whether or not the data are worth interpreting (habit 1). Assuming they are, "describe before you analyze" and summarize the data using appropriate measures of central tendency, dispersion, and outcome for the particular measurement scales involved (habit 2). Next, "accept the uncertainty of all data" as noted in habit 3, and qualify the point estimates in habit 2 with 95% confidence intervals to measure precision. When precision is low (e.g., the confidence interval is wide), proceed with caution. Otherwise, proceed with habits 4, 5, and 6, which deal with errors and inference.

Habit 4: Measure Error with the Right Statistical Test

To err is human—and statistical. When comparing two or more groups of uncertain data, errors in inference are inevitable. If one concludes that the groups are different, they may actually be equivalent. If one concludes that they are the same, a true difference may have been missed. Data interpretation is an exercise in modesty, not pretense—any conclusion we reach may be wrong. The ignorant data analyst ignores the possibility of error; the savvy analyst estimates this possibility by using the right statistical test.[19]

Now that we've stated the problem in English, let's restate it in thoroughly confusing statistical jargon (Table 6-9). We begin with some testable *hypotheses* about the groups we are studying, such as "Gibberish levels in group A differ from those in group B." Rather than keep it simple, we now invert this to form a *null hypothesis*: "Gibberish levels in group A are equal to those in group B." Next we fire up our personal computer, enter the gibberish levels for the subjects in both groups, choose an appropriate statistical test, and wait for the omnipotent *P* value to emerge.

The *P value* gives the probability of making a *type I error*: rejecting a true null hypothesis. In other words, if $P = .10$, there is a 10% chance of being wrong when we declare that group A differs from group B based on the observed data. Alternatively, there is a 10% probability that the difference in gibberish levels is explainable by random error—we cannot be certain that uncertainty is not the cause. In medicine, $P < .05$ is generally considered low enough to safely reject the null hypothesis. Conversely, when $P > .05$, the null hypothesis of equivalent gibberish levels is accepted. Nonetheless, one might be making a *type II error* by accepting a false null hypothesis. Rather than state the probability of a type II error directly, it is stated indirectly by specifying *power* (see Table 6-9).

Moving from principles to practice, two hypothetical studies are presented. The first is an observational, prospective study to determine whether tonsillectomy causes baldness: 20 patients undergoing tonsillectomy and 20 controls are examined 40 years later and the incidence of baldness is compared. The second study will use the same groups, but will determine whether tonsillectomy causes hearing loss. This allows one to explore statistical error from the perspective of a dichotomous outcome (bald vs. nonbald) and a numerical outcome (hearing level in decibels).

Suppose that baldness develops in 80% of tonsillectomy patients (16/20) but in only 50% of controls (10/20). If one infers that, based on these results in 40 specific patients, tonsillectomy predisposes to baldness *in general*, what is the probability of being wrong (type I error)? Because $P = .10$ (Fisher's exact test), there is a 10% chance of type I error, so one is reluctant to associate tonsillectomy with baldness based on this single study. Intuitively, however, a rate difference of 30% seems like a big difference, so what is the chance of being wrong when one concludes it is not significant (type II error)? The probability of a type II error (false-negative result) is actually 48% (same as saying 52% power), which means one may indeed be wrong in accepting the null hypothesis. Therefore, a larger study is needed before any definitive conclusions can be drawn.

Intrigued by the initial findings, one repeats the tonsillectomy study with twice as many patients in each group. Suppose that baldness again develops in 80% of tonsillectomy patients (32/40), but only 50% of controls (20/40). The rate difference is still 30%, but now $P = .01$ (Fisher's exact test). The conclusion is that tonsillectomy is associated with baldness, with only a 1% chance of making a type I error (false-positive result). By increasing the number of subjects studied, the precision is increased to a level where one could move from observation to generalization with a tolerable level of uncertainty.

Returning to the earlier study of 20 tonsillectomy patients and 20 controls, the hearing levels for the groups are 25 ± 9 decibels (dB) and 20 ± 9 dB, respectively (mean value ± SD). What is the chance of being wrong if one infers that post-tonsillectomy patients have hearing levels 5 dB lower than controls? Because $P = .09$ (*t*-test), there is a 9% probability of a type I error. If, however, one concludes there is no true difference between the groups, there is a 58% chance of making a type II error. Thus, there is little to say about the impact of tonsillectomy on hearing based on this study, because power is only 42%. In general, studies with "negative" findings should be interpreted by power, not *P* values.

When making inferences about numerical data, precision may be increased by studying more subjects or subjects with less variability in

Table 6-9

Glossary of Statistical Terms Encountered When Testing Hypotheses

Term	Definition
Central tendency	A supposition, arrived at from observation or reflection, that leads to predictions which can be tested and refuted
Null hypothesis	Results observed in a study, experiment, or test that are no different from what might have occurred due to chance alone
Statistical test	Procedure used to reject or accept a null hypothesis; statistical tests may be parametric, nonparametric (distribution-free), or exact
Type I (alpha) error	Rejecting a true null hypothesis (false-positive error); declaring that a difference exists when in fact it does not
P value	Probability of making a type I error; $P < .05$ indicates a statistically significant result that is unlikely to be caused by chance
Confidence interval	A range of values considered plausible for the population from which the study sample was selected
Type II (beta) error	Accepting a false null hypothesis (false-negative error); declaring that a difference does not exist when in fact it does
Power	Probability that the null hypothesis will be rejected if it is indeed false; mathematically, power is 1.00 minus type II error

their responses. For example, suppose again that there are 20 tonsillectomy patients and 20 controls, but this time the hearing levels are 25 ± 3 dB and 20 ± 3 dB. Although the difference remains 5 dB, the SD is only 3 for this study compared with 9 in the preceding paragraph. For whatever reason, the second subjects had more consistent (less variable) responses. What effect does this reduced variability have on the ability to make inferences? The *P* value is now less than .001 (*t*-test), indicating less than a 1:1000 probability of a type I error if one concludes that the hearing levels truly differ.

All statistical tests measure error. Choosing the right test for a particular situation (Tables 6-10 and 6-11) is determined by (1) whether the observations come from independent or related samples, (2) whether the purpose is to compare groups or to associate an outcome with one or more predictor variables, and (3) the measurement scale of the variables.[20] Despite the myriad of tests available, the principles underlying each remain constant.

Two events are independent if the occurrence of one is in no way predictable from the occurrence of the other. A common example of *independent samples* is two or more parallel (concurrent) groups in a clinical trial or observational study. Conversely, *related samples* include paired organ studies, subjects matched by age and sex, and repeated measures on the same subjects (e.g., before and after treatment). Measurement scales are previously discussed, but the issue of frequency distribution deserves reemphasis. The tests in Tables 6-10 and 6-11 labeled as "parametric" assume an underlying symmetric distribution for data. If the data are sparse, asymmetric, or plagued with outliers, then a "nonparametric" test must be used.

Using the wrong statistical test to estimate error invalidates results. For example, suppose intelligence quotient (IQ) is measured in 20 subjects before and after tonsillectomy, and the mean IQ increases from 125 to 128. For this 3-point increase, $P = .29$ (*t*-test, independent samples) suggests a high probability (29%) of reaching a false-positive conclusion. However, the observations in this example are related before and after IQ tests in the same subjects. What is really of interest is the mean *change* in IQ for each subject (related samples), not how the mean IQ of all subjects before surgery compares with the mean IQ of all subjects postoperatively (independent samples). When the proper statistical test is used (*t*-test, paired samples), $P = .05$ suggests a true association. Related (matched) samples are common in biomedical studies and should never be analyzed as though they were independent.

Habit 5: Put Clinical Importance Before Statistical Significance

Results are *statistically significant* when the probability of a type I error is low enough ($P < .05$) to safely reject the null hypothesis. If the statistical test compared two groups, one concludes that the groups differ. If the statistical test compared three or more groups, one concludes that there are global differences among them. If the statistical test related predictor and outcome variables (regression analysis), one concludes that the predictor variables explain more variation in the outcome than would be expected by chance alone. These generalizations apply to all the statistical tests in Tables 6-9 and 6-10.

The next logical question after "Is there a difference?" (statistical significance) is "How big a difference is there?" (*clinical importance*). Unfortunately, most data interpretation stops with the *P* value, and the second question is never asked. For example, a clinical trial of nonsevere acute otitis media found amoxicillin superior to placebo as initial treatment ($P = .009$).[21] Before we agree with the author's recommendation for routine amoxicillin therapy, let's look more closely at the magnitude of clinical effect. Initial treatment success occurred in 96% of amoxicillin-treated children vs. 92% of controls, yielding a 4% rate difference favoring drug therapy. Alternatively, one must treat 25 subjects (100/4) with amoxicillin to increase the success rate by one subject over what would occur from placebo alone. Is this clinically important? Maybe, or maybe not.

Statistically significant results must be accompanied by a measure of *effect size* that reflects the magnitude of difference between groups.[22] Otherwise, findings with minimal clinical importance may become statistically significant when a large number of subjects are studied. In the above example, the 4% difference in success rates was highly statistically significant because more than 1000 episodes of otitis media contributed to this finding. Large numbers provide high precision (repeatability), which in turn reduces the likelihood of error. The final result is a hypnotically tiny *P* value, which may reflect a clinical difference of trivial importance.

Common measures of effect size when comparing groups include the odds ratio, relative risk, and rate difference (see Table 6-8). For example, in the hypothetical study of tonsillectomy and baldness noted earlier, the rate difference was 30% ($P = .01$), with a 95% confidence interval of 10% to 50%. Therefore, one is 95% confident that tonsil-

Table 6-10

Statistical Tests for Independent Samples

Situation	Parametric Test	Nonparametric Test
Comparing 2 Groups of Data		
Numerical scale	*t*-test	Mann Whitney U,* median test
Numerical (censored) scale	Mantel-Haenszel life table	Wilcoxon, Logrank, Mantel-Cox
Ordinal scale	—	Mann Whitney U,* median test, chi-squared test for trend
Nominal scale	—	Chi-squared, log-likelihood ratio
Dichotomous scale	—	Chi-squared, Fisher's exact test, odds ratio, relative risk
Comparing 3 or More Groups of Data		
Numerical scale	One-way ANOVA	Kruskal-Wallis ANOVA
Ordinal scale	—	Kruskal-Wallis ANOVA, chi-squared test for trend
Dichotomous or nominal scale	—	Chi-squared, log-likelihood ratio
Associating an Outcome with Predictor Variables		
Numerical outcome, 1 predictor	Pearson correlation	Spearman rank correlation
Numerical outcome, 2 or more predictor variables	Multiple linear regression, two-way ANOVA	—
Numerical (censored) outcome	Proportional hazards (Cox) regression	—
Dichotomous outcome	Discriminant analysis	Multiple logistic regression
Nominal or ordinal outcome	Discriminant analysis	Log-linear model

*The Mann Whitney U test is equivalent to the Wilcoxon rank-sum test.
ANOVA, analysis of variance.

Statistical Tests for Related (Matched, Paired, or Repeated) Samples

Situation	Parametric Test	Nonparametric Test
Comparing 2 Groups of Data		
Dichotomous scale	—	McNemar's test
Ordinal scale	—	Sign test, Wilcoxon signed rank test
Numerical scale	Paired *t*-test	Sign test, Wilcoxon signed rank test
Comparing 3 or More Groups of Data		
Dichotomous scale	—	Cochran Q test, Mantel-Haenszel chi-squared
Ordinal scale	—	Friedman ANOVA
Numerical scale	Repeated measures ANOVA	Friedman ANOVA

ANOVA, analysis of variance.

lectomy increases the rate of baldness between 10% and 50%, with only 1% chance of a type I error (false-positive). Alternatively, results could be expressed in terms of relative risk. For the tonsillectomy study, relative risk is 1.6 (the incidence of baldness was 1.6 times higher after surgery), with a 95% confidence interval of 1.1 to 2.3. Effect size and 95% confidence limits may be calculated manually[23] or with a computer program.

Effect size is measured by the correlation coefficient (r) when an outcome variable is associated with one or more predictor variables in a regression analysis (see Table 6-10). Suppose that a study of thyroid surgery reports that shoe size had a statistically significant association with intraoperative blood loss (multiple linear regression, $P = .04$, $r = .10$). A correlation of only .10 implies little or no relationship (see Habit 2), and an r^2 of .01 means that only 1% of the variance in survival is explainable by shoe size. Who cares if the results are "significant" when the effect size is clinically irrelevant, not to mention nonsensical. Besides, when $P = .04$, there is a 4% chance of being wrong when the null hypothesis is rejected, which may in fact be the case here. A nonsensical result should prompt a search for confounding factors that may not have been included in the regression, such as TMN stage, comorbid conditions, or duration of surgery.

Confidence intervals (CI) are more appropriate measures of clinical importance than P values, because they reflect *both* magnitude and precision.[24] When a study reports "significant" results, the *lower* limit of the 95% CI should be scrutinized; a value of minimal clinical importance suggests low precision (inadequate sample size). When a study reports "nonsignificant" results, the *upper* limit of the 95% CI should be scrutinized; a value indicating a potentially important clinical effect suggests low statistical power (false-negative finding). Confidence intervals are essential for interpreting effect size, which is a critical concept in evidence-based medicine.[25]

Habit 6: Seek the Sample Source

When we interpret medical data, we ultimately seek to make inferences about some target population based on results in a smaller sample (Table 6-12). Rarely is it possible to study every patient, medical record, DNA strand, or fruit fly with the condition of interest. Nor is it necessary—inferential statistics allow one to generalize from the few to the many, provided that the few studied are a *random and representative* sample of the many. However, random and representative samples rarely arise from divine providence. Therefore one must seek the sample source before generalizing the interpretation of the data beyond the confines of the study that produced it.

As an example of sampling, consider a new antibiotic that is touted as superior to an established standard for treating acute otitis media. When you review the data on which this statement is based, you learn that the study end point was bacteriologic efficacy—the ability to sterilize the middle ear after treatment. Furthermore, the only patients included in the study were those whose initial tympanocentesis revealed an organism with in vitro sensitivity to the new antibiotic; patients with no growth or resistant bacteria were excluded. Can you apply these results to your clinical practice? Most likely not, because you probably do not limit your practice to patients with antibiotic-susceptible bacteria. In other words, the sample of patients included in the study is not representative of the target population in your practice.

A statistical test is valid only when the study sample is *random* and *representative*. Unfortunately, these assumptions are frequently violated or overlooked. A random sample is necessary because most statistical tests are based on probability theory—playing the odds. The odds apply only if the deck is not stacked and the dice are not rigged; that is, all members of the target population have an equal chance of being sampled for study. Investigators, however, typically have access to only a small subset of the target population because of geographic or temporal constraints. When they choose an even smaller subset of this *accessible population* to study, the method of choosing (sampling method) affects the ability to make inferences about the original target population.

Of the sampling methods listed in Table 6-13, only a random sample is theoretically suitable for statistical analysis. Nonetheless, a consecutive or systematic sample offers a relatively good approximation, and provides data of sufficient quality for most statistical tests. The worst sampling method occurs when subjects are chosen based on convenience or subjective judgments about eligibility. Applying statistical tests to the resulting convenience (grab) sample is the equivalent of asking a professional card counter to help you win a blackjack game when the deck is stacked and cards are missing—all bets are off because probability theory will not apply. A brute force sample of the entire population is also unsatisfactory, because lost, missing, or incomplete units tend to differ systematically from those that are readily accessible.

Seek the sample source means identifying the sampling method and selection criteria (inclusion and exclusion criteria) that were applied to the target population to obtain the study sample. When the process appears sound, one concludes that the results are generalizable and *externally valid* (see Table 6-12 and Figure 6-2). If the process appears flawed, one cannot interpret or extrapolate the results beyond the confines of the study sample.

Sometimes a study is internally valid but may not be generalizable. Paradise and colleagues[26] concluded that prompt vs. delayed insertion of tubes for persistent otitis media does not affect child development. Although the study was meticulously designed and analyzed (internally valid), the participants had mostly unilateral (63%) or discontinuous (67%) otitis media with effusion; bilateral continuous effusions were uncommon (18%). Moreover, children with syndromes, developmental delays, or other comorbidities were excluded. Whereas no benefits were seen in the healthy children studied, the results are not generalizable to the more typical population of children who receive tubes, many of whom have chronic bilateral effusions with hearing loss and developmental comorbidities.

The impact of sampling on generalizability is particularly important when interpreting a diagnostic test.[27] For instance, suppose an audiologist develops a new test for diagnosing middle ear effusion (MEE). After testing 1000 children, she reports that 90% of children with a positive result did in fact have MEE (positive predictive value of 90%). Yet when you screen unselected kindergarten children for MEE, the positive predictive value of the test is only 50%. Why does this occur? Because the baseline prevalence of MEE is lower in the kindergarten class (10% have MEE) than in the referral-based audiol-

Table 6-12

Glossary of Statistical Terms Related to Sampling and Validity

Term	Definition
Target population	Entire collection of items, subjects, patients, and observations about which one makes inferences; defined by the selection criteria (inclusion and exclusion criteria) for the study
Accessible population	Subset of the target population that is accessible for study, generally because of geographic or temporal considerations
Study sample	Subset of the accessible population that is chosen for study
Sampling method	Process of choosing a sample from a larger population; the method may be random or nonrandom, representative or nonrepresentative
Selection bias	Error caused by systematic differences between a study sample and target population; examples include studies on volunteers and those conducted in clinics or tertiary care settings
Sample size determination	Process of deciding, before a study begins, how many subjects should be studied; based on the incidence or prevalence of the condition under study, anticipated differences between groups, the power that is desired, and the allowable level of type I error
Internal study validity	Degree to which conclusions drawn from a study are valid for the study sample; results from proper study design, unbiased measurements, and sound statistical analysis
External study validity (generalizability)	Degree to which conclusions drawn from a study are valid for a target population (beyond the subjects in the study); results from representative sampling and appropriate selection criteria

Table 6-13

Methods for Sampling a Population

Method	How It Is Performed	Comments
Brute force sample	Includes all units of study (charts, patients, laboratory animals, or journal articles) accessible to the researchers	Time-consuming and unsophisticated; bias-prone because missing units are seldom randomly distributed
Convenience (grab) sample	Units are selected on the basis of accessibility, convenience, or by subjective judgments about eligibility	Assume this method when none is specified; study results cannot be generalized because of selection bias
Consecutive sample	Every unit is included over a specified time interval, or until a specified number is reached	Excellent method when intake period is long enough to adequately represent seasonal and other temporal factors
Systematic sample	Units are selected using some simple, systematic rule, such as first letter of last name, date of birth, or day of week	Less biased than a grab sample, but problems may still occur because of unequal selection probabilities
Random sample	Units are assigned numbers then selected at random until a desired sample size is attained	Best method; bias is minimized because all units have a known (and equal) probability of selection

ogy population in which the test was developed (50% have MEE). Whereas the sensitivity and specificity of the test are unchanged in both situations, the predictive value is related to baseline prevalence (Bayes' theorem). Therefore the ultimate utility of the test depends on the sample to which it will be applied.

Habit 7: View Science as a Cumulative Process

A single study—no matter how elegant or seductive—is rarely definitive. Science is a cumulative process that requires a large body of consistent and reproducible evidence before conclusions can be formed.[28] When interpreting an exciting set of data, the cumulative basis of science is often overshadowed by the seemingly irrefutable evidence at hand. At least until a new study, by different investigators in a different environment, adds a new twist.

Habit 7 is the process of *integration*: reconciling findings with the existing corpus of known similar research. It is the natural consequence of habits 1 through 3 that deal with *description* and habits 4 through 6 that deal with *analysis*. Thus data interpretation can be summarized in three words: describe, analyze, and integrate. This is a sequential process in which each step lays the foundation for subsequent ones, just as occurs for the six habits that underlie them.

Research integration begins by asking "Do the results make sense?" Statistically significant findings that are biologically implausible, or that are inconsistent with other known studies, can often be explained by hidden biases or design flaws that were initially unsuspected (habit 1). Improbable results can become statistically significant through biased data collection, natural history, placebo effects, unidentified confounding variables, or improper statistical analysis. A study with design flaws or improper statistical analysis is said to have low *internal validity* (see Table 6-12), and should be reanalyzed or discarded.

At the next level of integration, the study design that produced the current data is compared with the design of other published studies. The *level of evidence* generally increases as one progresses from uncontrolled observational studies (case reports, case series), to controlled observational studies (cross-sectional, retrospective, prospective), to controlled experiments (randomized trials).[25] Not all randomized trials, however, are of high quality, and reporting standards must be followed to ensure validity.[29] Levels of research evidence are most often applied to studies of therapy or prevention (Table 6-14), but can also be defined for diagnosis and prognosis.[30] Grades of recommendation (Table 6-15) are assigned based on the quality and consistency of supporting research evidence.

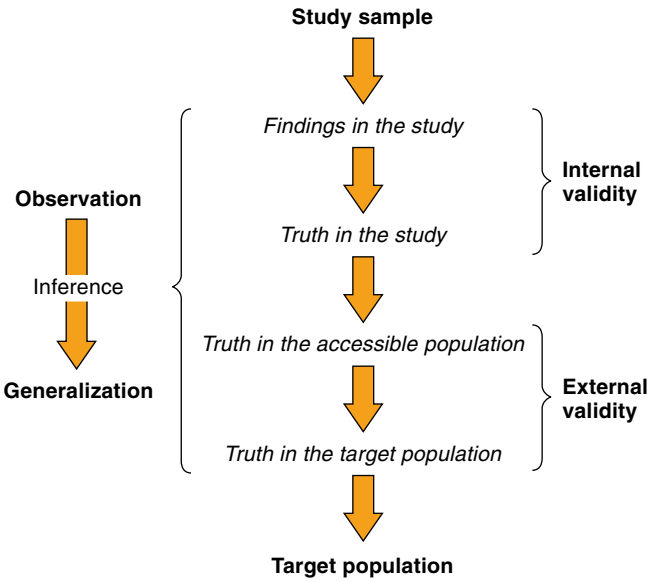

Figure 6-2. Relationship of validity to inference. A properly designed, executed, and analyzed study has internal validity, meaning the findings are valid for the study sample. This alone, however, is inadequate for inference to occur. Another requirement is external validity, which exists when the study sample is representative of an appropriate target population. When a study has internal and external validity, the observations can be generalized.

Bentsianov and Rosenfeld[31] assessed the levels of supporting evidence for therapeutic recommendations in leading otolaryngology journals. Of 1019 articles published in 1999, 72% were clinical research and 36% made therapeutic recommendations. The level of evidence for positive studies was lower than for negative studies, with twice as many negative recommendations supported by randomized trials or controlled studies (analytic research). Similarly, the level of evidence for surgery was lower than for medical therapy, with three times as many medical recommendations supported by analytic research. The authors concluded that a dual evidence standard appears to exist for

Table 6-14

Levels of Research Evidence for Clinical Recommendations

Level	Therapy or Prevention	Diagnosis	Prognosis
1	Randomized controlled trial; systematic review of randomized trials; "all or none" case series	Validating cohort study with good reference standard; CDR tested at one clinical center; SpPins and SpNouts	CDR validated in a single population or in cohort study with greater than 80% follow-up; "all or none" case series
2	Prospective controlled study: cohort study, outcomes research, ecological study	Exploratory cohort study with good reference standard; derivation of CDR; or CDR tested on split-sample or database	Retrospective cohort study or follow-up of untreated controls; derivation or CDR; or CDR tested on split-sample; outcomes research
3	Retrospective controlled study: case-control study	Nonconsecutive study, or without consistently applied reference standards	—
4	Case series and poor-quality cohort and case-control studies	Case-control study, or poor or nonindependent reference standard	Case-series and poor-quality prognostic cohort studies
5	Expert opinion without explicit critical appraisal; or based on physiology, bench research, or "first principles"	Expert opinion without explicit critical appraisal; or based on physiology, bench research, or "first principles"	Expert opinion without explicit critical appraisal; or based on physiology, bench research, or "first principles"

CD, clinical decision rule (algorithm or scoring system that leads to a prognostic estimation); SpPin, specificity is so high that positive result rules in the diagnosis; SpNout, sensitivity so high that a negative result rules out the diagnosis.

Table 6-15

Grades of Recommendation Based on Level of Supporting Evidence

Grade	Level of Supporting Evidence as Defined in Table 6-14
A	Consistent level 1 studies
B	Consistent level 2 or 3 studies or extrapolations* from level 1 studies
C	Level 4 studies or extrapolations* from level 2 or 3 studies
D	Level 5 evidence or troublingly inconsistent or inconclusive studies of any level

*Extrapolations occur where data are used in a situation that has potentially clinically important differences than the original study situation.
Adapted from Phillips B, Ball C, Sackett D, et al. Levels of evidence and grades of recommendation. Oxford Centre for Evidence Based Medicine. http://www.cebm.net/levels_of_evidence.asp.

negative vs. positive studies and for medical vs. surgical recommendations in the otolaryngology literature.

Quantitative data integration ranges from simple tabular listings to sophisticated health services, including systematic reviews, practice guidelines, decision analyses, and economic analyses.[25] Systematic reviews or *meta-analyses* are an ideal way to synthesize results from a group of logically related randomized trials or, less commonly, observational studies.[32,33] The "bottom line" in a systematic review typically includes a summary measure of effect size (e.g., rate difference), a 95% confidence interval, and a statistical test for heterogeneity among source articles. Graphical comparison of studies using forest and funnel plots helps assess publication trends, small-study bias, and overall combinability and consistency of included studies.[34] Systematic reviews differ greatly from traditional "narrative" review articles (Table 6-16), and are the preferred method for synthesizing research evidence.

Clinical practice guidelines are often the next step in evidence synthesis, using the bottom-line estimates of systematic reviews to develop action statements about appropriate health care in specific clinical circumstances. Guidelines are created through an explicit, evidence-based, multidisciplinary process that links evidence to recommendations and incorporates values and expert consensus.[35] The best guidelines focus on a limited number of specific actions that are likely to improve quality of care, and to not attempt to define comprehensive management of a disease, disorder, or condition. An example is the Adult Sinusitis Guideline from the American Academy of Otolaryngology—Head and Neck Surgery,[36] which focuses on accurate diagnosis, antimicrobial therapy of acute sinusitis, and evaluation and prevention of chronic and recurrent sinusitis.

Popular Statistical Tests Used by Otolaryngologists

Salient features of the most popular tests in otolaryngology journals[37] are listed here. Note that each test is simply an alternative way to measure error (habit 4), not a self-contained method of data interpretation. Tests are chosen using the principles outlined in Tables 6-10 and 6-11, then analyzed with readily available software (which can also help select the best test for a specific data set). Explicit guidelines are available to help authors, editors, and reviewers identify the optimal format for reporting statistical results in medical publications.[38]

t-test

Description

The *t*-test is a classic parametric test for comparing the means of two independent or matched (related) samples of numerical data; also called Student's *t*-test.

Table 6-16

Comparison of Narrative (Traditional) Reviews and Meta-analyses

Characteristic	Narrative Review	Meta-analysis
Research design	Free form	A priori protocol
Literature search	Convenience sample of articles deemed important by author	Systematic sample using explicit and reproducible article selection criteria
Data extraction	Selective data retrieval by one author	Systematic data retrieval by two or more authors to reduce error
Focus	Broad; summarizes a large body of information	Narrow; tests specific hypotheses and focused clinical questions
Emphasis	Narrative; qualitative summary	Numbers; quantitative summary
Validity	Variable; high potential for bias in article selection and interpretation	Good, provided articles are of adequate quality and combinability
Bottom line	Broad recommendations, often based on personal opinion	Estimates of effect size, based on statistical pooling of data
Utility	Provides a quick overview of a subject area	Provides summary estimates for evidence-based medicine
Appeal to readers	Usually very high	Varies depending on focus

Interpretation

A significant *P* value for independent samples implies a low probability that the mean values for the two groups are equal. When the samples are matched, a significant *P* value implies that the mean differences of the paired values are unlikely to be zero. Clinical importance is assessed by examining the magnitude of difference achieved and the associated 95% CI. Because valid results depend on relatively equal variances (standard deviation) within each group, a statistical test is required to verify this assumption (F test).

Precautions

t-tests produce an artificially low *P* value if the groups are small (less than 10 observations) or have an asymmetric distribution (one or more extreme outlying values); instead, a nonparametric test (Mann-Whitney U or Wilcoxon rank sum test) should be used. If, however, each group contains more than 30 observations, the underlying distribution can deviate substantially from normality without invalidating results. *t*-tests should *never* be used to compare more than two groups; analysis of variance (ANOVA) is required.[39] When the outcome of interest is time related (e.g., cancer survival, duration of hospital stay, disease recurrence), survival analysis is more appropriate than a *t*-test.

Analysis of Variance

Description

ANOVA tests if the means of *three or more* independent groups of continuous data differ significantly with regard to a single factor (one-way ANOVA) or two factors (two-way ANOVA). ANOVA also tests whether the effect of one factor on the response variable depends on the level of a second factor (interaction).

Interpretation

A significant *P* value implies a low probability that the mean values for all groups are equal. From a statistical standpoint, we say that the variance *between* groups is larger than the variance *within* each group. Note that ANOVA provides no information on whether *individual* pairs of groups differ significantly; it only tests for an overall global difference. For example, when comparing four groups of data (A, B, C, and D), the finding "$P < .05$, ANOVA" means there is less than a 5% chance that the statement "A = B = C = D" is true; however, it says nothing about AB or CD or DA, and so on. Once the investigators demonstrate a significant global difference ($P < .05$) using ANOVA, they can then use *multiple comparison* procedures (Bonferroni, Tukey, Newman-Keuls, Scheffe, Dunnett) for individual group comparisons.

Precautions

ANOVA will produce an artificially low *P* value if the groups contain small samples (less than 5 observations per group, or 20 in all groups combined) with asymmetric distributions; instead, a nonparametric test (Kruskal-Wallis ANOVA) should be used. A nonparametric test is also preferred if the groups have unequal variance as determined by an F test. Multiple pairwise *t*-tests cannot substitute for ANOVA; the effect is to greatly increase the odds of a false-positive result (type I statistical error).

Contingency Tables

Description

Contingency tables test for an association between two categorical variables by using the chi-square statistic. A modification, called the McNemar test, can be used for two groups of paired data.

Interpretation

A significant *P* value implies a significant association between the two variables, whose categorical values form the rows and columns of the contingency table. However, even a very small *P* value provides no information about the strength of the association (effect size). Therefore effect size can be measured with the odds ratio (2×2 table) or by Pearson's contingency coefficient (tables with more than two rows or columns). The chi-square statistic compares the observed values for each cell (row-column intersection) with the expected values that would occur if chance alone were operating.

Precautions

As with *t*-tests and ANOVA, small samples can produce an artificially small *P* value. If the *expected* frequency for any cell is less than 5, an alternative test must be used (e.g., Fisher's exact test or the log-likelihood ratio). Beware of authors who over-interpret a "significant" chi-square result. As with ANOVA, when $P < .05$, one claims a *global*

association between variables, but one cannot specify which subgroups of rows and columns are or are not associated.

Survival Analysis

Description

Survival analysis estimates the probability of an event (typically, but not necessarily, survival) based on the total period of observation, and tests for associations with other variables of interest. Survival analysis permits maximum use of data from *censored* observations, which occur when a subject is lost to follow-up, or if the study ends before the outcome of interest has occurred.

Interpretation

There are two main ways of analyzing survival data: the life table method divides the time into intervals and calculates survival at each interval; the Kaplan-Meier method calculates survival each time an event occurs. Both methods produce a graph (survival curve) showing the cumulative probability of the event vs. total period of observation. Authors sometimes eliminate the curve and instead give the event rates only for specific time periods (e.g., 1 year, 3 years, 10 years). When two or more survival curves are compared and the *P* value is low, a probable association exists between time to event and the factor used to stratify the curves.

Precautions

When you see a "survival cure," be sure that it has been calculated using survival analysis (life table or Kaplan-Meier), *not* by simply dividing cumulative events at a given time by the total subjects still around at that time. The latter method mistreats censored observations, yielding artificially low estimates. Nor is it desirable to simply exclude from analysis all subjects not meeting some arbitrary cutoff for observation time; resulting rates may be artificially high. Whereas the life table method requires a minimum sample size of 20 uncensored observations, Kaplan-Meier analysis requires only five uncensored observations for valid results.

Multivariate (Regression) Procedures

Description

Examine the *simultaneous* effect of multiple predictor variables (generally three or more) on an outcome of interest. In contrast, *t*-tests, one-way ANOVA, chi-square, and survival analysis examine the *univariate* effect of variables on an outcome one at a time. Different multivariate procedures are used depending on the measurement scale of the outcome variable (see Table 6-10). The most popular regression methods in general medical journals are multiple linear regression, Cox proportional hazards (for survival data), and multiple logistic regression (for a binary or dichotomous outcome).[40]

Interpretation

Multivariate analysis produces a statistical model that predicts outcomes based on combinations of individual variables. The adequacy of the model as a whole is determined by the coefficient of determination (r^2), which indicates how much variability in the response variable is accounted for by the predictors, and its associated *P* value. Each predictor variable also has an associated coefficient, whose magnitude represents the relative effect of the variable on outcome when adjusted for all the other variables in the model. A positive coefficient implies a positive association; a negative coefficient implies a negative association. When the coefficient's *P* value is small, the association is significant. Predictor variables should also be tested for interaction.

Precautions

Biased results may occur if the data set has outliers, or if variables in the model are highly correlated with each other ($r > .90$). Although a model may precisely fit the investigator's data, there is no guarantee that it will predict outcomes for subjects outside the study with equal precision. As with any statistical test: garbage in, garbage out. No degree of multivariate analysis can adjust for confounding variables that were not recorded at the start of the study.

Nonparametric Tests

Description

Test hypotheses *without* requiring that the data have a normal distribution. The nonparametric equivalents of the *t*-test, paired *t*-test, and one-way ANOVA are the Mann-Whitney U, Wilcoxon signed rank, and Kruskal-Wallis tests, respectively (Tables 6-10 and 6-11).

Interpretation

When an author uses a *parametric* test (e.g., *t*-test or ANOVA), the data must be normally distributed or come from a large enough sample (about 30 or more subjects) to relax this requirement of normality. Nonparametric tests avoid this requirement by ranking the data in each group, and then comparing rank sums instead of the actual values of individual observations. Whereas the parametric tests discussed above make inferences about *means*, nonparametric tests make inferences about *medians*. When there is doubt as to whether a nonparametric test is necessary, the *P* value should be calculated both ways—parametric and nonparametric. If the results differ significantly, the nonparametric test is preferred.

Precautions

Very sparse data sets are not suitable for either parametric or nonparametric analysis; more sophisticated *exact* significance tests must be used. Fisher's exact test is a well-known exact procedure for 2×2 contingency tables. Exact tests for other situations require special computer software.[41]

Common Statistical Deceptions

More than a century ago, Benjamin Disraeli noted, "There are three kinds of lies: lies, damn lies and statistics." Although such consummate skepticism is rarely justified, statistics can undoubtedly be misused—either by intent or through ignorance or carelessness—to produce incorrect conclusions (Table 6-17). Confidence and common sense have been advocated as a means to balance statistical significance with clinical importance.[42]

How does statistical misuse slip by editors, peer reviewers, and journal readers? Because of the "dazzle" phenomenon observed by Darrell Huff, author of *How to Lie with Statistics*: "If you can't prove what you want to prove, demonstrate something else and pretend that they are the same thing. In the daze that follows the collision of statistics with the human mind, hardly anybody will notice the difference."[43] Be particularly wary of the following dazzling phenomena:

Surgical Satisfaction Swindle

A surgeon claims a procedure is "highly effective" because 85% of patients were satisfied with results, 85% would have the surgery again, and 85% would recommend the procedure to family or friends. Unfortunately virtually any survey achieves 80% or higher respondent satisfaction for a given question and only a few patients actually express negative views.[44] Satisfaction surveys are particularly prone to positive-response bias because they often relate more to the interpersonal skills of the surgeon and the setting in which treatment was administered than the actual outcomes achieved. Moreover, without a comparison or control group, one cannot distinguish therapeutic effects from natural history or a placebo response.[7]

Survey results are credible only if the investigators use a previously validated instrument or perform their own validation process.[45,46] This process includes assessing (1) test-retest reliability to ensure response stability and consistent item (question) interpretation, (2) internal consistency to determine whether allegedly similar items tap similar content domains, (3) construct validity to verify that items actually measure what they purport to measure, (4) discriminant validity to show that respondents with different levels of satisfaction or disease have measurably different survey scores, and (5) responsiveness to demonstrate that the change in survey scores before and after intervention is able to detect clinically meaningful levels of change within an individual.

Table 6-17

Statistical Deceptions Used in Journal Articles

Deception	Problem	Solution
Standard error is used instead of standard deviation	Range is artificially low, making data look better than they are	Always use standard deviation when summarizing data
Small sample study results are taken at face value	Results are imprecise and would likely vary if study was repeated; uncertainty is ignored	Determine the range of results consistent with data by using a 95% confidence interval
Post hoc *P* values are used for statistical inference	Statistical tests are valid only when hypotheses are formulated before examining the data	Post hoc *P* values must be viewed as hypothesis-generating, not hypothesis-testing
Some results are "significant" but there are a large number of *P* values	"Significant" results may be false-positives because each *P* value has a 5% error rate*	Reduce the number of *P* values through multivariate analysis or analysis of variance
Subgroups are compared until statistically significant results are found	If you torture the data sufficiently, they will eventually confess to something	Subgroup comparisons are valid only when all groups as a whole are significantly different
No significant difference is found between groups in a small sample study	A significant difference may have been missed because of inadequate sample size	Be wary of study results until the authors discuss power and sample size results
Significant *P* values are crafted through improper use of hypothesis tests	Small studies with asymmetrically distributed data require special methods of analysis	Be wary of results unless a nonparametric or exact statistical test was used

*Assuming that .05 is selected as the level of statistical significance.

Standard Error "Switcheroo"

When you see results reported as "mean value ± X," do not assume that X is the standard deviation (SD) unless specifically stated. Sometimes X is actually the standard error (SE), a number that is *always* smaller than SD. Actually, SD and SE are very different; so understanding why many authors report the latter is difficult, unless they are enamored by the smaller value. When describing a set of data, SD is always preferred, because it measures how variable individual observations are within a sample.[47] If the data have a symmetric distribution, the mean ± 2 SD describes about 95% of observations. In contrast, the SE is an inferential, not a descriptive, statistic; it measures how variable the mean is from one sample to another.

Consider a study of 25 patients undergoing rhinoplasty that reports a mean blood loss of 150 ± 30 mL where 30 is the SD. We now know that 95% of subjects had a blood loss of 150 ± 60 mL (assuming the data are normally distributed). To obtain the SE, divide the SD by the square root of the sample size. In this example, the square root is 5, giving an SE five times smaller than the SD: 6 vs. 30. The mean blood loss now is written as 150 ± 6 mL, where 6 is the SE. Obviously this "looks" better than the SD, but what exactly does it mean? It means "based on our results, if we extrapolate to the general population of rhinoplasty patients, we estimate with 95% confidence that the mean blood loss will be 150 ± 12 mL." This statement no longer describes the study data, but makes an inference about some hypothetical population. Unless the authors clearly state that this is their intent, the SD should have been used.

Small Sample Whitewash

Because medical research is costly and time consuming, it is a luxury to study large samples. Fortunately, meaningful conclusions can be derived from small samples by estimating uncertainty (precision) with a 95% confidence interval. Remember—statistics is the art and science of dealing with uncertain data; the smaller the sample, the greater the uncertainty. Beware when authors claim their sample is too small for statistical analysis; that is when they need it most.

For example, while perusing the *Journal of Low Budget Research* an article on an innovative new surgical procedure captures your attention. The authors operate successfully on four of four elephants (100% success rate) and conclude that "testing in humans is indicated based on these superb results." Do you agree? Actually, the range of results (exact 95% binomial CI) consistent with this single experiment on four elephants is 47% to 100%! Knowing that the population success rate (for elephants, at least) may be as low as 47% you may now disagree with the need for human testing. Conversely, if the investigators succeeded in 40 of 40 elephants, the 95% CI would be 93% to 100%—a much greater level of confidence secondary to the 10-fold increase in sample size.

Here is another way to appreciate the value of confidence limits on small samples. Imagine you are about to cross a very flimsy and tenuous appearing bridge. Your reassuring guide states you have nothing to worry about because the first four travelers crossed it successfully. The statistical basis for your persistent trepidation stems from the fact that four of four successes is consistent with up to a 53% failure rate (as noted in the preceding paragraph)—not a very reassuring statistic to stake your life on!

Post Hoc *P* Values

A fundamental assumption underlying all statistical tests is that the hypothesis under study was fully developed before the data were examined in any way. When hypotheses are formulated *post hoc*—after even the briefest glance at the data—the basis for probability statements is invalidated. Unfortunately, there is no way of knowing at which stage of the research process a hypothesis was developed. Therefore, unless the investigators state specifically that the test was planned a priori, one should infer with caution.

As physician-friendly computer programs for statistical analysis continue to proliferate, more physicians are likely to analyze their own data. Unless the probability framework underlying hypothesis tests is understood and appreciated (habits 3 and 4), the risk of post hoc *P* values will increase dramatically as they become easier to produce.

When the primary research purpose is to test an a priori hypothesis, the *P* value will aid in statistical inference. When hypotheses are generated after the study, however, *P* values cannot be used to make inferences. Instead, they become a means of identifying promising associations that might form the new a priori hypotheses in a follow-up investigation.

Multiple *P* Value Phenomenon

When a journal article or data table is chock full of *P* values, realize that some "significant" *P* values ($P < .05$) are likely to occur by chance alone.[48] Consider, for example, that a researcher performs 20 individual hypothesis tests on a group of observations (e.g., calculates 20 *P* values). If the subjects studied do not differ beyond random variation, there is only a 36% chance that *none* of the *P* values will be significant! Furthermore, the chance of there being one, two, or three significant *P* values is 38%, 19%, and 6%, respectively.

What accounts for the multiple *P* value phenomenon? The problem arises because each test is based on a cutoff of $P < .05$ as a measure of significance; the effect of performing multiple tests is to inflate this 5% error level for the study as a whole. The probability of obtaining at least one spurious result is $1-(1-\text{alpha})^n$ where alpha is the level of significance for each individual test (generally .05) and n is the number of tests performed.

Multiple *P* values can arise when pairwise comparisons are made between several groups of data or when numerous hypothesis tests are applied to a single data set. When several groups are compared, ANOVA overcomes the multiple *P* value problem created by repeated *t*-tests. Furthermore, special multiple comparison tests are available with ANOVA that can search for subgroup differences as long as a global difference exists between groups. When a single data set is being studied, multivariate analysis will eliminate the multiple *P* value problem induced by repeated univariate tests (e.g., *t*-test, chi-square).

Selective Analysis of Results

One should check for selective analysis of the results in every study that compares three or more groups of subjects, including animal research. Authors may pluck out a few groups for pairwise comparisons and then pontificate on the "statistically significant" findings they discover. Unfortunately, this violates a basic tenet of statistics—you *cannot* compare subgroups of data *unless* you first check for statistically significant differences between *all* groups considered simultaneously. For categorical data, a chi-square is first calculated for the entire contingency table; if $P < .05$, the authors can then extract subsets of the table for selective analysis *as long as* they adjust for multiple comparisons. For continuous data, ANOVA should be used (not multiple pairwise *t*-tests) as described previously.

Powerless Equalities

Some authors would like to convince you that a new treatment or diagnostic test is *equivalent* to an established standard. In particular, support for the use of a new antibiotic or antihistamine often arises from a randomized trial claiming no significant difference ($P > .05$) from another drug. When interpreting these results, look not at the *P* value but at the statistical *power*; the size of the *P* value is pertinent only when a statistically significant result is given. Power tells the probability that the investigators would have detected a true difference, given that one really existed. The unique issues involved in equivalence (noninferiority) randomized trials have resulted in specific reporting guidelines to aid interpretation.[49]

Understanding Sample Size

A sample size calculation before beginning a study ensures that the planned number of observations will offer a reasonable chance of obtaining a clear answer at the end.[50] This is of paramount importance in animal studies, in which sample size is limited by financial constraints, concerns over animal welfare, and limited laboratory space.[51] For example, a groundbreaking experiment in 10 giraffes is of little value when a sample size of 20 is needed for adequate power or precision. Similarly, why experiment on 200 chinchillas when only 100 are adequate to test a hypothesis? Such considerations are by no means limited to basic science research. Why devote endless hours to abstracting data from 500 patient charts when only 150 observations would suffice?

Calculating sample size is an essential first step in evaluating or planning a research study.[52] Basic requirements for all sample size calculations include (1) estimates of the smallest difference desired to be detected between the groups, (2) level of confidence that any difference detected is not simply due to chance (typically 95% or 99%), and (3) level of confidence that the difference detected will be as small as what was specified earlier (typically 80% or 90%), assuming that such a difference truly exists. In addition, sample size calculations for numerical data require some estimate of the variability (variance) among observations.

Determining the minimally important difference desired to be detected is based solely on clinical judgment. When comparing categorical data, the difference of interest is between proportions (rate difference, see Table 6-8). For example, one may wish to know if success rates for two drugs differ by at least 20% for otitis media, but a difference of perhaps 5% may be important when treating cancer. In contrast, differences in numerical data are expressed as a difference in means. For example, one may wish to know if a potentially ototoxic drug decreases mean hearing by at least 5 dB or if a new surgical technique decreases blood loss by at least 200 mL.

Outcomes measured on a numerical scale require an estimate of variance to calculate sample size. Because variance is defined as the square of the SD, a method is needed to estimate SD to derive variance. If pilot data are available, some estimate of SD may already exist. Alternatively, one can "guess" the SD by realizing that the mean value ± 2 SD typically encompasses 95% of the observations. In other words, the SD of a set of measurements can be approximated as one fourth of the range of that set of measurements. Suppose you are interested in detecting a 200-mL difference in blood loss between two procedures, and based on your clinical experience you expect that about 95% of the time you will see a difference ranging from 100 and 500 mL. Subtracting 100 from 500 and dividing by 4 gives 100 as an estimate of SD. Squaring the SD yields 10,000, which estimates variance.

The remaining elements of a sample size calculation reflect basic principles of statistical error (habit 4). Recognizing that errors are unavoidable (see Table 6-9), one can specify in advance the levels of tolerance and then calculate a sample size that will accomplish this goal. Tolerating a 5% probability of type I error (false-positive) is the same as being 95% certain that any difference detected is not simply due to chance. Tolerating a 20% probability of a type II error (false-negative) is the same as being 80% certain that a true difference of the magnitude already specified (80% statistical power) is not missed.

The size of the sample needed in a given study increases when the difference of interest is small, the variance of the observations is high (applies to numerical data only, not proportions), and the tolerance for error is low. More subjects are also required to determine whether any difference at all exists between groups (two-tailed statistical test) than if one group fares either better or worse than another (one-tailed statistical test). A two-tailed test is considered more conservative and should always be used unless it was determined a priori—before examining the data—that a one-tailed test was appropriate. A one-tailed test requires about half the sample size as a two-tailed test to show significance and produces *P* values about half as small when applied to the data.

The Importance of Principles

My goal throughout this chapter has been to convince you that effective interpretation of medical data involves much more than statistics or numerical formulae. Rather, it is a systematic process of moving from observations to generalizations with predictable degrees of certainty (and uncertainty). Every physician is involved in this process to some extent, whether a solo practitioner in a rural community or a full-time academician in a large university. Moving from observations to generalizations is the foundation for all scientific progress, a foundation that could not exist without a systematic process for interpreting data.

The seven habits listed in Table 6-1 provide a systematic framework for interpreting data, of which statistical tests are only a small

part. Although habit 4—measure error with the right statistical test—generates P values, it is sandwiched between habits 1 through 3 and habits 5 through 7. *P* values are part of the process, but represent neither the beginning nor the end. We begin by verifying that the data are of sufficient quality and precision to merit statistical analysis (habits 1 through 3). We end by seeking clinically significant findings that can be generalized beyond the study and are consistent with prior knowledge and experience (habits 5 through 7). Obsession with *P* values, which has been called the "religion of statistics," may produce medical publications but rarely achieves effective data interpretation.[53,54]

Every clinician need not be a statistician, but all should understand the fundamental principles of data analysis and interpretation. When understood and applied, the habits in Table 6-1 will permit intelligent, synergistic dialogue between clinicians and statisticians. Such dialogue ideally precedes any serious research endeavor, because even the most elegant statistics cannot adjust for biased data or confounders that were never measured.[55] The statistician excels at analyzing data the right way, but the clinician's leadership ensures that the right data are analyzed. Furthermore, clinical importance (habit 5) is best determined by clinicians, not statisticians.

In conclusion, here are some suggestions for putting principles into practice. Dawson and Trapp[20] provide a delightfully palatable overview of research methodology and biostatistics in *Basic & Clinical Biostatistics*. *Making Sense of Data* by Abramson[56] is a useful self-instruction manual on association, causation, odds ratios, and other rates and measures. The essentials of research design and interpretation are discussed admirably by Troidl and colleagues[57] in *Surgical Research* and by Hulley and colleagues[58] in *Designing Clinical Research*. Finally, those ready to enter the brave new world of evidence-based medicine will find a warm welcome in *Users' Guides to the Medical Literature* by Guyatt and Rennie.[25]

CHAPTER SEVEN

Evidence-Based Performance Measurement

David R. Nielsen

Key Points

- All physicians have a moral and ethical obligation to act professionally as a fiduciary agent for the health of their patients by engaging in quality improvement.
- Physician performance measurement can be used for research, medical error reduction, patient safety, certification, credentialing, or licensing and disciplining. The purpose for which a measure is intended will determine how the measure is created.
- A performance measure is an equation or fraction representing the frequency of an appropriate and recommended intervention. It has a denominator of those who require a recommended intervention, a numerator of those who received the intervention, and defined exclusions or risk adjustments.
- Health services research demonstrating quality gaps and rising health care costs is fueling demand for clinical performance measures.
- Quality can be measured by assessing clinical outcomes, processes of care, capacity and structure, administrative parameters, cost and efficiency, and patient experience.
- Physician measurement should be founded on evidence-based guidelines, relevant and reliable data, and best clinical expertise.
- Physicians should educate themselves about the various perspectives of other stakeholders and their roles in supporting quality care.

Motivation for Physician Performance Measurement

Over the past decade, professional, political, and societal interest in measuring quality in health care has exploded to be the most dominant theme in medicine, integrating clinical care, physician education, research, and health policy. One of the most dramatic changes in the clinical environment is the emphasis on individual physician documentation of quality in daily practice. The striking increase in demand for quality initiatives and measuring the outcomes of health care delivery is motivated by multiple events and conditions. Most prominent among these is the sustained rapid increase in health care costs (at five times the average rate of inflation) and the observation from health services research that, despite spending more per capita than any other nation in the world on health care, the United States lags in many areas of public health and wellness measures.[1-5]

Current economic and market forces incentivize and pay for volume and intensity of service. Yet research shows that higher volume and intensity of health care services do not lead to better aggregated quality of life or public health. Overall, only about half of all Americans receive the recommended health interventions identified by consensus standards of care. And even more striking than the low overall proportion of those receiving recommended care is the wide variation that exists across conditions, races, gender, and financial status.[6-8] Dissatisfaction with the health care system is higher in the United States than in parallel Western nations. Likewise, the percentage of U.S. citizens who did not get health care because of cost constraints is higher than in many other Western nations. There is a huge gap between the consensus recommended appropriate care and the care that is actually delivered for easily identifiable and definable conditions.[3] Large geographic variations in care, unexplainable by patient demographics and characteristics, are easily observable over a broad range of conditions. These geographic variations are far more significant than even the health care disparities seen due to ethnic or health literacy differences in the population.[6-11] Unacceptably high rates of mortality and morbidity related to medical error have been the subject of many reports from federal agencies and independent health services researchers.[2,6,12] And finally, there does not seem to be any correlation between per capita costs of health care and quality of health care delivered on a range of observations and bases.[10]

What Is Quality and Who Defines It?

As quality improvement and physician performance have taken center stage, the question arises as to who will define quality and its measurement. Each stakeholder has a reasonable perspective for viewing quality differently, including the patient and the physician.[1,3] A patient might define quality as the relief of a symptom, the perception of a cure, or an improvement in lifestyle. However, the physician might define quality as the achievement of a particular desired or expected medical or surgical outcome. An employer may see quality as a return on investment for premiums paid, reduced liability for injury, and a workforce that is healthy, productive, and present in the workplace. A health plan purchaser may look at global health outcomes and the need to spread vast resources over large populations with competing

needs. Therefore defining quality and deciding exactly what to measure to determine whether quality is being delivered continues to be debated.

In oversimplified terms, most measures of clinical quality or performance today fall into the following categories:

- Outcomes measures
- Process measures
- Capacity and structure measures
- Administrative measures
- Cost and efficiency measures
- Patient experience or satisfaction measures

Argument continues over choosing what to measure. Purchasers of health care have access to voluminous claims and economic data, making administrative, cost effectiveness, and capacity measures attractive.[13,14] Although many physicians opposed to administrative or efficiency measures clamor for outcomes measures as the only valid assessment of physician performance, in truth, physicians rarely have complete control over all the factors that determine medical outcomes. Additionally, for valid outcome measures, effective risk adjustment needs to occur to reflect differences in the case mix of the patients served; this is often neglected, which results in misleading outcome data. Process measures are easier to define and are more attributable to the practitioner. However, focusing primarily on processes of care can be deceptive when no one takes responsibility for the final outcome. Levels of evidence for different types of interventions can vary greatly, especially when comparing chronic medical care that may involve primarily medication management to acute surgical care for which randomized, double-blind, controlled studies may not exist or even be feasible. Because elements such as availability of support services and tertiary care, patient compliance, comorbidities, ethnic and religious practices, and preferences can all influence the assessment of any medical outcomes, measuring performance attributable to and under the control of the physicians being measured must be a common basic theme if fairness and true patient-centered quality improvement are to be achieved.[13,15]

The purpose for which measures are developed has a powerful influence on how those measures look and what kinds of measures are employed. Among other reasons, performance is measured today for the following overlapping purposes:

- Researching, developing, and improving the effectiveness of an intervention
- Reducing medical error
- Improving patient safety
- Certifying achievement—meeting standards for maintaining board certification or privileges
- Credentialing or accreditation—documenting competence or proficiency for payment or inclusion in a plan, group, or tier
- Licensing and disciplining—identifying, limiting, and punishing poor performance

There is both overlap and synergy between these categories, as well as distinct subcategories further separating these types of measures. The AMA House of Delegates recently addressed criteria and standards for acceptable elements of any pay-for-performance system. As the quality movement matures and value-based purchasing takes different forms, such criteria will become increasingly important to ensure patient-centeredness.

The Process of Building a Coherent System of Performance Measurement

There are three basic principles that must underscore the role of physicians and their organizations in addressing performance and quality improvement.

- First, it is essential that *practicing physicians*, not just methodologists and health policy scientists, actively and formally engage in prioritizing, developing, field testing, and implementing quality initiatives and performance measures.
- Second, demand for quality and its definition and measurement must be aggregated.
- Third, physicians and their organizations must be unified in their response to this demand.

Engaging in Performance Measures Development

As can be seen from even a cursory scan of the practice environment during the first part of the twenty-first century, every stakeholder group is placing powerful impetus behind defining quality improvement and implementing measurement primarily motivated by the desire to improve efficiency in utilization of resources, reduce medical error, advance patient safety, address inequity and maldistribution of health care, and control a national and global crisis of escalating health care costs.[1,14,16] As described in more detail later, failure of physicians to engage and ensure that any definition of quality or program for improvement is truly based on scientific evidence and is relevant and valid to improving patient health outcomes will allow proprietary measurement to focus solely on administration, capacity, and cost. Although these are legitimate concerns, physicians must insist on keeping the focus on improving the patient's health, not on driving profitability for purchasers of health care.[17]

Aggregating Demand for Performance Measurement

With so many organizations involved in quality initiatives and the development of measures, one of the largest concerns that physicians have is trying to "aggregate the demand" for measures—in other words, to make sure that payers, purchasers, licensing and certification processes, and quality improvement organizations are all asking for the same measures, that the measures are based on solid evidence, and that they are focused on similar quality improvement goals. Imagine an environment in which each independent insurance carrier, every major employer who pays premiums for employee health care benefits, government purchasers such as Medicare or state Medicaid contractors, state licensing boards, and specialty certifying boards all developed and required a physician to gather and report data on quality through a separate mechanism and with differing goals and purposes. The administrative quagmire would be a nightmare and virtually impossible to navigate, even for large clinics and groups with sophisticated electronic medical record systems and resources. The ideal situation would be to standardize data points, create a single or simplified set of measures for a given clinical condition or intervention, and establish agreement among stakeholders to accept a unified process of measuring quality.

Unifying the Response to the Demand for Performance Measurement

The medical profession is not homogeneous. Specialists of varying backgrounds, training, and experience may treat similar conditions and bring diverse perspectives to their delivery of health care services. Undesired variation in health care and its outcomes is one of the hallmarks of poor quality.[3,7,12] It is not in the patient's or society's best interest to have varying processes and quality measures for a given clinical condition coming from competing specialties or groups. For example, pediatricians, family physicians, otolaryngologists, emergency physicians, and infectious disease specialists could all develop and implement competing guidelines and performance measures for treating otitis media based on limited perspective and with varying data points and recommendations. This fosters unhealthy competition and turf battles, and

is unlikely to improve quality care. By engaging in multidisciplinary work groups, definitions can be standardized, best evidence can be reviewed and analyzed, scope and purpose of measurement can be agreed upon, learning can take place, and acceptable guidelines and measures can be developed that all physicians who treat otitis media, regardless of specialty perspective, can use to improve their clinical care. Creating evidence-based guidelines and performance measures is labor intensive and costly. By collaborating in a multidisciplinary fashion, waste of resources from competing and parallel development processes can be avoided.

In designing a validated, relevant, and attributable system of measurement, the following process is useful and involves the best combination of rigor and scientific foundation with practical implementation at the physician-patient level.

- Identify and prioritize areas that can be measured and improved
- Develop or identify the best evidence or guidelines for clinical care
- Develop specific performance measures that are physician attributable, implementable, effective, practical, and affordable (See Institute of Medicine domains for quality care: effective, efficient, equitable, timely, safe, patient-centered).[12]
- Use validated, relevant, patient-oriented performance measures in systems and populations for credentialing, licensing, certifying, and documenting competence.[18,19]

Quality-Based or Value-Based Purchasing

Currently there is a sea change in the manner in which physician services are recognized, reported, and remunerated. The traditional system of paying for volume and intensity of care is being replaced by quality-based or value-based purchasing of health care services.[14] In this discussion, the popular term "pay for performance" is not used. *Performance* can apply to any required activity, regardless of whether it leads to better quality or health outcomes. Focus should remain on delivering high-quality patient care, not on some arbitrarily contractually required performance. The term "pay for performance" currently is highly politicized and is not well defined; it routinely means widely different things to different people. It will likely be replaced in a few years with other descriptors, but the underlying concept of recognizing and rewarding excellence (quality-based purchasing) is likely to be a longstanding foundation for future models of paying for health care.

The concept of rewarding excellence is based not only on the desire for improved quality, but also on the premise that poor quality care is more expensive than high quality care.[7,10,20,21] Although certainly debatable, there is evidence to support this contention in specific areas. Intuitively, healthy populations consume fewer health care interventions and cost less than sick ones. So improving public health, encouraging healthier lifestyles, and employing effective preventive medical interventions all make sense. Schematically, many discussions have linked the issue of quality to cost by relegating poor quality medical care into three categories:

- Too little care
- Too much care
- The wrong kind of care

It is clear that if poor quality in medical outcomes is the result of unneeded care, then reducing the overuse of services and improving quality would reduce health care costs. It is also not hard to believe that if the wrong kind of care is replaced by the most effective care, then costs could also be reduced. It is less obvious that correcting the problem of too little care or providing more timely care would also reduce costs. But global statistics from developed nations with better public health, preventive health, and healthy behavior or lifestyle systems that have demonstrably superior public health outcomes (e.g., infant mortality, longevity, chronic disease management) when compared with the United States at a much lower per capita cost are suggestive.[22,23]

As a result of this premise, purchasers of health care are implementing strategies that reward better medical outcomes and improved effectiveness and efficiency of care. The forces behind these strategies include the dramatic increases of health care costs in the United States at a rate more than five times the annual inflation rate, evidence that higher intensity and volume of services do not lead to better outcomes, and the increasing development and acceptance of standards for organizing and implementing quality initiatives.[4]

Medical Professionalism—The Physician-Patient Relationship

At the core of physician performance measurement is the ethical and moral obligation of all physicians to practice according to the highest standards. This is true globally, and the issues and discussions of evidence-based practice, quality improvement, and physician performance measurement are universal. The difference between a "profession" and a "trade" has often been defined by the fiduciary responsibility of the professional to act in the best interest of the public or the receiver of the service, rather than in the personal self-interest of the provider.[17,24,25] In medicine, in addition to legal requirements, virtually every association or physician group has an ethical code or stated commitment to act in the best interest of the patient.[26]

Medical professionalism is defined as a set of values, behaviors, and relationships responsible for public trust in physicians.[25] In the absence of sustained physician leadership in addressing quality, this trust is in serious danger of erosion. Many decry the commercialization of health care over the last century as a repudiation of the tradition of "doing good" in exchange for "making a profit." The ancient tradition of the covenant between the physician and patient has become a contract between physician and intermediary, creating a split loyalty to both the patient and the organization that contracts on behalf of the patient whose motive is cost containment and profit for shareholders.[17] As a result of the observation of this decline, a statement of medical professionalism has recently been developed jointly by The American College of Physicians–American Society of Internal Medicine Foundation, the American Board of Internal Medicine, and the European Federation of Internal Medicine that has been endorsed by many major physician associations in the United States, including the American Academy of Otolaryngology–Head and Neck Surgery (AAOHNS).[27]

The ethical basis of medical care is called into question as a result of the recent well-documented health services research focused on irrefutable data that undesirable variations in physician practice and in clinical outcomes are not explained by patient factors, but are due to failure of medical practitioners and systems of care that do not incorporate the latest and best evidence or practices in health care delivery. This has stirred extensive political, public, and private debate. Because health care delivery in most parts of the Western world is still highly individual, reliance on individual physician judgment remains dominant. Unequivocal data show unwarranted and unexplained variations from recommended care on a regular basis across all disciplines.[3,4,7] Physician judgment is being challenged as population and systems studies suggest that patients are being harmed because best practices are not being observed. Personal physician accountability is an increasing focus.[3,28] Because the practice of medicine is so individualized and often unpredictable, and because a past tradition of unchallenged reliance on physician judgment exists, doctors are vulnerable to the charge that their decisions are not transparent, nor are they accountable for the global results of all they do. By combining the best available evidence for treating a condition with the physician's judgment and patient preferences, more optimal care can be achieved.[4,25,29,30]

Professionalism and the ethical and moral imperative for physicians to put their patients first should be *the* major driving force for physician performance measurement. This needs to be done in conjunction with the creation and application of systems and processes to eliminate the opportunity for error, identify error before it impacts patients, mitigate the effects of error, and thus improve patient safety and outcomes.[20,21] Physicians will need to work in concert with

all elements of health care delivery systems to accomplish this. Employers, governments, and other purchasers, contractors, administrators, and managers of health care have a reciprocal duty to help create the organizational capacity and infrastructure to support physicians in providing optimal care and fulfilling their ethical obligation to the patient. Optimal health care implies both organizational and clinical excellence. In order for a physician to maintain professionalism in our current environment, there must be a shared commitment and collaboration with the patient, fellow professionals, and the institution or system within which health care is provided, but only to the extent that all elements of the system support patients' interests first.[13,15,25,31-33]

Stakeholder Roles in Defining and Implementing Quality Improvement and Measurement Activity

To understand the landscape of physician performance measurement, one must first identify and understand the roles of key stakeholders in the public health care arena, as well as their confluent and sometimes competing perspectives. Current demand for measuring physician performance is driven by patients and public interest groups, as well as by physicians and their associations. In addition to physicians and their patients, many other groups have a legitimate and often powerful stake in measuring outcomes and performance. These stakeholders include physician educators and academic institutions, certifying boards and bodies, agencies whose missions revolve around quality, public and private purchasers of health care services (e.g., federal and state governments, employers, and private insurers), hospitals and health care systems, outpatient clinics and free-standing procedural centers, public interest groups, and many group collaboratives and agencies of all of these. Table 7-1 outlines some of the major stakeholder groups and participants in defining and advancing quality in health care delivery.[31,34]

Interface between Physician Education and Performance Measurement

Historically, practicing physicians have augmented their skills and education by engaging in continuing medical education (CME). There is currently tremendous interest in how medical education processes can be improved to advance quality in health care and institute behaviors early in training and careers that will serve physicians and their patients throughout a professional lifetime.[35,36] The most valued and acceptable form of ongoing postresidency education has been formalized by standards developed and monitored by the Accreditation Council for Continuing Medical Education (ACCME). The ACCME is made up of seven member organizations: the American Board of Medical Specialties, the American Hospital Association, the American Medical Association, the Association for Hospital Medical Education, the Association of American Medical Colleges, the Council of Medical Specialty Societies, and the Federation of State Medical Boards. Examples of the types of organizations that are evaluated and accredited by ACCME include hospitals, universities, medical associations, and proprietary medical education providers.

ACCME assists its accredited providers and shares their goal to ensure that physician education is relevant, valid, and free from bias or commercial influence in order to maintain the focus on professionalism and patient-centered care. The ACCME accomplishes this by establishing and promoting standards for physician education, by accrediting organizations that provide educational activities for physicians, and by monitoring and ensuring compliance. The issues related to quality and physician performance measurement are linked more tightly than ever before to the activities surrounding medical education, the care of patients, and the health policy and political activity related to our economy.

Traditional methods of physician CME have been mostly didactic, with minimal emphasis on other multifaceted activities, interactive media, hands-on learning, and demonstrations. Physicians have also been charged with assessing their own performance, learning, and application of new material. However, until now there has been no effective method to ensure that what is being learned is actually changing physician behavior for the better or improving patient outcomes. In fact, studies have shown that physicians are poor assessors of their own knowledge and competence. Health policy and clinical research have suggested that traditional CME has little impact on improving health outcomes or changing performance. Such research also suggests a significant difference in improving physician practice when active interventions such as reminders, patient-mediated interventions, outreach visits, and audits of performance are used with a focus on measuring outcomes.[37-39]

As a result of this evidence, the ACCME is continually expanding its requirements for accreditation of CME providers to include documentation that what is being learned will actually change behavior and lead to physician implementation and performance improvement. How that is to be measured and reported is an ongoing challenge.

Board Certification and Maintenance of Certification (MOC)

Throughout most of the twentieth century, specialty certifying boards have focused on the mission of being a public trust—ensuring that those qualifying as diplomates of the certification process meet a rigorous standard of education, knowledge, and professional standing. The American Board of Medical Specialties (ABMS) is the oversight body whose member organizations are the individual independent specialty

Table 7-1

Box 7-1

The Mission of the American Board of Otolaryngology

The mission of the American Board of Otolaryngology (ABOto) is to assure that, at the time of certification and recertification, diplomates certified by the ABOto have met the ABOto's professional standards of training and knowledge in otolaryngology–head and neck surgery.

The American Board of Otolaryngology (www.aboto.org) was founded in 1924 and is the second oldest of the 24 member boards of the ABMS.

For a more complete review of board certification in otolaryngology–head and neck surgery, refer to *Booklet of Information* published by ABOto at www.aboto.org/BOI.htm.

certifying boards representing most of allopathic medicine (including otolaryngology). See Box 7-1. Within the ABMS there are 24 member boards representing the major practice specialty areas. There are also subspecialty certifications sponsored by one or more of the 24 major boards.

Specialty certifying boards have made it clear that they do not define, measure, or certify proficiency, competence, or performance, but rather a high standard of preparation, education, and knowledge. Following an era in the nineteenth and early twentieth centuries in which quackery, charlatanism, and undocumented claims of education and background were common, certifying boards were a major step forward. Having raised the bar significantly and successfully promoted standardized medical education and strong oversight in training and professionalism, the boards had not significantly altered their approach to certification in decades until recently. With the rapid expansion and application of biotechnology, major advances in basic and clinical science, and the identification of new disease processes and management techniques, it has become increasingly apparent that traditional board certification, without any attention to performance in practice, could become irrelevant shortly after a physician becomes certified. With the expanding emphasis on improving the quality of health care over the last decade, the public, purchasers of health care, physicians and even the licensing boards themselves began to question the value of the previous traditional method of board certification alone as evidence of competence or quality in practice. As the quality movement has gained momentum, so has the desire for certifying boards to find a method to enable the ongoing competence of their diplomates and require evidence that they maintain the standard that certification has always implied.

In the 1980s, the first ABMS specialty boards began to issue time-limited certificates. This prohibited a physician who did not recertify from using ABMS "board certification" as a credential beyond a defined period of time. Today, all ABMS board certificates are time-limited and none currently being issued are valid beyond 10 years.

There is a critical distinction between specialty certifying boards and the professional specialty societies that represent physicians. The certifying boards are independent from, and are not governed by or responsible to, physician associations. The missions of the certifying boards are to serve as a public trust, to promote standards of quality, and do not represent physician interests, except those interests that support patients and public health. Furthermore, there are many other certifying bodies outside of the ABMS. There also exists a framework of osteopathic certifying boards—The Bureau of Osteopathic Specialists, an agency of the American Osteopathic Association. Each of 18 osteopathic specialty boards offers certification of a specialty area, including osteopathic ophthalmology and otolaryngology–head and neck surgery (www.do-online.org).

The ABMS has six core competencies (formed in conjunction with the Accreditation Council on Graduate Medical Education, or ACGME) on which all member boards focus to ensure their diplomates possess a high standard of professionalism and training when first certified (Box 7-2). In 2000, in response to the demand for improved quality measures over the certificate holder's lifetime of practice, the ABMS through a vote of its member boards established standard criteria for Maintenance of Certification (MOC) with common elements that each member board would be expected to require of its diplomates (Box 7-3). The four required areas are Part I: professional standing; Part II: evidence of life-long learning and self-assessment; Part III: cognitive expertise; and Part IV: practice performance assessment. Although boards have Part IV processes in place, most are still working to determine how best to demonstrate evidence of practice quality and performance, and all boards are looking for ways to improve this criterion. This provides another strong motivation for physicians to be engaged in quality improvement and performance measurement activity: to qualify for board certification—a longstanding and respected element of a physician's credentials.

Box 7-2

ACGME/ABMS Six Core Competencies

All ABMS member boards are required to ensure that their diplomates qualify in the following competencies:

The six core competencies of all ABMS certifying boards:

1. Patient Care: Provide care that is compassionate, appropriate, and effective for the treatment of health problems and promotes health.
2. Medical Knowledge: Demonstrate knowledge about established and evolving biomedical, clinical, and cognate sciences and their application in patient care.
3. Interpersonal and Communication Skills: Demonstrate skills that result in effective information exchange and teaming with patients, their families, and professional associates (e.g., fostering a therapeutic relationship that is ethically sound, using effective listening skills with nonverbal and verbal communication, working as both a team member and at times as a leader).
4. Professionalism: Demonstrate a commitment to carrying out professional responsibilities, adherence to ethical principles, and sensitivity to diverse patient populations.
5. Systems-Based Practice: Demonstrate awareness of and responsibility to larger context and systems of health care. Call on system resources to provide optimal care (e.g., coordinating care across sites or serving as the primary case manager when care involves multiple specialties, professions, or sites).
6. Practice-Based Learning and Improvement: Investigate and evaluate patient care practices, appraise and assimilate scientific evidence, and improve practice of medicine.

ABMS, American Board of Medical Specialties; *ACGME,* Accreditation Council on Graduate Medical Education.

State Medical Boards and Maintenance of Licensure

The legal permission to practice medicine in the United States is granted by state licensure. Each state has its own professional practice act that defines the practice of medicine and establishes a medical board charged with licensing qualified physicians and prescribes the manner in which physicians will be scrutinized to ensure the public will be protected and well served by each licensee. State medical boards and their requirements are fairly standardized and uniform in most respects, and states support each other in weeding out the incompetent and unprofessional.

The Federation of State Medical Boards (FSMB) is a membership organization whose constituents are independent state licensing boards

Box 7-3

Maintenance of Certification Requirements

Whereas the American Board of Medical Specialties (ABMS) guides the Maintenance of Certification (MOC) process, the 24 member boards of the ABMS set the criteria and curriculum for each specialty. All certificates issued by the American Board of Otolaryngology (ABOto) since 2002 are time-limited for 10 years. To maintain ABOto certification, all diplomates with time-limited certificates must participate in MOC, which includes these requirements.

A Four-part Process for Continuous Learning

Part I—Professional Standing

- Possess an unrestricted license in all states in which the diplomate practices
- Maintain hospital or ambulatory surgical center privileges (if diplomate does not have privileges, he or she must attest that the lack of privileges is not due to an adverse action)

Part II—Lifelong Learning and Self-Assessment

- Obtain sufficient CME credits to meet the individual's state CME requirements (15 credits minimum)
- Participate in the ABOto self-assessment program, which includes on-line clinical management modules

Part III—Cognitive Expertise

- Since many otolaryngologists tend to focus on a limited area of practice, the examination consists of two modules:
  - Fundamentals module for all otolaryngologists, which covers material all otolaryngologists should know such as patient safety, antibiotics, anesthetics, and pain management
  - Specialty specific module; diplomates select one module:
    - Allergy
    - General
    - Head and neck
    - Laryngology
    - Otology/audiology
    - Pediatric otolaryngology
    - Plastic and reconstructive
    - Rhinology
    - Sleep medicine and neuro-otology for subcertification in these areas

Part IV—Practice Performance Assessment

- The plan is to initially have participants complete an online chart survey and receive feedback on how their outcomes compare with that of their peers
- Ultimately, the ABOto hopes to obtain outcomes data from other sources

See http://www.aboto.org/BOI.htm for more information.

and their appointed leadership. Traditionally, initial licensure requires the young physician to engage in rigorous examination and scrutiny before being allowed to practice. For a variety of reasons, most state medical boards devote little time and energy in prospectively ensuring continuing competence of licensed physicians thereafter. With the exception of requiring a physician to demonstrate CME credits, there is no method for licensing boards to measure competence or performance other than reviewing complaints or accusations of malfeasance. After initial licensure, according to an FSMB draft report, "In virtually all states, it is possible for a physician to practice medicine for a lifetime without having to demonstrate to the state medical board that he or she has maintained an acceptable level of continuing qualifications or competence." The report goes on to say, "State medical boards recognize that such practices are no longer acceptable … State medical boards have historically functioned in a policing capacity, responding to complaints and devoting their resources to removing from practice the 'bad apples.' In order to meet increased public demands for greater accountability, state medical boards will need to broaden their responsibilities to include facilitating the continued competence of all licensees."[40]

In 2003, the FSMB established a special committee to study the role of independent state medical boards in ensuring the continued competence of licensees and to develop recommendations for implementation. The Special Committee on Maintenance of Licensure (MOL) responded by developing a position statement addressing the responsibility of state medical boards and suggested strategies for implementing programs to achieve that goal.

In 2004, the FSMB House of Delegates adopted a policy recommendation stating that state medical boards have a responsibility to the public to ensure the continuing competence of physicians seeking relicensure. In a subsequent report the following year, the FSMB stated that collaboration with other stakeholders interested in physician performance and competence would be essential and that state licensing boards should set the standards for relicensure and rely on other parties to develop the tools, resources, programs, and processes that would help physicians achieve those standards for ongoing competence. In its next report, released in 2008, FSMB addressed the current environmental trends that will support a climate conducive to state boards' efforts in maintenance of licensure, guidelines for reentry into practice, and ways in which FSMB can assist state boards in implementing standards for MOL.[40]

The Institute of Medicine

As managed care grew exponentially during the 1990s, autonomous physician judgment became less dominant, and medical necessity and utilization were scrutinized more closely, it became apparent that traditional accountability for quality was being shared in new ways. Few organizations have had as powerful an influence on the climate of quality improvement and measuring physician performance as the Institute of Medicine (IOM). Among the many white papers, studies, and reports it has produced, the statements on accountability, "To Err is Human," and "Crossing the Quality Chasm," have continuing impact on galvanizing stakeholders to address quality. One of the most basic standards is the statement including the IOM's six defined characteristics of acceptable care against which all performance must be measured. The IOM states that quality health care must be:

- Safe
- Patient-centered
- Timely
- Efficient
- Effective
- Equitable

An earlier IOM conference report on how accountability for quality and performance should be divided among relevant stakeholders is a landmark concept whose principles are still being used today.[41] The domains of professional accountability, market accountability, and regulatory accountability are identified and their relationships and scope described. This report clearly recognizes that historically, quality and performance have not been major features in health care contracts. A brief summary of the descriptors follows:

1. Professional accountability: "Fiduciary relationships in medicine are an essential part of any quality accountability mechanism, and it will be important to maintain the strength of the professional model in the changing health care system."

2. Market accountability: "[C]onsumers will select options based on perceived value to them and will make new choices based on their information and experience. Market accountability requires choice … and information to inform choice. In health care, however, individuals rarely have the information they need and often do not have choice."

3. Regulatory accountability: Because of a "perception of defects in a market-based health care system … there is a need for a regulatory structure to correct market failures. The use of regulation to impose accountability for quality requires that a regulatory framework, penalties for violations, and effective enforcement mechanisms are all established."

The powerful conclusion drawn a decade ago still holds true today as performance measurement is both imposed upon and shared by physicians: "[T]he medical profession … must be accountable to society for providing leadership in the development of knowledge about effective medical care, in defining high-quality care, and in advocating for and improving the quality of care."[34] More about other stakeholder perspectives is discussed later.

The Anatomy of Performance Measures

If physicians are to retain their traditional leadership role in caring for patients, they and their organizations must take a leadership role in defining and measuring quality and performance in their professional behavior. Specialty societies, representing the content and practice experts, must insist that performance measures be relevant, patient-centered, focused on medical and health outcomes, validated, practical, affordable, and attributable to those whose performance is being measured. Performance measures should be based on the best available evidence, such as high-quality clinical guidelines that systematically inform and assist physicians and their patients in decision making about appropriate care.[30] Developers of performance measures, including medical specialty societies, academicians, methodologists, and systems experts, must have a process in place with agreed-upon standards for reviewing and evaluating clinical evidence and creating guidelines for treating relevant conditions. With this in mind, the American Academy of Otolaryngology–Head and Neck Surgery convenes a Guidelines Development Task Force with representatives from all national otolaryngology societies and ABOto to identify, prioritize, and plan the development of guidelines based on the best clinical evidence to serve as the foundation for performance measures. To ensure rigor in this process, a guidelines development manual has been published with input from multiple disciplines, which is used by each topic-specific task force.[42] Representation from all relevant specialties on each guideline is sought to ensure that guidelines are broadly acceptable and to prevent specialty bias.

A clinical performance measure can be most simply viewed as an equation or fraction representing the frequency of an appropriate and recommended intervention. It contains a denominator—the number of patients for whom a given intervention or recommendation applies; a numerator—the number of patients who actually received the recommended intervention; and exclusions—those patients for whom the recommended care was not given for specific reasons identified and excluded by the measure (Fig. 7-1). Although simple in concept, in reality the development and implementation of a performance measure can be extremely complicated and controversial. The process of translating guidelines into performance measures involves reviewing the action statements inherent or explicitly recommended in the guideline, defining the patient populations to whom the actions do and do not apply, developing a logical scheme for collecting information to measure how often the actions recommended in the guideline are carried out, and creating the tools for physicians to efficiently and accurately collect that information affordably and with little disruption of their clinical activity. In order to achieve high quality, standardization, unity, and collaboration, closely related specialty societies agree to work together within the framework of the AMA's Physician Consortium for Performance Improvement (PCPI, also called the Consortium). This allows multiple societies with common areas of interest to work collegially, coordinate care, create measurement that can easily cross specialty boundaries, and unify physician response to the multifaceted demand for measures.

The Consortium is comprised of more than 100 national medical specialty and state medical societies, as well as methodologic experts and other stakeholders in measures development. They select topics for developing measures that are attributable to physicians, that can be implemented, for which established clinical recommendations (often guidelines) are available, and for which feasible data sources exist. They then recruit multidisciplinary work groups from all of the specialties relevant to a measure set. The Consortium work groups review the levels of evidence provided in clinical practice guidelines that demonstrate potential positive impact on health outcomes and propose feasible measures for inclusion in a physician performance measurement set. The Consortium then assists in developing and assessing tools for collecting the data required for measurement in practice, using either centralized or distributed, paper or electronic methods.

Other Stakeholder Perspectives

Virtually every stakeholder group is heavily involved in quality initiatives and performance measures development. In this section a representative sample of additional major agencies and organizations is briefly introduced. Because of the varying perspectives and backgrounds of these stakeholders, an extensive collection of collaborations and consortia has emerged to promote quality across stakeholder groups, to align incentives and goals, and to combine resources. This has created a dizzying array of potential activity with which physicians might be required to engage. Table 7-2 summarizes some of the related acronyms and terms. A few of them are briefly discussed here.

The Agency for Healthcare Research and Quality (AHRQ) is charged by the federal government to serve as the health services research arm, just as the National Institutes of Health (NIH) serves as the basic and clinical research arm. In addition to fostering research into quality, performance measurement, technology assessment, preventive medical care, delivery systems, and health care costs, AHRQ is a major source of funding for academic and community-based organizations engaged in health services research and implementation activity. AHRQ supports evidence-based clinical practice, develops and tests measures, and promotes the use of measures through dissemination of guidelines and measures. AHRQ also provides support for many of the quality improvement initiatives undertaken by the Centers for Medicare and Medicaid Services (CMS).

The National Committee for Quality Assurance (NCQA) is a private nonprofit quality organization that has been accrediting health plans and developing performance measures since 1990. Their goal is simple—measure, analyze, improve, repeat. Organizations that qualify for the NCQA seal must first pass rigorous review, report annually on a set of measures, and deliver high-quality care and service. The performance measurement set used in NCQA's accreditation process and most frequently reported to purchasers and the public are HEDIS (Health Plan Employer Data and Information Set) measures and CAHPS (Consumer Assessment of Health Providers and Services) surveys of patient experiences of care. CAHPS was developed by AHRQ and has survey instruments that apply not only to patient experiences with health plans but also with individual physicians and clinician group practices.

The Joint Commission (formerly the Joint Commission on Accreditation of Healthcare Organizations, or JCAHO) creates standards and measures performance for hospitals, freestanding ambulatory care centers, office-based surgery, long-term care facilities, and others. Its mission is to continuously improve the safety and quality of care provided to the public through the provision of health care accreditation and related services that support performance improvement in health care organizations. Its standards cover structural characteristics and processes of care and include standards that measure the degree to

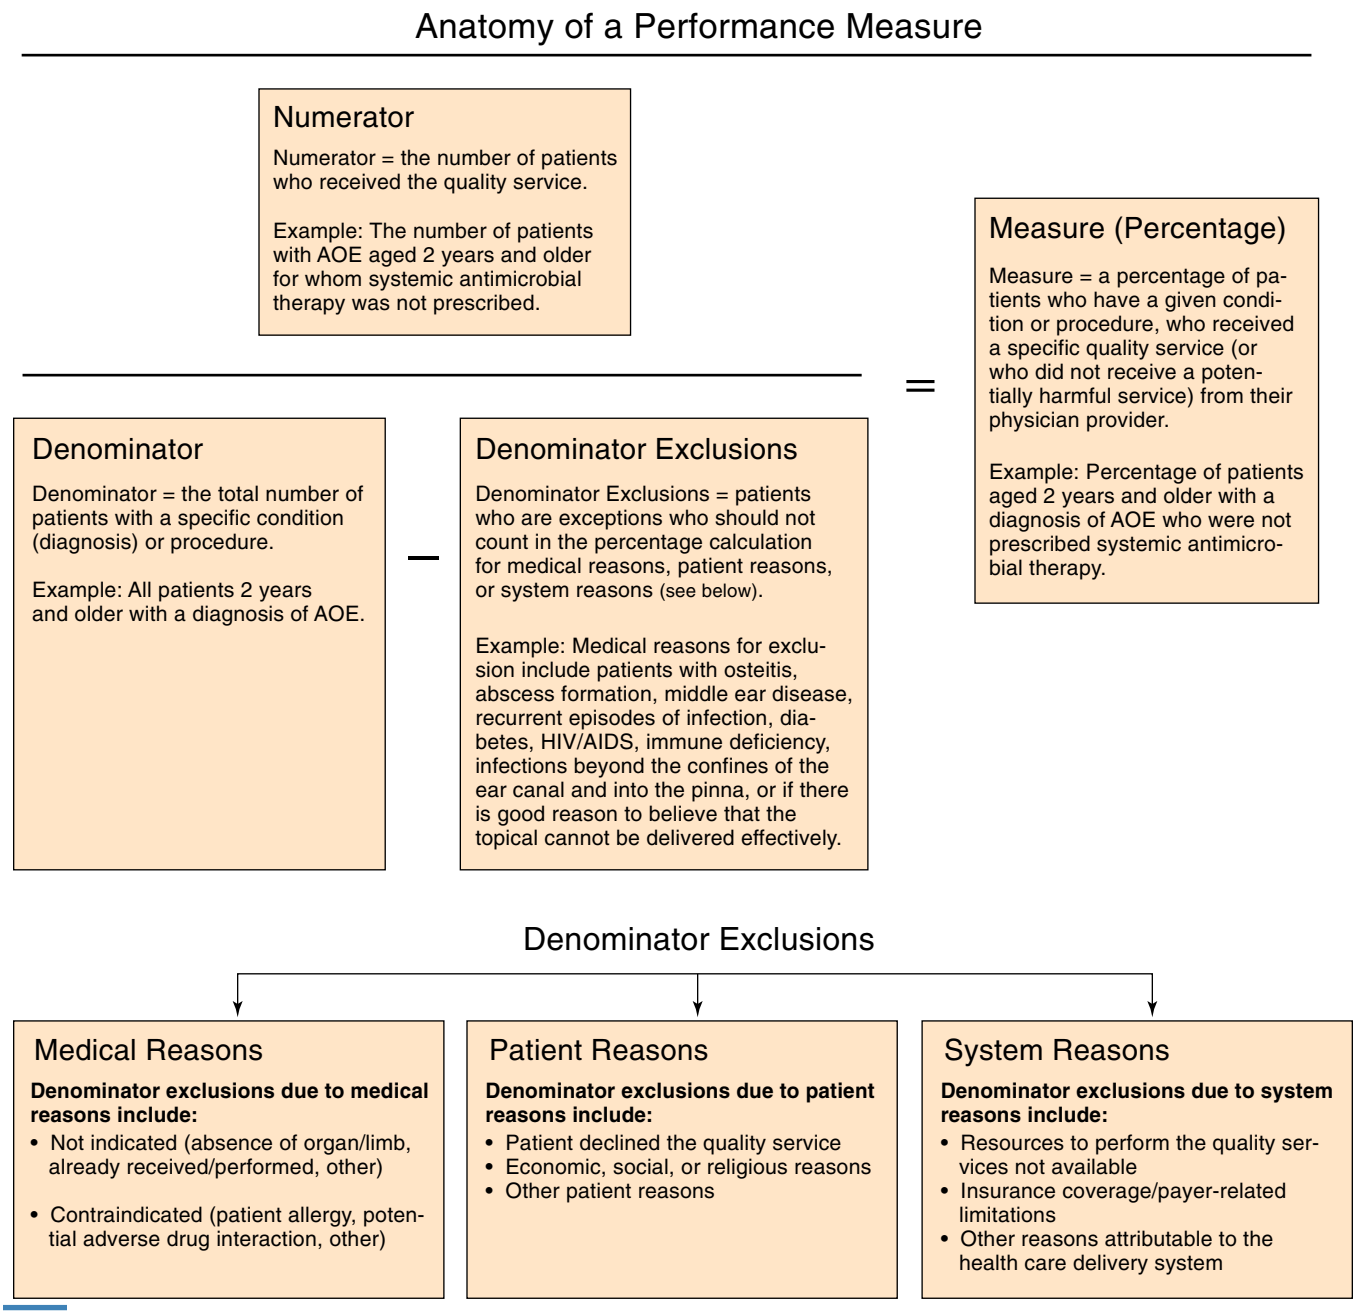

Figure 7-1. Anatomy of a performance measure. Both the schematic and a current example of an existing measure of quality in treating acute otitis externa (AOE) are applied for illustration. One of the measures of improved quality in treating acute otitis externa is the avoidance of unnecessarily administering systemic antibiotics. Compliance with this measure of quality is demonstrated in the formula. *(With permission of the American Academy of Otolaryngology–Head and Neck Surgery Foundation.)*

which facilities conform to guidelines for promoting a set of National Patient Safety Goals.

The Physician Consortium for Performance Improvement (PCPI, or the Consortium) is composed of representatives of more than 100 specialty societies and methodologic experts in measures development. They select topics for performance measures development that are actionable, for which established clinical recommendations are available, and for which feasible data sources exist. They then recruit cross-specialty work groups from all of the specialties relevant to a measures set. The Consortium work groups review the levels of evidence provided in clinical practice guidelines that demonstrate potential positive impact on health outcomes and propose feasible measures for inclusion in a physician performance measurement set. The Consortium then develops and tests tools for collecting the data required for measurement in practices with both paper and electronic records systems.

The organizations that are (and should be) most actively engaged in the development of performance measures are the physicians, usually through their medical specialty societies. Performance measures should be based on high-quality clinical guidelines that systematically develop and assist practitioners and patients in decision making about appropriate care. Each medical specialty society has a process in place for reviewing and evaluating clinical evidence and creating guidelines for treating conditions relevant to that specialty society.

The process of translating guidelines into performance measures involves reviewing the action statements inherent in the guideline, defining the patient populations to whom the actions do and do not apply, developing a logical scheme for collecting information to measure

Table 7-2

Glossary of Terms and Acronyms of Groups Engaged in Defining, Measuring, or Reporting on Quality in Health Care

Acronym or Abbreviation	Title of Group and Description
AAMC	The Association of American Medical Colleges (AAMC) is a nonprofit organization established in 1876. AAMC is the principal administrator of the Medical College Admission Test (MCAT) and is involved in the accreditation of medical schools that grant medical degrees and of teaching hospitals in the United States and Canada.
ABMS	The American Board of Medical Specialties (ABMS) was established in 1933 and is a nonprofit physician-led organization that oversees the certification and ongoing professional development of physician specialists by its 24 medical specialty member boards. ABMS works closely with the member boards to set educational and professional standards for the evaluation and certification of physician specialists.
ABOto	The American Board of Otolaryngology, founded in 1924, is the second oldest of the 24 ABMS member boards. See Boxes 7-1 and 7-3.
ACCME	The Accreditation Council for Continuing Medical Education (ACCME) is the overseeing body for continuing medical education (CME) in the United States. The ACCME sets the standards for the accreditation of all providers of CME activities. The ACCME's seven member organizations are the American Board of Medical Specialties (ABMS), the American Hospital Association (AHA), the American Medical Association (AMA), the Association of American Medical Colleges (AAMC), the Association for Hospital Medical Education (AHME), the Council of Medical Specialty Societies (CMSS), and the Federation of State Medical Boards (FSMB).
ACGME	The Accreditation Council for Graduate Medical Education (ACGME) is the body responsible for the accreditation of postgraduate medical training programs (i.e., internships, residencies, and fellowships—now all called "residencies") for medical doctors in the United States. It is a nonprofit private council that evaluates and accredits medical residency programs. The ACGME oversees the postgraduate education and training for all allopathic and the majority of osteopathic physicians in the United States.
ACS	The American College of Surgeons (ACS) is an educational association of surgeons created in 1913 to improve the quality of care for the surgical patient by setting high standards for surgical education and practice. Members of the ACS are referred to as "Fellows." The letters FACS (Fellow, American College of Surgeons) after a surgeon's name mean that the surgeon's education and training, professional qualifications, surgical competence, and ethical conduct have passed a rigorous evaluation, and have been found to be consistent with the high standards established and demanded by the College.
AHIP	America's Health Insurance Plans (AHIP) is a national political advocacy and trade association with about 1300 member companies that provide health insurance coverage to more than 200 million Americans. AHIP was formed through the merger of Health Insurance Association of America (HIAA) and American Association of Health Plans (AAHP).
AHRQ	The Agency for Healthcare Research and Quality (AHRQ) (formerly known as the Agency for Health Care Policy and Research), is a part of the United States Department of Health and Human Services which supports research designed to improve the outcomes and quality of health care, reduce its costs, address patient safety and medical errors, and broaden access to effective services.
AMA	The American Medical Association (AMA), founded in 1847 and incorporated in 1897, is the largest association of medical doctors and medical students in the United States. The AMA's mission is to promote the art and science of medicine for the betterment of the public health, to advance the interests of physicians and their patients, to promote public health, to lobby for legislation favorable to physicians and patients, and to raise money for medical education. It also publishes the *Journal of the American Medical Association* (JAMA), which has the largest circulation of any weekly medical journal in the world.
AMA PCPI (also known as the Consortium)	The AMA-convened Physician Consortium for Performance Improvement is a physician-led initiative that includes methodologic experts, clinical experts representing more than 100 national medical specialty societies, state medical societies, medical specialty boards, AHRQ, NCQA, the Joint Commission, CMS, and other stakeholders. The Consortium, in conjunction with the stakeholders represented, develops performance measurement sets and clinical quality improvement tools useful for the practicing physician. The Consortium's vision is to fulfill the responsibility of physicians to patient care, public health, and safety by becoming the leading source organization for evidence-based clinical performance measures and outcomes reporting tools for physicians.

Table 7-2

Glossary of Terms and Acronyms of Groups Engaged in Defining, Measuring, or Reporting on Quality in Health Care—cont'd

Acronym or Abbreviation	Title of Group and Description
AQA	Formerly called the Ambulatory Care Quality Alliance, the AQA was formed in 2004 by AHRQ, AHIP, ACP, and AAFP (American Academy of Family Physicians). The AQA is one of two consensus organizations (along with the NQF) that can approve measures for implementation on a national level for CMS (Medicare and Medicaid) programs and other health plans. The AQA is composed primarily of health plans (payers including CMS), employers (purchasers), clinicians—physicians and nonphysicians, consumer groups, and supporting industries.
B2E or BTE	Bridges to Excellence, a not-for-profit coalition-based organization (predominantly purchaser-driven) was created to encourage voluntary participation in quality health care initiatives by recognizing and rewarding health care providers who demonstrate that they deliver safe, timely, effective, efficient, equitable, and patient-centered care.
CAHPS	The Consumer Assessment of Healthcare Providers and Systems is a public-private initiative to develop standardized surveys of patients' experiences with ambulatory and facility-level care, first launched and funded by AHRQ in 1995. Health care organizations, public and private purchasers, consumers, and researchers use CAHPS results from standardized surveys to assess the patient-centeredness of care, compare and report on performance, and improve quality of care. A surgical CAHPS instrument has been developed with support from the ACS with participation from other surgical societies, including otolaryngology.
CMS	The Centers for Medicare and Medicaid Services (CMS), previously known as the Health Care Financing Administration (HCFA), is a federal agency within the United States Department of Health and Human Services (HHS) that administers the Medicare program and works in partnership with state governments to administer Medicaid, the State Children's Health Insurance Program (SCHIP), and health insurance portability standards.
DoD	The United States Department of Defense (DoD) is a major purchaser and provider of health care for its military employees, service men and women, and their beneficiaries. It partners with the VA, CMS, HHS, and other government organizations in quality measurement and reporting initiatives.
DOQ-IT	The Doctor's Office Quality—Information Technology (DOQ-IT) program is a national initiative that promotes the adoption of Electronic Health Record (EHR) systems to improve quality and safety for Medicare beneficiaries in small- and medium-sized physician offices.
EHR (EMR; HIT)	Electronic Health Record (Electronic Medical Record or Health Information Technology)
FSMB	The Federation of State Medical Boards (FSMB) is a not-for-profit organization composed of 70 medical licensing and disciplinary boards of the United States and its territories and serves as an authoritative source of research, policy development, education, and information. The FSMB's primary mission is to improve the quality, safety, and integrity of health care by promoting high standards for physician licensure and practice and assisting state medical boards in protecting the public. The FSMB monitors state and federal legislative initiatives, works collaboratively with state and federal regulatory agencies, and offers legislative assistance to and on behalf of its member medical boards.
HQA	The Hospital Quality Alliance (HQA) works to improve care through information—it is a public and private collaboration to improve the quality of care provided by the nation's hospitals by measuring and publicly reporting on that care. Quality performance information collected from the more than 4000 participating hospitals is reported on *Hospital Compare*, a website tool developed by the CMS.
IHI	The Institute for Healthcare Improvement (IHI) is a not-for-profit organization that aims to lead the improvement of health care throughout the world. Their goals are to improve the lives of patients, the health of communities, and the joy of the health care workforce by focusing on initiatives in safety, effectiveness, patient-centeredness, timeliness, efficiency, and equity.
IOM	The Institute of Medicine (IOM) is one of the four United States National Academies, and is a not-for-profit, nongovernmental American organization chartered in 1970 as a part of the National Academy of Sciences. The IOM reports, such as "To Err Is Human," are often referred to in developing quality improvement initiatives. The IOM domains are effectiveness, efficiency, equity, patient-centeredness, safety, and timeliness.
The Joint Commission	The Joint Commission, until 2007 the Joint Commission on Accreditation of Healthcare Organizations (JCAHO), is a United States–based nonprofit organization formed in 1951 with a mission to maintain and elevate the standards of health care delivery through evaluation and accreditation of health care organizations.

Continued

Table 7-2

Glossary of Terms and Acronyms of Groups Engaged in Defining, Measuring, or Reporting on Quality in Health Care—cont'd

Acronym or Abbreviation	Title of Group and Description
Leapfrog Group	The Leapfrog Group is an employer group formed by a number of major U.S. corporations that strongly encourages the adoption of a number of safer practices in hospitals, including EMR, proper staffing of intensive care units, concentrating highly technical surgical procedures in high-volume centers, and implementation of the NQF Safe Practices.
NBGH	The National Business Group on Health (NBGH) members are primarily Fortune 500 companies and large public sector employers—including the nation's most innovative health care purchasers—who provide health coverage for more than 50 million U.S. workers, retirees, and their families. The NBGH fosters the development of a safe, high-quality health care delivery system and treatments based on scientific evidence of effectiveness.
NCQA	The National Committee for Quality Assurance is a private nonprofit committee creating standards and measures for quality. It was established in 1990 with support from the Robert Wood Johnson Foundation. NCQA accredits and certifies a wide range of health care organizations including health plans and physician organizations. Health plans seeking accreditation by NCQA measure performance often utilizing data from tools such as the Healthcare Effectiveness Data and Information Set (HEDIS) and the CAHPS survey. The NCQA also has a voluntary program to recognize individual physicians who follow evidence-based guidelines and use evidence-based measures and up-to-date information and systems to enhance patient care.
NGC	The National Guidelines Clearinghouse at www.guideline.gov is a public online comprehensive database of evidence-based clinical practice guidelines. NGC is an initiative of the AHRQ and the HHS. The mission of NGC is to provide physicians, nurses, and other health professionals, health care providers, health plans, integrated delivery systems, purchasers and others an accessible mechanism for obtaining objective, detailed information on clinical practice guidelines and to further their dissemination, implementation, and use. NGC was originally created by AHRQ in partnership with the AMA and the American Association of Health Plans (now AHIP).
NSQIP	The ACS National Surgical Quality Improvement Program (ACS NSQIP) is the first nationally validated, risk-adjusted, outcomes-based program to measure and improve the quality of hospital surgical care. The program employs a prospective, peer-controlled, validated database to quantify 30-day risk-adjusted surgical outcomes, which allows valid comparison of outcomes among all hospitals in the program. The ACS NSQIP is available to all private sector hospitals that meet the minimum participation requirements, complete a hospital agreement, and pay an annual fee. The goal is the reduction of surgical mortality and morbidity. The VA has a parallel system (VA NSQIP) to compare its results against the ACS NSQIP private sector data.
NQF	The National Quality Forum (NQF) is a voluntary consensus standards-setting organization as defined by the National Technology Transfer and Advancement Act of 1995. The NQF is the other of two consensus organizations (along with the AQA) that can endorse measures on a national level for CMS quality programs and for other health plans. The NQF is a membership organization created to develop a national strategy for health care quality measurement and reporting. The NQF has participation from consumers, purchasers, health plans, hospitals (providers), health professionals (including physicians and non-physicians), accrediting bodies, labor unions, and supporting industries.
NQMC	The National Quality Measures Clearinghouse (NQMC), www.qualitymeasures.ahrq.gov, sponsored by the AHRQ and HHS, is a public repository for evidence-based quality measures and measure sets. The NQMC also provides excellent educational resources for those who want to learn more about quality measures.
ONC	The Office of the National Coordinator for Health Information Technology (ONC) provides counsel to the Secretary of HHS and departmental leadership for the development and nationwide implementation of an interoperable health information technology infrastructure. Use of this infrastructure will improve the quality, safety, and efficiency of health care and the ability of consumers to manage their health information and health care.
PCPI	Physician Consortium for Performance Improvement (see AMA PCPI above).
PBGH	The Pacific Business Group on Health (PBGH), a business coalition of 50 purchasers, seeks to improve the quality and availability of health care while moderating cost. Since 1989, PBGH has played a leading role both nationally and in California in health care quality measurement and system accountability through public reporting.
QASC	Government agencies, physicians, nurses, pharmacists, hospitals, insurers, employers, consumers, accrediting agencies, and others have formed the Quality Alliance Steering Committee (QASC) to better coordinate the promotion of quality measurement, transparency, and improvement in care. Through the efforts of the QASC, Americans will have helpful information on health care available through the Internet.

Table 7-2

Glossary of Terms and Acronyms of Groups Engaged in Defining, Measuring, or Reporting on Quality in Health Care—cont'd

Acronym or Abbreviation	Title of Group and Description
QIO	Quality Improvement Organizations (QIOs) monitor the appropriateness, effectiveness, and quality of care provided to Medicare beneficiaries. They are private contractor extensions of the federal government that work under the auspices of the CMS.
SQA	The Surgical Quality Alliance (SQA), which is convened by the ACS, aims to bring more than 20 surgical specialties and anesthesiology together to coordinate the definition and measurement of surgical quality and respond to federal and private quality-related initiatives. SQA provides a forum to coordinate efforts among specialties to monitor and participate effectively in patient data registries, data aggregation, and the development, validation, and implementation of physician performance measures.
VA	The United States Department of Veterans Affairs (VA) is a government-run military veteran benefit system with Cabinet-level status. It is responsible for administering benefits, including health care, for veterans, their families, and survivors (see also DoD).

how often the actions recommended in the guideline are carried out, and creating the tools for physicians to collect that information as part of their ongoing clinical activities. Some medical specialty societies undertake the translation of guidelines into performance measures themselves, but many choose to work through the AMA's Physician Consortium for Performance Improvement (Fig. 7-2).

The National Quality Forum (NQF) is a voluntary consensus standards organization with a broad membership of providers, payers, and health plans working to create a standardized national set of measures that can be used to evaluate the entire spectrum of care. The NQF endorses national standards for measurement created by other groups and promotes public reporting of health care performance data that provide meaningful information about quality of care. Because of its broad stakeholder makeup, its endorsement facilitates the rapid acceptance and implementation of quality activity. The NQF has endorsed quality measures developed by the AMA's Consortium, which have then been adopted for use by both CMS and private-sector purchasers of health care.

The NQF derives most of its clout in the health care marketplace from a provision in the National Technology Transfer and Advancement Act of 1995 (Public Law 104-113) that requires federal agencies to use technical standards that are developed or adopted by voluntary consensus standards organizations. Because NQF is such an organization, Medicare (CMS), as a federal agency, is required to use NQF-endorsed measures if it intends to engage in quality initiatives in those areas addressed by NQF. Developers of performance measures who want to aggregate demand and have their measures become the national standard will submit them to the NQF's technical review and consensus process, knowing that if the measures are endorsed by NQF they are likely to be broadly adopted in the marketplace.

The AQA alliance (formerly the Ambulatory Care Quality Alliance) was formed in September 2004 by the American Academy of Family Physicians (AAFP), the American College of Physicians (ACP), America's Health Insurance Plans (AHIP), and the Agency for Healthcare Research and Quality (AHRQ). These organizations joined together to lead an effort for determining, under the most expedient timeframe, how to most effectively and efficiently improve performance measurement, data aggregation, and reporting in the ambulatory care setting. However, its activity has now expanded to all treatment and care settings. AQA's mission and goals focus on key areas that can help identify quality gaps, control skyrocketing cost trends, reduce confusion over redundant measures, and alleviate administrative burdens for physicians and purchasers.[43-45]

The Hospital Quality Alliance (HQA) is a voluntary alliance led by the Association of American Medical Colleges (AAMC), American Hospital Association (AHA), and the Federation of American Hospitals (FAH). CMS participates in this national effort that encourages hospitals to publicly report quality performance data. The data set is posted on Medicare's Hospital Compare website. The website started with a core set of clinical measures and will be adding additional clinical indicators and patient experience of care data in coming years. The activities of the HQA do not directly affect otolaryngologists because they are focused on measurement at the hospital/facility level; however, the HQA provided the prototype for the AQA, which directly affects all physicians.

The Centers for Medicare and Medicaid Services (CMS, not to be confused with CMSS, the Council of Medical Specialty Societies) is an agency of the federal government responsible for managing the health care services for all qualifying civilian beneficiaries of federal health care. *The Department of Veterans Affairs (VA)* has a similar responsibility for qualifying retired or ex-military personnel, as does the *Department of Defense (DoD)* for active military personnel. These agencies are critical to include in this discussion because they cover the health care of large numbers of people, they have been charged by presidential order to measure and improve the delivery of quality health care, and each is engaged in specific independent and collaborative quality initiatives.[46]

In addition to the alliances and consortia mentioned above, independent private groups of purchasers and administrators of health care have been organizing for years in an attempt to control what they observe to be unsustainable increases in health care costs in the private sector, just as CMS, the VA, and the DoD are working to do the same for government health care beneficiaries. Private collaborations on quality are numerous at local, state, and federal levels. A sampling of examples of the activities of several of these can be seen in a report from AAMC. However, a representative group of prominent and influential corporations and employers would include the *Leapfrog Group, the National Business Group on Health (NBGH),* and the *Pacific Business Group on Health (PBGH).* Because these groups' constituent employer members collectively pay billions of dollars in health care premiums, their concerns carry great weight in the debate about quality and cost.

Standardization and Implementation of Measures

For years, the management of expensive chronic conditions by specialty medical care providers fueled the impetus for measuring performance. Some surgical societies have less experience and often a greater challenge in finding high levels of evidence for surgical interventions. However, a number of activities are under way in many surgical societies and within the specialty of otolaryngology—head and neck surgery that are intended to bring all of the various stakeholders together to agree on standard data fields common to all surgeons, and the quality measures to be used to assess perioperative care and the performance of the health care system and individual physicians within that system. Otolaryn-

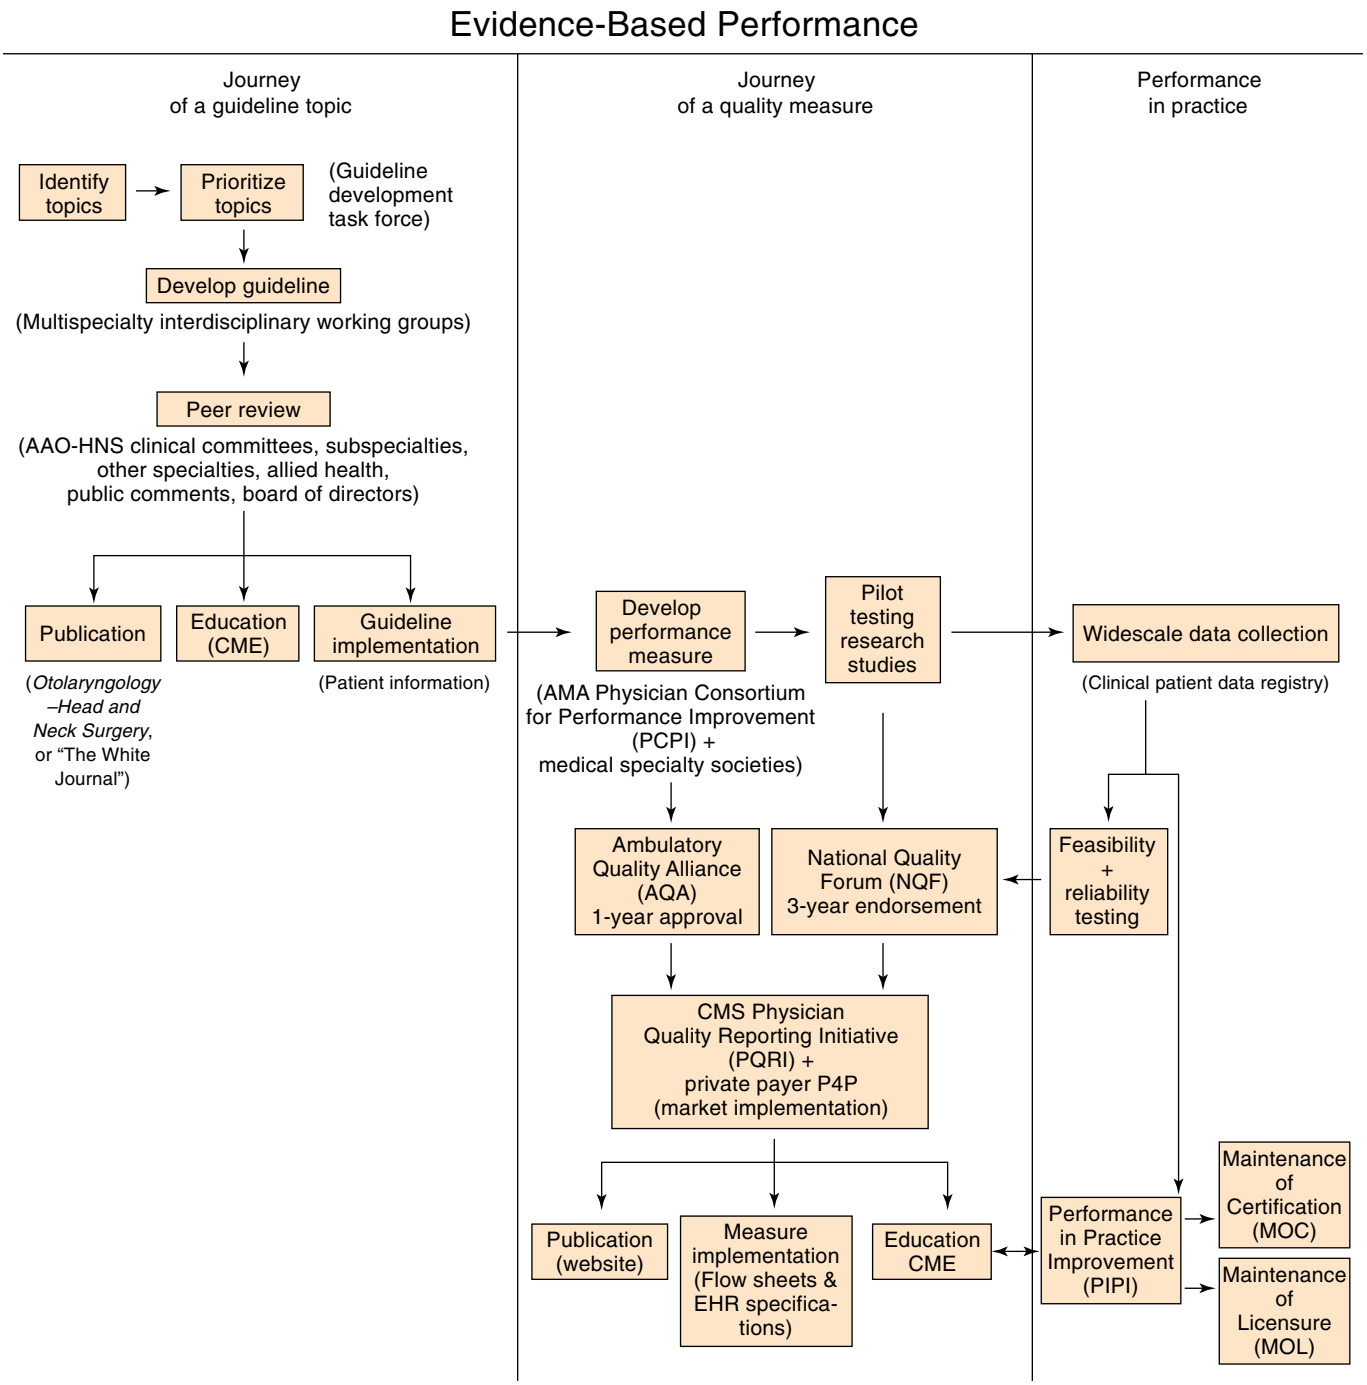

Figure 7-2. Evidence-based performance. This figure outlines the current pathway from topic identification to implementation of quality measures. AAO-HNS, American Academy of Otolaryngology–Head and Neck Surgery. *(With permission from the American Academy of Otolaryngology–Head and Neck Surgery Foundation.)*

gologists should be aware of the leadership role that their societies are playing in surgical quality.

As the AQA has gained momentum, many surgical specialty societies have recognized that the distinctive characteristics of acute surgical care and the unique issues related to measurement, data collection, and reporting for surgical care were not adequately addressed through other committees and processes. In response, the American College of Surgeons convenes the surgical specialty societies in an effort to educate surgeons about the issues, to strategize about how to best communicate the message of the unique aspects of surgical care, and to speak with one unified voice on those issues of surgical quality measurement where there is consensus. This activity has led to the formation of the *Surgical Quality Alliance (SQA),* of which the American Academy of Otolaryngology–Head and Neck Surgery (AAO-HNS) is a member. The SQA is staffed by the American College of Surgeons and supported through the staff and volunteer physician time of its member surgical specialty societies.

There are hundreds of existing "guidelines" related to otolaryngology from many sources. They are of variable quality, rigor, and usefulness. Most are consensus statements, with low levels of evidence, weak recommendations, or merely suggested clinical pathways or indicators. Although currently more rigorous processes for increasing the level of evidence for head and neck medical and surgical care are being employed, it is useful to examine the strength of past recommendations,

to identify best evidence, and to strengthen existing evidence where possible.

In 2006 the AAO-HNS convened the specialty's first quality conference entitled Translating Research into Cross-Specialty Measures. A follow-on conference was convened in summer 2007. As a result of the conference, an ongoing rigorous process for identifying, prioritizing, developing, validating, and implementing multidisciplinary evidence-based guidelines has been created and successfully launched. Nine otolaryngology societies and the ABOto form the Guidelines Development Task Force (GDTF), which meets quarterly throughout the year to formulate a pipeline of evidence for quality improvement activity. At this point, the GDTF and prioritized content-specific work groups are producing guidelines rigorous enough for high-quality performance measures developed through the Consortium. In ensuing years a stable of measures for every subspecialty area of otolaryngology will exist, in addition to general surgical and perioperative measures so that every otolaryngologist, regardless of practice type, will be able to comply with demand for measurement with relevant, validated, patient-centered quality activity in his or her practice.[14,17]

Barriers to Implementation of Performance Measurement

The development of performance measures should be founded on the best science. Combining health services research *with type 2 translational research*, that is, the extension of clinical advances from the bedside into populations and systems, should always be about making patients better. The processes should not be taken for granted and not every proposed quality initiative (even those that look good in print) turns out to be implementable or effective when broadly applied. An open, curious, and critical mind is no less necessary in investigating the effectiveness of quality initiatives than in basic science and clinical research. There are significant challenges to be overcome in implementing and benefiting from measuring performance in practice. First, as described, the process of identifying and strengthening the level of evidence for the care being delivered is daunting. *Eminence based medicine*, that is, patient care based on tradition or uncritical opinion, must be replaced by the best available evidence in practice. Residency training programs must engage and educate their residents and fellows in these processes and keep focus on evidence and data, combined with the best clinical expertise and patient preferences.[29,35,36] Educational (CME) processes must be implemented to ensure that physicians are aware of existing guidelines and best practices, rather than relying on the idiosyncrasies and unwarranted variation from undocumented past experience. Electronic medical records, office and hospital systems, imaging centers, laboratories, and other clinical sites must develop, implement, and integrate data collection systems that protect physician and patient privacy while seamlessly importing and exporting relevant data on practice that can be used to improve quality and patient safety and reduce medical error. The cost of such integration of systems can be tens of thousands of dollars in a small office, hundreds of thousands for larger practices, millions for clinics and groups, and close to $100 billion for national integration and standardized implementation. The Office of the National Coordinator (ONC) for health information technology (HIT) has developed a road map for creating synergistic or integrated platforms by 2014. The financial and technical barriers alone will be difficult to overcome. Much work is needed to standardize data fields, coordinate specialty requirements for data entry, integrate existing platforms, and consolidate resources. One of the most significant and difficult barriers is the resistance to change at all levels from organizations, departments, and entrenched practitioners. Even in processes as innocuous as safe medication review and coordination of care, it is difficult to alter a professional lifetime of behavior. And in an environment of cost consciousness and budget neutrality, individual physicians are feeling the pressure of having to personally fund a change in behavior being imposed by outside influences.[47]

The Surgeon's Role in Performance Measurement

Perhaps no other issue will affect physicians' clinical practice, quality of care, professional satisfaction, and economics more in the next decade than performance measurement. Otolaryngologists, their colleagues in related specialties, and their medical societies have embarked on a bold course to ensure that practicing clinicians develop an inventory of evidence-based guidelines that can apply to every practicing otolaryngologist as quickly and efficiently as possible. Every otolaryngologist who is offered an opportunity or required to participate in programs that provide incentives for quality of care should have evidence-based performance measures that are relevant to his or her practice, that are easy to collect and report, and that are shown to have a measurable impact on patient outcomes.

Acknowledgment

The author expresses appreciation to Robert H. Miller, MD, Executive Director of the American Board of Otolaryngology; James N. Thompson, MD, President and CEO of the Federation of State Medical Boards; David Witsell, MD, MHS, Coordinator for Research of the American Academy of Otolaryngology–Head and Neck Surgery Foundation for their review and editing of the manuscript; Kris Schulz, MPH, Senior Director–Research and Quality; Stacie Jones, MPH, Program Manager—Quality Improvement of the American Academy of Otolaryngology–Head and Neck Surgery Foundation for their review and editing of the manuscript and assistance with production of tables and figures.

CHAPTER EIGHT

History, Physical Examination, and the Preoperative Evaluation

Marion Everett Couch

Key Points

- In patients with head trauma, postauricular ecchymosis (or Battle's sign) suggests that a temporal bone fracture may have occurred.
- The pretracheal, paratracheal, precricoid (Delphian), and perithyroidal nodes are contained in level VI, which extends from the hyoid bone to the suprasternal region.
- A Virchow node, often a left supraclavicular node associated with visceral metastasis, is not in the V_B region but is located in level IV.
- When removing cerumen, remember that the canal is well supplied with sensory fibers: CN V3, the auricular branch of CN X, C3, and CN VII. CN X is also the source of referred throat pain to the ear.
- The tympanic membrane is oval, not round, and has a depressed central part called the *umbo*, where the handle of the malleus attaches to the membrane.
- This superior flaccid area is critical to examine carefully because retraction pockets may develop here, which may develop into cholesteatomas.
- In congenital cholesteatomas, often diagnosed in young children, the tympanic membrane is intact and a white mass is seen in the anterior superior quadrant. In contrast, acquired cholesteatomas in adults are often in the posterior superior quadrant and are associated with retraction pockets, chronic otitis media with purulent otorrhea, and tympanic membrane perforations.
- A midline Weber result is referred to as "negative." "Weber right" and "Weber left" refer to the direction to which the sound lateralized.
- To compare air conduction with bone conduction, perform the Rinne test using the 512-Hz tuning fork placed by the ear canal and then on the mastoid process. A "positive test" result is air conduction louder than bone conduction.
- While examining the buccal membranes, note the location of the parotid duct, or Stensen's duct, as it opens near the second upper molar.
- Small yellow spots in the buccal mucosa are sebaceous glands, commonly referred to as *Fordyce spots*, and are not abnormal.
- The hard palate may have a bony outgrowth known as a *torus palatinus.*
- The point wherein numerous small branches of the external and internal carotid arteries meet, or Kiesselbach's plexus, is the most common site for epistaxis.
- Risk factors for a perioperative cardiovascular complication include jugular venous distention, third heart sounds, recent myocardial infarction (MI) (within 6 months), nonsinus heart rhythm, frequent premature ventricular contractions (>5 per minute), age older than 70 years, valvular aortic stenosis, previous vascular or thoracic surgery, and poor overall medical status.
- The term *thyroid storm* refers to a life-threatening exacerbation of hyperthyroidism that results in severe tachycardia, fever, and hypertension.
- Treatment of hyperthyroidism attempts to establish a euthyroid state and to ameliorate systemic symptoms.
- Chvostek's sign (facial nerve hyperactivity elicited by tapping over the common trunk of the nerve as it passes through the parotid gland) and Trousseau's sign (finger and wrist spasm after inflation of a blood pressure cuff for several minutes) are clinically important indicators of latent hypocalcemia.
- Congenital deficiencies of hemostasis affect up to 1% of the population.
- Preoperatively, the platelet count should be greater than 50,000; at levels below 20,000, spontaneous bleeding may occur.
- Severe azotemia secondary to renal failure may lead to platelet dysfunction (uremic platelet syndrome). Dialysis should be performed as necessary.
- Approximately 50% of all postoperative deaths in older adults occur secondary to cardiovascular events, thus severe cardiac disease should be treated before any elective procedure and should be weighed against the benefit of any more urgent procedure.

A physician is privileged when requested to evaluate a person and render an opinion and diagnosis. The importance of obtaining an accurate, detailed patient history cannot be overemphasized because it is the framework upon which the otolaryngologist places all available information. Without this, the evaluation may be incomplete and the diagnosis flawed. Unnecessary testing may ensue, and at a minimum, a delay in symptom management may result. In the worst scenario, a misdiagnosis may occur. Therefore the energy expended in obtaining a complete history is always worthwhile.

Preoperative evaluation of surgical patients is, in its broadest sense, an extension of the diagnostic process. The surgeon should (1) strive to determine the extent of disease, (2) prove the necessity of surgery or clearly demonstrate its benefit to the patient, (3) optimize the choice of surgical procedure, and (4) minimize the risk to the patient by defining concomitant health problems and instituting appropriate therapy or precautionary measures. Integral to each of these goals is an appreciation of the ideal set forth in the Hippocratic Oath—above all else, do no harm. It is the surgeon's responsibility to ensure that an appropriate patient assessment has been completed before entering the surgical suite. Surgical complications can often be avoided by recognizing the physiologic limitations of the patient preoperatively. Documentation of findings, decision making, and discussion between surgeon and patient regarding surgical risks and benefits have become medicolegal imperatives.

Gathering a Patient History

The otolaryngologist should always try to request that previous medical records pertaining to the patient's current problem be sent to the office before the visit. If previous operations have been performed, operative reports can be important sources of information. In addition, pertinent radiographic imaging is helpful to obtain for review. Reports of computed tomography (CT) or magnetic resonance imaging (MRI) scans are valuable but cannot substitute for actual review of the imaging by the otolaryngologist. For head and neck cancer patients, any pathologic slide specimens from past biopsies should be sent to the pathology department for review so that a second opinion may be rendered. This is especially helpful when patients are referred with an unusual pathologic diagnosis. Finally, laboratory values can provide much information and should be carefully reviewed.

The physician should address the patient's chief complaint by determining its duration, intensity, location, frequency, factors that make the problem worse or better, any past therapy, and related symptoms. Whether the complaint is vertigo, pain, sinusitis, hearing loss, allergies, or a neck mass, the approach should entail asking many of the same basic questions followed by more specific ones designed to elucidate the full scope of the problem.

A discussion of the patient's medical history not only leads the otolaryngologist to a better understanding of the patient, but also often reveals pertinent information. For instance, a patient with an otitis externa who also is diabetic requires a high level of concern for malignant otitis externa, which may be reflected in the management plan. If the patient requires surgery, complete knowledge of the patient's medical problems is necessary before the operative procedure.

The surgical history is equally valuable. All the past operations of the head and neck area are important to note, including surgery for past facial trauma, cosmetic facial plastic surgery, otologic surgery, and neoplasm. However, full disclosure of all past operations may be critical. The otolaryngologist needs to know whether a patient scheduled for surgery has had adverse reactions to anesthetic agents or a difficult intubation.

Any known drug allergies and side effects are crucial to note prominently in the medical chart. True allergies should be distinguished from side effects of a medication. In addition, all medications and current dosages should be accurately recorded. Often it is valuable to inquire whether the patient has been compliant with the prescribed medication regimen because the physician needs to know what dose the patient actually is taking.

It is also advantageous to assess for risk factors associated with certain disease states. Tobacco use is important to note. It is helpful to specifically ask about cigarette, cigar, and chewing tobacco consumption—either current or past use. Alcohol consumption also is occasionally difficult to quantitate unless the interviewer asks direct questions regarding frequency, choice of beverage, and duration of use. Recreational drug use should be addressed, as should risk factors for communicable diseases such as the human immunodeficiency virus (HIV) and hepatitis virus. For patients being assessed for hearing loss, major risk factors such as exposure to machinery, loud music, or gunfire should be discussed. Finally, past irradiation (implants, external beam, or by mouth) and dosage (either high or low dose) should be ascertained. A history of accidental radiation exposure also is important to document.

Box 8-1

History

Introduce yourself

Review:
- Questionnaire
- Medical records
- Radiographic imaging
- Laboratory values
- Pathology specimens

Inquire about chief complaints:
- Location
- Duration
- Characteristics
- Medical history
- Surgical history
- Allergies
- Medications

Risk factors:
- Tobacco, alcohol
- Social history
- Family history

Review of systems:
- Respiratory
- Neurologic
- Cardiac
- Endocrine
- Psychiatric
- Gastrointestinal
- Urogenital
- Skin
- Musculoskeletal

The patient's social history should not be overlooked because it may often reveal more occult risk factors for many diseases. For instance, a retired steel worker may have an extensive history of inhaling environmental toxins, whereas a World War II veteran may have noise-induced hearing loss from his or her military service. Family history often is equally revealing, and asking patients questions about their familial history of such conditions as hearing loss, congenital defects, atopy, or cancer may uncover useful information that they had not previously considered.

Finally, a review of systems is part of every comprehensive history. This review includes changes in the patient's respiratory, neurologic, cardiac, endocrine, psychiatric, gastrointestinal, urogenital, cutaneous skin, or musculoskeletal systems. The otolaryngologist often may derive more insight into the patient's problem by inquiring about constitutional changes such as weight loss or gain, fatigue, heat or cold intolerance, rashes, and the like (Box 8-1).

Physical Examination

The otolaryngologist must develop an approach to the head and neck examination that allows the patient to feel comfortable while the phy-

sician performs a complete and comprehensive evaluation. Many of the techniques used by the otolaryngologist, such as fiberoptic nasopharyngolaryngoscopy, may leave a patient feeling alienated if not done correctly. Thus, it is essential to establish a rapport with a patient before proceeding with the examination.

A word of caution is necessary. The head and neck examination should only be done with the examiner wearing gloves and, in some instances, protective eye covering. Universal precautions are mandatory in today's practice of medicine. This has the added benefit of showing the patient that the examiner is concerned about not transmitting any diseases, which builds trust between the patient and physician.

General Appearance

Much information can be obtained by first assessing the general behavior and appearance of the patient. For instance, the patient's affect may suggest possible depression, anxiety, or even alcoholic intoxication. Psychotic behavior in the office may be a result of many factors but may indicate profound hypothyroidism in head and neck cancer patients. Astute observation of the patient's appearance is equally important. Tar-stained fingernails, teeth, or moustache are harbingers for heavy tobacco consumption. Even the gait of patients as they enter or leave the office may reveal information. Neurologic impairments, especially involving the cerebellum, may affect the patient's ability to navigate the room.

Facies

After assessing the patient's overall appearance, the face should be analyzed for facial asymmetry by positioning the head squarely in front of the examiner. For instance, in patients considering facial plastic surgery, a hemifacial microsomia may affect the final outcome, which should be discussed before the operation. In addition, a paretic facial nerve always is a serious finding that can be detected by observing the tone of the underlying facial musculature and overlying facial skin. Facial wrinkles are more prominent when the facial nerve is functioning. For patients recovering from facial nerve paralysis, the American Academy of Otolaryngology–Head and Neck Surgery (AAO-HNS) Facial Nerve Grading System is a respected standard for reporting gradations of nerve function (Table 8-1).

Table 8-1

AAO-HNS Facial Nerve Grading System

Grade	Facial Movement	
I	Normal	Normal facial function at all times
II	Mild dysfunction	Forehead: moderate-to-good function Eye: complete closure Mouth: slight asymmetry
III	Moderate dysfunction	Forehead: slight-to-moderate movement Eye: complete closure with effort Mouth: slightly weak with maximum effort
IV	Moderately severe dysfunction	Forehead: none Eye: incomplete closure Mouth: asymmetrical with maximum effort
V	Severe dysfunction	Forehead: none Eye: incomplete closure Mouth: slight movement
VI	Total paralysis	No movement

Facial Skeleton

The facial skeleton then should be carefully palpated for bony deformities. This is especially true in patients with recent facial trauma. The periorbital rims may be irregular as a result of fractures involving the zygomatic arches or orbital floor. The dorsum of the nose may be displaced as a result of a comminuted nasal fracture. After evaluation of the facial skeleton, the regions overlying the paranasal sinuses may be firmly palpated or tapped for tenderness, which may be present during an episode of sinusitis.

Evaluation of the temporomandibular joint (TMJ) is convenient to perform at this point in the examination. By having the examiner place three fingers over the TMJ region, which is anterior to the external auditory canal, anteromedial dislocation (caused by the action of the lateral pterygoid muscle) or clicking of the joint can be ascertained. The patient should open and close the jaw to assist in evaluating this synovial joint.

Parotid

Masses in the parotid may be benign or malignant neoplasms of the parotid, cysts, inflammatory masses, or lymph node metastasis from other areas. The tail of the parotid extends to the region lateral and inferior to the angle of the mandible. This is a common site for parotid masses to reside. The parotid-preauricular and retroauricular lymph nodes also should be systematically assessed in every patient. By facing the patient and placing both hands behind the ears before palpating the preauricular nodes, the often-neglected retroauricular nodes will not be missed.

Skin

Skin covering the face and neck should be examined, and suspicious lesions should be noted. The external auricles often receive sun exposure and are at risk for developing the skin malignancies such as basal cell and squamous cell carcinomas. The scalp should be examined for hidden skin lesions, such as melanoma, basal cell carcinoma, or squamous cell carcinoma. All moles should be inspected for irregular borders, heterogeneous color, ulcerations, and satellite lesions.

Neck

The neck, an integral part of the complete otolaryngology examination, is best approached by palpating it while visualizing the underlying structures (Fig. 8-1). The midline structures such as the trachea and larynx can be easily located and then palpated for deviation or crepitus. If there is a thyroid cartilage fracture, tenderness and crepitus may be present. In thick, short necks, the "signet ring" cricoid cartilage is a good landmark to use for orientation. The hyoid bone can be inspected and palpated by gently rocking it back and forth.

Thyroid Gland

Traveling more inferior in the neck, the thyroid gland, which resides below the cricoid cartilage, should be examined by standing behind the patient and placing both hands on the paratracheal area near the cricoid cartilage. Having the patient swallow or drink a sip of water often helps better delineate the thyroid lobes by having the trachea rise and fall. Pressing firmly in one tracheal groove allows the contents of the other side to be more easily distinguished by gentle palpation. Nodules or cystic structures should be carefully noted and evaluated, often by fine-needle aspiration. Adjacent adenopathy also should be carefully assessed.

Adenopathy

After assessing the thyroid gland, palpation of the supraclavicular area—from the paratracheal grooves posteriorly to the sternocleidomastoid muscle to the trapezius muscle—will help detect masses or enlarged lymph nodes, which are worrisome for metastasis from sources such as the abdomen, breast, or lung. Proceeding more superiorly, the area inferior to the angle of the mandible houses the carotid arteries and often has many lymph nodes, either "shoddy" and indistinct or firm. Palpable nodes always should be noted and may need evaluation with either fine-needle aspiration or radiologic imaging when observation is not appropriate. The carotid artery, often mistaken for a prominent node, can be assessed for the presence of bruits. The entire jugulodi-

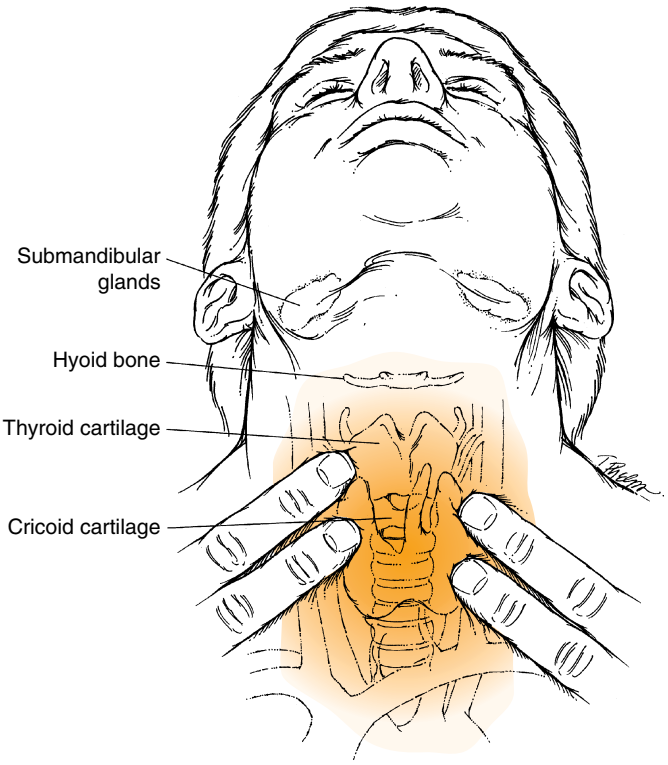

Figure 8-1. Basic anatomy of the anterior neck. Visualize structures while performing neck examination.

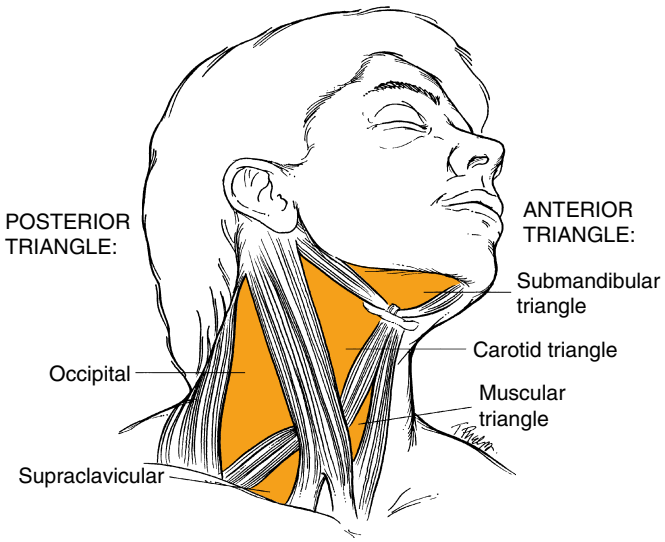

Figure 8-2. Triangles of the neck. The anterior triangle is divided from the posterior triangle by the sternocleidomastoid muscle.

gastric chain of lymph nodes merits careful inspection by outlining the sternocleidomastoid muscle and palpating the soft tissue anterior and posterior to it. The submandibular and submental regions are palpated by determining the outline of the glands and any masses present. It often is difficult to distinguish masses from the normal architecture of the submandibular gland. Therefore, bimanual palpation of this area using a gloved finger in the floor of the mouth is helpful.

Triangles of the Neck

Most physicians find it helpful to define the neck in terms of triangles when communicating the location of physical findings (Fig. 8-2). The sternocleidomastoid muscle divides the neck into a posterior triangle—whose boundaries are the trapezius, clavicle, and sternocleidomastoid muscles—and an anterior triangle—bordered by the sternohyoid, digastric, and sternocleidomastoid muscles. These triangles are further divided into smaller triangles. The posterior triangle houses the supraclavicular and the occipital triangles. The anterior triangle then may be divided into the submandibular, carotid, and muscular triangles.

Lymph Node Regions

Another classification system for neck masses, endorsed by the American Head and Neck Society and the AAO-HNS, uses radiographic landmarks to define six levels to depict the location of adenopathy (Fig. 8-3). Level I is defined by the body of the mandible, anterior belly of the contralateral digastric muscle, and the stylohyoid muscle. Level IA contains the submental nodes, and level IB consists of the submandibular nodes. They are separated by the anterior belly of the digastric muscle.

The upper third of the jugulodigastric chain is level II, whereas the middle and lower third represent levels III and IV, respectively. More specifically, the jugulodigastric lymph nodes from the skull base to the inferior border of the hyoid bone are located in level II. Sublevel IIA nodes are located medial to the plane defined by the spinal accessory nerve and sublevel IIB nodes are lateral to the nerve.

Level III extends from the inferior border of the hyoid bone to the inferior border of the cricoid cartilage, and level IV includes the

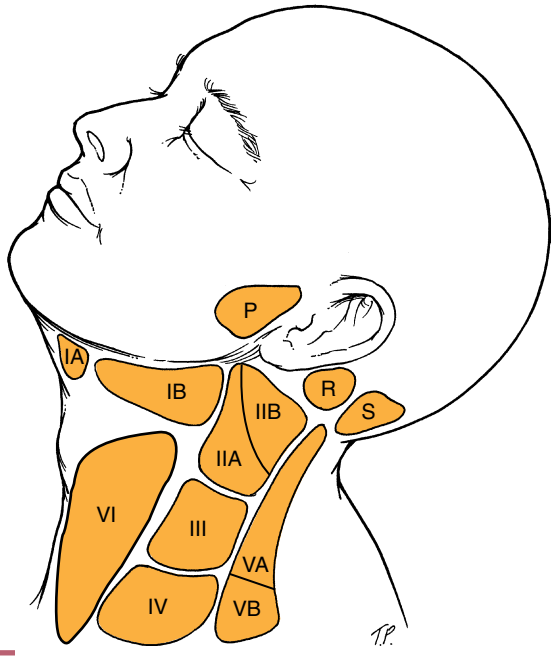

Figure 8-3. Lymph node regions of the neck. See text for details.

lymph nodes located from the inferior border of the cricoid to the superior border of the clavicle. For levels III and IV, the anterior boundary is the lateral border of the sternohyoid muscle and the posterior limit is the lateral border of the sternocleidomastoid muscle.

Level V is the posterior triangle, which includes the spinal accessory and supraclavicular nodes, and encompasses the nodes from the lateral border of the sternocleidomastoid muscle to the anterior border of the trapezium muscle. Sublevel VA (spinal accessory nodes) is separated from sublevel VB (transverse cervical and supraclavicular nodes) by a plane extending from the inferior border of the cricoid cartilage. Of note, the Virchow node is not in the VB region but is located in level IV.

The pretracheal, paratracheal, precricoid (Delphian), and perithyroidal nodes are contained in level VI, which extends from the hyoid bone to the suprasternal region. The lateral borders are the common carotid arteries.

Although not part of this classification system, the parotid-preauricular, retroauricular, and suboccipital regions are commonly designated as the P, R, and S regions.

Ears

Auricles

The postauricular region, which is frequently overlooked, often has many hidden physical findings. For instance, well-healed surgical incisions signify that previous otologic procedures have been performed. In children, the postauricular mastoid area may harbor important clues that mastoiditis with a subperiosteal abscess has developed. Finally, in patients with head trauma, postauricular ecchymosis (or Battle's sign) suggests that a temporal bone fracture may have occurred.

The area anterior to the pinna, at the root of the helix, may have preauricular pits or sinuses, which may become infected. The external auricles also may show abnormalities or congenital malformations, including canal atresia, accessory auricles, microtia, and prominent protruding "bat ears." The outer ears may have edema with weeping, crusting otorrhea, which may signify an infection. Psoriasis of the auricle or external auditory canal with its attendant flaking, dry skin, and edema is another common finding.

Careful examination of the auricles may reveal conditions that require prompt management. For instance, an auricular hematoma—with a hematoma separating the perichondrium from the underlying anterior auricular cartilage—will present as a swollen auricle with distortion of the normal external anatomy. If not surgically drained, a deformed "cauliflower ear" may result. Another important diagnosis is that of carcinoma of the auricle. Because early diagnosis is important, all suspicious lesions or masses should be judiciously biopsied or cultured. A maculopapular rash on the auricle and the external auditory canal in patients with facial nerve paralysis most likely is a result of herpes zoster oticus or Ramsay-Hunt syndrome. Finally, an erythematous painful pinna may represent many diseases, such as perichondritis, relapsing polychondritis, Wegener's granulomatosis, or chronic discoid lupus erythematosus. Metabolic disorders also may have manifestations that affect the auricles. Patients with gout may have tophus on the pinna that exudes a chalky white substance if squeezed. Ochronosis is an inherited disorder of homogentisic acid that will cause the cartilage of the auricles to blacken. These examples of various diseases and syndromes illustrate the importance of routinely examining the auricles.

External Auditory Canal

The outer third (approximately 11 mm) of the auditory canal is cartilaginous. The adnexa of the skin contain many sebaceous and apocrine glands that produce cerumen. Hair follicles also are present. The inner two thirds (approximately 24 mm) of the canal is osseous and has only a thin layer of skin overlying the bone. Cerumen is commonly found accumulating in the canal, often obstructing it. When removing cerumen, remember two points. The canal is well supplied with sensory fibers: first, CN V3, the auricular branch of CN X, C3, and CN VII. Second, the canal curves in an S-shape toward the nose. To visualize the ear canal, gently grasp the pinna and elevate it upward and backward. This will open the external auditory canal and allow atraumatic insertion of the otoscopic speculum. Cerumen impaction may be removed with many techniques, such as careful curetting, gentle suctioning, or irrigation with warm water.

Otitis externa, or "swimmer's ear," is a painful condition with an edematous, often weeping external canal. If severe, the entire canal may be so edematous and inflamed that it closes, making inspection of the tympanic membrane difficult. Gently tugging on the auricle is painful for many patients. The periauricular lymph nodes may be tender and enlarged. If the patient is immunocompromised or diabetic, the canal should be carefully inspected for the presence of granulation tissue at the junction of the cartilaginous and bony junction. This may signify that a malignant otitis externa is present, which, as an osteomyelitis of the temporal bone, requires aggressive management, including prompt intravenous antibiotics.

In older patients, atrophy of the external auditory canal skin is frequently seen and may be associated with psoriasis or eczema of the canal. If patients attempt to soothe an itch with foreign objects such as keys, hair pins, or cotton-tipped swabs, scabs or areas of ecchymosis may be present in the posterior canal wall.

Children are the most likely patients to insert foreign materials into the ear canal. Although most objects lodge lateral to the narrowest part of the canal, the isthmus, some are found in the anterior recess by the tympanic membrane. This makes it especially difficult for the physician to visualize with an otoscope, so patients should turn their head for this area to be viewed. In adults, cotton plugs are commonly lodged and often are impacted against the tympanic membrane. In patients of all ages, insects may find their way into the canal. An operating microscope allows excellent visualization and enables the physician to use both hands to manipulate the instruments needed to remove the object.

Otorrhea is commonly seen in the external auditory canal. The characteristics of the aural discharge may reveal the etiology of the otorrhea. For instance, mucoid drainage is associated with a middle ear chronic suppurative otitis media because only the middle ear has mucus glands. In these patients, a tympanic membrane perforation should be present to allow the mucoid otorrhea to escape. Foul-smelling otorrhea may be caused by chronic suppurative otitis media with a cholesteatoma. Bloody, mucopurulent otorrhea frequently is seen in patients with acute otitis media, trauma, or carcinoma of the ear. Otorrhea with a watery component may signify a cerebrospinal fluid leak or eczema of the canal. Black spores in the otorrhea may be present in a fungal otitis externa caused by *Aspergillus* species. Gentle suctioning is used to thoroughly clean and inspect the canal.

In patients with head trauma, a temporal bone fracture is important to recognize. Bloody otorrhea in conjunction with an external canal laceration or hemotympanum is a very serious finding. Longitudinal fractures often involve the external canal. Because longitudinal fractures may be bilateral, careful inspection of both canals is essential.

Tympanic Membrane

To view the tympanic membrane, the correct otoscope speculum size is used to allow a seal of the ear canal. With pressure from the pneumatic bulb, the tympanic membrane will move back and forth if the middle ear space is well aerated. Perforations and middle ear effusions are common causes for nonmobile tympanic membranes.

The tympanic membrane is oval, not round, and has a depressed central part called the *umbo*, wherein the handle of the malleus attaches to the membrane. The lateral process of the malleus is located in the superior anterior region and is seen as a prominent bony point in atelectatic membranes. Superior to this process is the pars flaccida, wherein the tympanic membrane lacks the radial and circular fibers present in the pars tensa, which is the remainder of the ear drum. This superior flaccid area is critical to examine carefully because retraction pockets may develop here, which may develop into cholesteatomas. In congenital cholesteatomas, often diagnosed in young children, the tympanic membrane is intact, and a white mass is seen in the anterior superior quadrant. Acquired cholesteatomas in adults are different in that they often are in the posterior superior quadrant and are associated with retraction pockets, chronic otitis media with purulent otorrhea, and tympanic membrane perforations.

To assess the middle ear for effusions, use the tympanic membrane as a window that allows a view of the middle ear structures (Fig. 8-4). Effusions may be clear (serous), cloudy with infection present, or bloody. When the patient performs a Valsalva maneuver, actual bubbles may form in the effusion.

Hearing Assessment

Tuning fork tests, usually done with a 512-Hz fork, allow the otolaryngologist to distinguish between sensorineural and conductive hearing loss (Table 8-2). They also may be used to confirm the audiogram, which may give spurious results because of poor-fitting earphones or variations in equipment or personnel. All tests should be conducted in a quiet room without background noise. Furthermore, one should ensure that the external auditory canal is not blocked with cerumen.

The Weber test is performed by placing the vibrating tuning fork in the center of the patient's forehead or at the bridge of the nose. If

the patient has difficulty with these locations, the mandible or front teeth may be used; however, the patient then should tightly clench his or her teeth. The patient then is asked if the sound is louder in one ear or is heard midline. The sound waves should be transmitted equally well to both ears through the skull bone. A unilateral sensorineural hearing loss causes the sound to lateralize to the ear with the better cochlear function. However, a unilateral conductive hearing loss causes the Weber test to lateralize to the side with the conductive loss because the cochlea are intact bilaterally and because bone conduction causes the sound to be better heard in the ear with the conductive loss (because there is less background noise detected through air conduction). Interestingly, a midline Weber result is referred to as "negative." "Weber right" and "Weber left" refer to the direction to which the sound lateralized.

To compare air conduction with bone conduction, perform the Rinne test. The 512-Hz tuning fork is placed by the ear canal and then on the mastoid process. The patient determines whether the sound is louder when the tuning fork is by the canal (air conduction) or on the mastoid bone (bone conduction). A "positive test" result is air conduction louder than bone conduction. A conductive hearing loss will make bone conduction louder than air conduction, and this is called "Rinne negative." When the air and bone conduction are equal, it is called "Rinne equal."

The Schwabach test compares the patient's hearing with the examiner's hearing and uses multiple tuning forks such as the 256-, 512-, 1024-, and 2048-Hz forks. The stem of the vibrating tuning fork is placed on the mastoid process of the patient and then on the mastoid of the physician. This is done, alternating between the two participants, until one can no longer hear the tuning fork. This test assumes that the examiner has normal hearing. If the patient hears the sound as long as the physician, the result is "Schwabach normal." If the patient hears the sound longer than the physician, it is called "Schwabach prolonged." This may indicate a conductive hearing loss for the patient. If the patient hears the sound for less time than the physician, it is called "Schwabach shortened." This is consistent with sensorineural hearing loss for the patient.

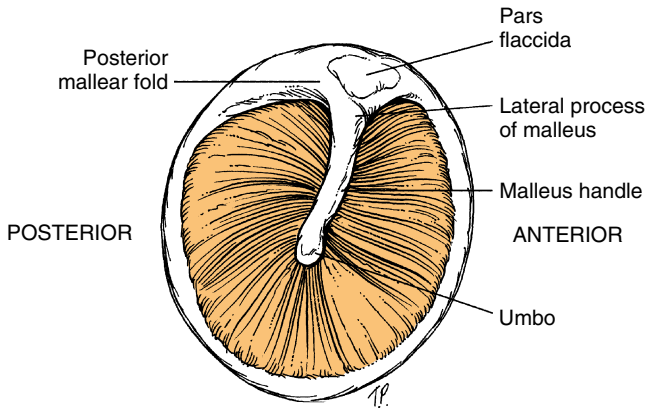

Figure 8-4. The tympanic membrane.

Oral Cavity

The boundaries of the oral cavity extend from the skin-vermillion junction of the lips, hard palate, anterior two thirds of the tongue, buccal membranes, upper- and lower-alveolar ridge, and retromolar trigone to the floor of the mouth. This region may be best seen by having the otolaryngologist use a well-directed headlight and a tongue depressor in each gloved hand. The lips should be carefully inspected. Remember that lip squamous cell carcinoma is more common on the lower lip. The commissures may have fissuring, which is seen in angular stomatitis or cheilosis. When the fissures and cracking are present on the mid-portion of the lips, this may be cheilitis.

The occlusion of the teeth and the general condition of the alveolar ridges, including the gums and teeth, should be noted. The tongue, especially the lateral surfaces where carcinomas are most common, should be inspected for induration or ulcerative lesions. Gently grabbing the anterior tongue with a gauze sponge allows the examiner to move the anterior tongue from side to side. By having the patient lift the tongue toward the hard palate, the floor of mouth and Wharton's ducts (associated with submandibular glands) can be viewed. Pooling of carcinogens in the saliva on the floor of the mouth has been postulated to cause this area to have a high incidence of carcinoma. The examiner should palpate the floor of the mouth using a bimanual approach with one gloved hand in the mouth.

Table 8-2

Tuning Fork Testing

Begin with 512-Hz fork, then include 256- and 1024-Hz forks

Weber

Place tuning fork in center of patient's forehead. Ask patient if sound is louder on one side or is heard midline.

	Weber "Negative"	Weber Right	Weber Left
Patient response	"Sound is midline"	"Sound is louder on right"	"Sound is louder on left"
Interpretation	Bone-conducted sound equal in both ears	Unilateral right conductive hearing loss; unilateral left sensorineural hearing loss	Unilateral left conductive hearing loss; unilateral right sensorineural hearing loss

Rinne

Place tuning fork lateral to ear canal, then place it firmly on mastoid process. Ask patient if sound is louder by canal or on mastoid bone.

	Rinne "Positive"	Rinne "Negative"	Rinne "Equal"
Patient response	"Sound louder when fork by canal"	"Sound louder when fork on mastoid process"	"Sound equal"
Interpretation	Air conduction louder than bone conduction; normal	Bone conduction louder than air conduction; conductive hearing loss	Air and bone conduction equal

The buccal membranes should be inspected for white plaques that may represent oral thrush, which easily scrapes off with a tongue blade, or leukoplakia, which cannot be removed. More worrisome for a precancerous condition is erythroplakia; therefore all red lesions and most white lesions should be judiciously biopsied for cancer or carcinoma in situ. While examining the buccal membranes, one should note the location of the parotid duct, or Stenson's duct, as it opens near the second upper molar. Small yellow spots in the buccal mucosa are sebaceous glands, commonly referred to as *Fordyce spots*, and are not abnormal. Aphthous ulcers, or the common canker sore, are painful white ulcers that can be on any part of the mucosa but are commonly present on the buccal membrane.

The hard palate may have a bony outgrowth known as a *torus palatinus*. These midline bony deformities are benign and should not be biopsied, although growths that are not in the midline should be more carefully evaluated as possible cancerous lesions.

Oropharynx

The oropharynx includes the posterior third of the tongue, anterior and posterior tonsillar pillars, the soft palate, the lateral and posterior pharyngeal wall, the soft palate, and the vallecula (Fig. 8-5). It is best visualized using a head lamp and two tongue depressors. A dental mirror is beneficial in viewing the vallecula and the posterior pharyngeal wall, which often are obscured. Using a gloved finger to examine the base of tongue or tonsil may reveal indurated areas that may be appropriate for biopsy for neoplasm. The patient should be aware of the possibility that gagging may ensue when this is done. In patients with especially strong gag reflexes, a fiberoptic examination may be necessary to fully assess the base of tongue, posterior pharyngeal wall, and vallecula. By carefully passing the flexible fiberoptic endoscope through the anesthetized nose, the interaction of the soft palate and tongue base during swallowing also may be viewed. The uvula should be inspected because a bifid structure may signify a submucosal cleft palate. In addition, an inflamed large uvula may mean the uvula has been traumatized during the night if the patient snores heavily. Small carcinomas or papilloma lesions also may be present, so careful palpation may be indicated.

The size of the tonsils usually is denoted as 1+, 2+, 3+, or 4+ (for "kissing tonsils" that meet in the midline). The tonsils and the base of tongue may contribute to upper-airway obstruction, especially if the soft palate and uvula extend posteriorly. Therefore the oropharyngeal aperture should be carefully assessed in each patient. Tonsillitis, caused by either bacterial or viral sources such as group A streptococci or mononucleosis, often presents with an exudate covering the cryptic tonsils. Tonsilliths are a common cause for a foreign body sensation in the back of the throat. These yellow or white concretions in the tonsillar crypts are not caused by food trapping or infection, but they often cause the patient to have halitosis and may be removed with a cotton-tipped swab.

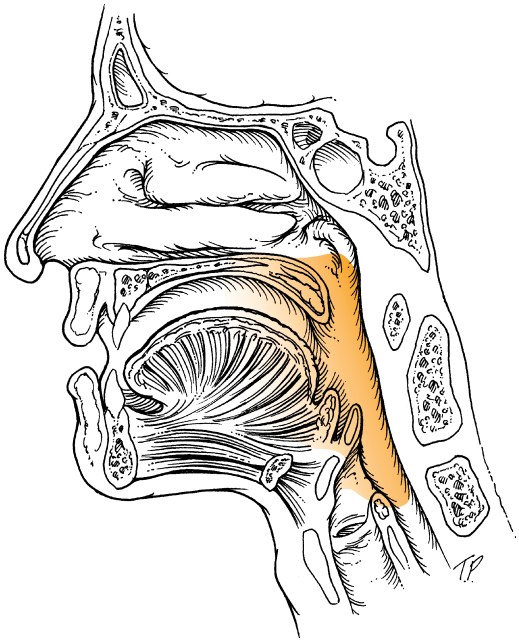

Figure 8-5. The oropharynx, which includes the posterior third of the tongue, soft palate, tonsillar pillars (anterior and posterior), lateral and posterior pharyngeal wall, and vallecula.

Larynx and Hypopharynx

The larynx often is subdivided into the supraglottis, glottis, and subglottis. The supraglottic area includes the epiglottis, the aryepiglottic folds, the false vocal cords, and the ventricles. The glottis comprises the inferior floor of the ventricle, the true vocal folds, and the arytenoids. The subglottis region generally is considered to begin 5 to 10 mm below the free edge of the true vocal fold and to extend to the inferior margin of the cricoid cartilage, although this is somewhat controversial (Fig. 8-6).

The hypopharynx can be challenging to understand. It extends from the superior edge of the hyoid bone to the inferior aspect of the cricoid cartilage by the cricopharyngeus muscle. It connects the oropharynx with the esophagus. This region comprises three areas: the pyriform sinuses, posterior hypopharyngeal wall, and the postcricoid area. This area, rich in lymphatics, may harbor tumors that often are detected only in an advanced stage. Thus early detection of these relatively "silent" carcinomas is important and should not be missed.

The examiner should not only detect anatomic abnormalities but also should observe how the larynx and hypopharynx are functioning to allow the patient to have adequate airway, vocalization, and swallow function. To survey the larynx for lesions and assess the true vocal fold function is not enough. For example, the patient with a normal-appearing larynx may have decreased laryngeal sensation with resultant aspiration and may need further diagnostic and therapeutic evaluation. Therefore important information can be obtained when the physician carefully assesses the anatomic and functional aspects of this complex area.

Correct positioning of patients increases their comfort while maximizing the examiner's view of the larynx. The legs should be uncrossed and placed firmly on the footrest. The back should be straight with the hips planted firmly against the chair. Patients, while leaning slightly forward from the waist, should place their chin upward so that the examiner's light source is sufficiently illuminating the oropharynx. After discussing the examination procedure with the patient, the patient's tongue is pulled forward by the examiner, who uses a gauze sponge between the thumb and index finger. This allows the physician's

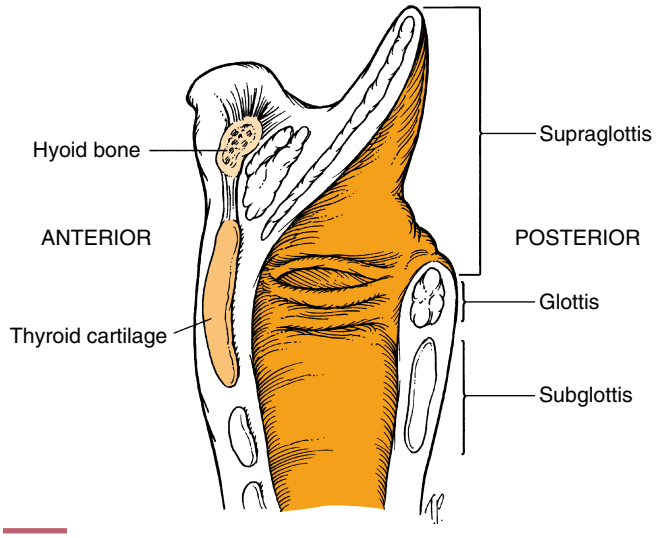

Figure 8-6. The larynx.

Figure 8-7. The laryngeal examination.

long middle finger to retract the patient's upper lip superiorly. A warm dental mirror (to prevent fogging) is placed in the oropharynx and elevates the uvula and soft palate to view the larynx (Fig. 8-7). The patient with a strong gag reflex may benefit from a small spray of local anesthetic to help suppress the reflex.

Some maneuvers allow better visualization of the larynx and its related structures. Panting, quiet breathing, and phonating with a high-pitched E aid in assessing true vocal fold function.

The epiglottis should be crisp and whitish. An erythematous, edematous epiglottis may signify epiglottitis, a serious infection or inflammation that mandates consideration of airway control. The petiole of the epiglottis is a peaked structure on the laryngeal surface of the epiglottis above the anterior commissure of the true vocal folds. It may be confused for a cyst or mass but is a normal prominence. Irregular mucosal lesions may be carcinomas and require further evaluation.

In the posterior glottis, movement of the arytenoids allows determination of true vocal fold mobility. The interarytenoid mucosa may be edematous or erythematous, sometimes representing gastroesophageal reflux laryngitis. The mucosa over the arytenoids may be erythematous as a result of rheumatoid arthritis or as a result of recent intubation trauma. Posterior glottic webs or scars also may be present.

The true vocal folds should have translucent white, crisp borders that meet each other. Edema of the folds that extends for the entire fold length often is caused by Reinke's edema, seen in tobacco users. Actual polypoid degeneration of the vocal cord with obstructing polyps may occasionally be seen in patients and may be a result of tobacco use or hypothyroidism. Ulcerative or exophytic lesions deserve further investigation, usually requiring operative direct laryngoscopy. True vocal fold paralysis and subtle gaps present between the folds during cord adduction should be noted.

During abduction of the cords, the subglottic area may be viewed. A prominent cricoid cartilage, seen inferiorly to the anterior commissure, may be mistaken for a subglottic stenosis. It is difficult to fully inspect the subglottic area in the office setting. Any concerns about subglottic inflammatory swelling, masses, or stenosis should be addressed in an operative setting or through radiographic imaging.

Flexible Endoscopy

Perhaps the best technique to evaluate the function of the larynx uses the flexible fiberoptic nasopharyngolaryngoscope. In conjunction with a strong light source, this allows a more complete evaluation of the structures of the larynx than a mirror examination.

A topical decongestant and anesthetic spray usually is applied to the nares. The patient is asked to gently sniff these nose sprays. Commonly used as topical anesthetics are 1% Pontocaine and 2% lidocaine. Another way to administer anesthesia is to carefully apply a viscous 2% lidocaine solution to the nares with a cotton-tipped applicator. It is important to allow time for these topical agents to anesthetize the nasal mucosa. While the physician is waiting, the scope can be prepared. The focus ring is used to get the brightest possible image. Often a small amount of residue is at the end of the fiberoptic scope. This can be carefully removed using either a pencil eraser or an alcohol swab. If the image is unclear before the scope is put in the nose, the image will be inadequate when the fiberoptic scope has been passed through the nares. Once the best possible focus has been obtained, before passing the scope through the nares, a small amount of water-soluble lubricant should be applied approximately 1 cm from the tip of the scope. This is to prevent breakage of the fiberoptic component of the scope while it is passed through the nose.

The laryngoscope then is gently passed along the floor of the nose and, with the instrument tip held above the epiglottis, the larynx may be viewed. Pooling of secretions in the pyriform sinuses is abnormal and is common in patients with decreased laryngeal sensation, neurologic impairment, or tumors. Saliva freely flowing in and out of the true cords is another indication of decreased laryngeal function. In some patients, having patients inhale and hold their breath often aids in viewing the pyriform sinuses. Asking the patient to cough and swallow and then viewing the residual saliva or phlegm also is helpful. The flexible fiberoptic examination enables the patient to freely phonate, unlike with the mirror examination. The true vocal folds may be assessed by moving the instrument tip into the laryngeal vestibule for closer inspection.

Rigid telescopic examination with 70-, 90-, and 110-degree telescopes is performed in a similar fashion to the mirror examination. It permits photographic documentation of the laryngeal examination. In patients with trismus, this is better tolerated than the mirror examination, and a minimal amount of local anesthetic usually is necessary.

Nose

Anterior rhinoscopy, using a head lamp and nasal speculum, allows assessment of the nasal septum and inferior turbinates. The speculum should be directed laterally to avoid touching the sensitive septum with the metal edges. The point wherein numerous small branches of the external and internal carotid arteries meet, or Kiesselbach's plexus, is the most common site for epistaxis; prominent vessels in this area should be noted. Anterior septal deviations and bony spurs often are evident. The characteristics of the mucosa of the inferior turbinate may range from the boggy, edematous, pale mucosa seen in those with allergic rhinitis to the erythematous, edematous mucosa seen in those with sinusitis.

Nasal endoscopy using rigid endoscopes allows thorough examination of even the most posterior portions of the nasal cavity. After applying a local anesthetic to the nares (either lidocaine or Pontocaine spray or topical 4% cocaine), the rigid 0-degree endoscope may be passed into the nose along the floor of the nasal vault. The septum, inferior turbinate, and eustachian tube orifices in the nasopharynx may be seen this way. Often at this time it is necessary to spray a decongestant to shrink the nasal mucosa. It is helpful to attempt to view the nasal anatomy in both the native state and after the decongestant so that the effect of the decongestant may be seen. After inspecting both sides, the endoscope is placed above the inferior turbinate to view the middle turbinate. Accessory ostia from the maxillary sinus often are present, especially in patients with chronic sinusitis. These openings into the lateral nasal wall often are mistaken for the true maxillary ostium.

Nasopharynx

The nasopharynx extends from the skull base to the soft palate. This is a challenging area to examine, but with the available technology, there are many ways to approach this region. The technique used often

depends on the anatomy of the patient. In the patient with a high posterior soft palate and small tongue base, an otolaryngologist may use a small dental mirror and a head lamp to visualize the nasopharynx. By having the patient sit upright in the chair, the physician may firmly pull the tongue forward while opening the mouth to place the mirror just posterior to the soft palate. In a manner analogous to that used to view the larynx with a mirror, the structures in the nasopharynx are seen when the mirror is oriented upward.

Another method uses a fiberoptic nasopharyngoscope, which allows excellent visualization of this area. After anesthetizing the nares with either topical cocaine (on pledgets) or applying lidocaine spray, many otolaryngologists spray the nares with a decongestant. The flexible fiberoptic scope then is gently passed along the floor of the nostril beneath the inferior turbinate. The eustachian tube orifice, torus tubarius, and fossa of Rosenmüller should be inspected on each side. This may be accomplished by using the hand control to turn the tip of the scope from side to side. The midline also should be inspected for any masses, ulcerations, or bleeding areas. Rigid endoscopes offer good visualization also, although the ability to view both sides of the nasopharynx often means passing the endoscope through each nostril. The endoscopes have various angles (e.g., 70, 90, and 110 degrees).

Arguably, the best view may be obtained using a 90-degree rigid scope in the oropharynx. By advancing the rigid scope through the mouth and by placing the beveled edge posterior to the soft palate, the nasopharynx may be seen in its entirety. Both sides of the nasopharynx may be compared for symmetry using this technique.

Whereas children have adenoid tissue present, adults should not have much adenoid tissue remaining in this area. Thus adenoid tissue should not be a cause of nasal or eustachian tube obstruction in adults. One possible exception is in patients with HIV infections, who may manifest adenoid hypertrophy as part of their disease. Nonetheless, adults with an otitis media, especially unilateral in nature, should have their nasopharynx inspected for possible nasopharyngeal masses. If present, it is important to diagnose nasopharyngeal carcinomas, which are most common lateral to the eustachian tube orifice in the fossa of Rosenmüller. In young male patients, nasopharyngeal angiofibromas are locally aggressive but histologically benign masses that are most commonly present in the posterior choana or nasopharynx. These masses should not be missed. Another malignancy to consider is non-Hodgkin's lymphoma. Cysts in the superior portion of the nasopharynx may represent a benign Tornwaldt cyst or a malignant craniopharyngioma.

Neurologic Examination

Table 8-3 outlines the basics of a neurologic examination appropriate for most head and neck patients. Certainly patients presenting with vertigo or dysequilibrium require a highly specialized neurologic examination, but that is beyond the scope of this chapter. Much valuable clinical information can be obtained with an evaluation of the cranial nerves.

Table 8-3

Neurologic Examination

Cranial Nerves	Tests
I	Sense of smell to several substances Do not use ammonia (common chemical sense caused by CN V stimulation)
II	Visual acuity Visual fields Inspect optic fundi
III	Extraocular movements in six fields of gaze
IV	Pupillary reaction to light
V	Palpate temporal and masseter muscles Patient should clench teeth Test forehead, cheeks, jaw for pain, temperature, and light (cotton) touch Corneal reflex (blinking in response to cotton touching the cornea)
VI	Near reaction to light Ptosis of upper eyelids
VII	Symmetry of face in repose Raise eyebrows, frown, close eyes tightly, smile, puff out cheeks
VIII	Auditory—tuning fork tests for hearing Vestibular—nystagmus on lateral gaze; Hallpike-Dix test; head shaking; caloric testing; Frenzel lenses
IX, X	Hoarseness True vocal cord mobility Gag reflex (CN IX or X) Movement of soft palate and pharynx
XI	Shrug shoulders against examiner's hand (trapezius muscle) Turn head against examiner's hand (sternocleidomastoid muscle)
XII	Stick tongue out Tongue deviates toward side of lesion Tongue atrophy, fasciculations

CN, cranial nerve.

Preoperative Evaluation

The patient presenting with an otolaryngologic disease process that requires surgical management must be evaluated by both general and specialty-specific criteria. Additional testing, prophylactic measures, and behavioral modification before surgery can then be implemented to maximize the surgical outcome. In addition, the patient's prior anesthetic record provides invaluable insight into issues such as airway management and overall tolerance of general, regional, local, or neuroleptic anesthesia. A social history can often be extremely beneficial as well, providing a means of anticipating postoperative needs and circumventing some prolonged admissions. Any significant issues should be raised with the departmental or hospital social worker, preferably before surgery. Last, it is important to elicit a detailed list of current medications and allergies.

In uncomplicated cases, the history and physical examination are followed by routine screening tests. Blood is drawn for a complete blood count (CBC), serum electrolytes, blood urea nitrogen (BUN), creatinine, glucose, and a clotting profile to rule out a wide range of possible occult abnormalities. In patients older than 40 years of age or in those with pertinent past medical histories, chest radiography and electrocardiography (ECG) are performed. Additionally, women of childbearing age should undergo pregnancy testing.

When the need arises, consultation with appropriate specialties should be sought quickly. The consultant should be clearly informed about the nature of the proposed procedure and should be asked to comment specifically on the relative safety of performing the procedure with respect to concomitant disease processes. In cases complicated by many medical problems or those in which the establishment of a safe airway is an issue, close consultation with the anesthesia team is advised to avoid undue delay, cancellation of the procedure, or an undesirable outcome.

It is imperative to have copies of all laboratory results, radiographs, and pertinent tests available for review before surgery. Additional studies should be ordered by the surgeon as deemed necessary.

Consent

Although a detailed discussion of the legal ramifications of informed consent is beyond the scope of this chapter, the ethical ideal deserves consideration. An integral part of the preoperative process is the physician's thorough and candid explanation to the patient of the procedure, its risks, and the probable outcomes. The relationship that develops between the surgeon and patient at this time often does more to prevent litigation if an unfortunate circumstance occurs than any legal document detailing the risks and benefits. The potential risks and outcomes that would sway a patient's decision to undergo the procedure must be discussed with the patient and documented in the chart.

Allergy

The surgeon must guard against anaphylactic reactions in all patients. The crux of this process is to have the patient identify any untoward reactions to medications, foods, or other materials. In most instances, many of the drug "reactions" described by patients do not represent true allergic phenomena. Instead, they are simply drug side effects. Nonetheless, these reactions require thorough documentation and avoidance of the allergens in the perioperative period.

Anaphylaxis results in the release of potent inflammatory agents, vasoactive substances, and proteases, all of which bring about the shock reaction. Urticaria, profound hypotension, tachycardia, bronchoconstriction, and airway-compromising edema of the mucosal surfaces of the upper aerodigestive tract may develop. Even in intubated patients, rapid oxygen desaturation is often a prominent feature. As the reaction progresses, cardiac arrest can ensue despite maximal resuscitative efforts. Given the potential morbidity and mortality of anaphylactic reactions, the otolaryngologist must identify all of a patient's allergens in the preoperative phase.

The incidence of serious adverse reactions to penicillin is about 1%. It is widely believed that there is a 10% to 15% chance that patients who manifest these reactions also react adversely to cephalosporins. Based on my empirical observations, I believe that unless these patients have had a history of significant atopy or penicillin-induced urticaria, mucosal edema, or anaphylaxis, they can be given cephalosporins with relative impunity. Anaphylactic reactions to cephalosporins in true penicillin-allergic patients are probably less than 2%. Moreover, cephalosporins cause their own independent hypersensitivity reactions. The notion of cross-reactivity with penicillin on skin testing seems to stem from data obtained in the 1970s, in which contamination of cephalosporins with penicillin was subsequently proven. Finally, if a serious penicillin allergy is evident, alternative antibiotics such as clindamycin may be substituted for the cephalosporins.

Mucosal absorption of latex protein allergens from the surgeon's gloves can rapidly incite anaphylactic shock in patients who are highly sensitive to latex. About 7% to 10% of health care workers regularly exposed to latex and 28% to 67% of children with spina bifida demonstrate positive skin tests to latex proteins. Preoperatively, if a patient gives a history suspicious for latex allergy, it should be investigated before surgery. If the allergy is documented, perioperative precautions to avoid latex exposure must be instituted.

Similarly, patients with allergic or adverse reactions to soybean or eggs may react to propofol, a ubiquitous induction agent. Protamine and intravenous contrast agents can potentially provoke hypersensitivity responses in patients with known shellfish or other fish allergies. Although rare, some patients have allergic reactions to ester types of local anesthetics such as cocaine, procaine, and tetracaine.

Finally, if the suspicion of allergy or adverse reaction exists, the best course of action is to avoid use of the potential offending agent altogether during surgery. If this is not feasible for some reason, then the surgeon and anesthesiologist should plan on premedicating the patient with systemic steroids, histamine antagonists, and even bronchodilators. The physicians should then be prepared to deal with the potential worst-case scenario of anaphylactic shock.

Systems

Cardiovascular

Cardiovascular complications are the most common cause of perioperative mortality. Specifically, an almost 50% mortality rate is associated with perioperative myocardial infarction. Meticulous review of the cardiovascular system is of utmost importance in determining a patient's surgical candidacy, especially those who will require a general anesthetic. Risk factors for a perioperative cardiovascular complication include jugular venous distention, third heart sounds, recent myocardial infarction (MI) (within 6 months), nonsinus heart rhythm, frequent premature ventricular contractions (>5 per minute), age older than 70 years, valvular aortic stenosis, previous vascular or thoracic surgery, and poor overall medical status. Emergency surgery poses an additional risk for cardiovascular complications. In the head and neck oncology patient population, the high incidence of tobacco and alcohol abuse leads to a relatively high incidence of coronary artery disease, cardiomyopathy, and peripheral vascular disease.

The otolaryngologist should obtain a history of previous MIs, angina, angioplasty or bypass surgery, congestive heart failure (CHF) or dyspnea on exertion, hypertension, general exercise tolerance, paroxysmal nocturnal dyspnea, claudication, stroke or transient ischemic attack, syncope, palpitations or other arrhythmias, as well as known anatomic or auscultative cardiac anomalies. The presence or suspicion of coronary artery disease, heart failure, untreated hypertension, or significant peripheral vascular disease should prompt a specific anesthesiology or cardiology consultation before surgery. This evaluation would include an assessment of the electrocardiogram, as well as possible exercise or chemical stress testing, echocardiography, and cardiac catheterization as indicated. The result of this consultation should determine the surgical and anesthetic risk and should optimize the patient's preoperative cardiovascular status. Furthermore, specific intraoperative and postoperative physiologic (e.g., invasive monitors) and pharmacologic precautionary measures should be delineated, as should the level of postoperative observation.

In general, patients are maintained on their antihypertensive, antianginal, and antiarrhythmic regimens up to the time of surgery. Certain medications such as diuretics and digoxin may be withheld at the discretion of the anesthesiologist or cardiologist. Preoperatively, serum electrolytes and antiarrhythmic levels should be checked and adjusted as necessary. Coagulation studies (prothrombin time [PT]/partial thromboplastin time [PTT]) and platelet quantification are routinely obtained in patients with cardiovascular risk factors because significant bleeding can lead to major perioperative cardiovascular complications. A relatively current chest radiograph is considered essential in this high-risk group.

Preoperatively, the otolaryngologist must be aware of the types of procedures that may have specific cardiovascular ramifications. Patients with prosthetic valves and those with a history of rheumatic fever, endocarditis, congenital heart defects, mitral valve prolapse with regurgitation, or hypertrophic cardiomyopathy should receive prophylactic antibiotics at the time of surgery. Such prophylaxis is especially important during procedures performed on the oral cavity and upper aerodigestive tract. This is also important when dealing with surgical drainage of head and neck infections, in which the risk of hematogenous bacterial seeding is high. For low-risk procedures, intravenous ampicillin—2 g given 30 minutes before surgery, followed by 1 g given 6 hours later—is sufficient prophylaxis. In high-risk procedures, intravenous gentamicin (1.5 mg/kg) and intravenous ampicillin (2 g) are administered 30 minutes before surgery, followed by the same doses of each 8 hours later. Patients with pacemakers or implanted defibrillators and those with mitral valve prolapse without regurgitation do not require endocarditis prophylaxis.

Airway, carotid, and vagus nerve manipulation can induce bradycardia and hypotension. Agents such as lidocaine, epinephrine, and cocaine, which are frequently used in sinonasal surgery, can trigger undesirable cardiovascular events. Injury to the cervical sympathetic chain may precipitate postural hypotension postoperatively. Finally, the surgeon must also be cognizant that a unipolar electrocautery device can reprogram a pacemaker during surgery.

Respiratory

Postoperative pulmonary complications are considered the second most common cause of perioperative mortality. This is not surprising considering the effects of general anesthesia and surgery on pulmonary

performance. Atelectasis and ventilation/perfusion mismatch occur secondary to a number of factors, including the use of anesthetic agents and positive pressure ventilation, as well as supine positioning. Anesthetic agents, barbiturates, and opioids tend to diminish the ventilatory response to hypercarbia and hypoxia. Endotracheal intubation bypasses the warming and humidifying effects of the upper airway, leading to impaired ciliary function, thickened secretions, and subsequent decreased resistance to infection. Furthermore, postoperative pain substantially affects a patient's ability to cough, especially following thoracic or abdominal procedures (e.g., chest myocutaneous flap, gastric pull-up, percutaneous endoscopic gastrostomy, rectus free-flap, iliac crest bone graft). Because of their attenuated respiratory reserve, patients with chronic pulmonary disease are much more likely to suffer postoperative pulmonary complications than are healthy patients. For instance, heavy smokers have a threefold increase in the risk of postoperative pulmonary complications when compared with nonsmokers. Hence it is imperative to identify these patients during the preoperative evaluation.

Specifically, a positive history of asthma, chronic obstructive pulmonary disease, emphysema, tobacco abuse, pneumonia, pulmonary edema, pulmonary fibrosis, or adult respiratory distress syndrome requires heightened attention before surgery. The prior treatment of these lung problems, including the number of hospitalizations and emergency department visits; the use of medications like steroids, antibiotics, and bronchodilators; and the need for intubation or chronic oxygen therapy should be addressed. The otolaryngologist should obtain an estimate of the patient's dyspnea, exercise limitation, cough, hemoptysis, and sputum production. Factors that exacerbate chronic lung disease must be identified. Once again, it is of paramount importance to investigate the tolerance of previous anesthetics in this high-risk group. Coexisting cardiac and renal disease such as CHF and chronic renal failure also impact heavily on pulmonary function. Pulmonary hypertension and cor pulmonale secondary to obstructive sleep apnea, cystic fibrosis, muscular dystrophy, emphysema, or kyphoscoliosis further complicate anesthetic management. Congenital diseases affecting the lungs such as cystic fibrosis and Kartagener's syndrome (rare) present the challenge of perioperative clearance of secretions.

On physical examination, the clinician should be attuned to the patient's body habitus and general appearance. Obesity, kyphoscoliosis, and pregnancy can all predispose to poor ventilation, atelectasis, and hypoxemia. Cachectic patients are more likely to develop postoperative pneumonia. It should be noted that clubbing and cyanosis, although suggestive, are not reliable indicators of chronic pulmonary disease. The patient's respiratory rate is determined, and the presence of accessory muscle use, nasal flaring, diaphoresis, or stridor should be documented. Auscultation that reveals wheezing, rhonchi, diminished breath sounds, crackles, rales, and altered inspiratory/expiratory time ratios should raise the suspicion of pulmonary compromise.

In patients with pulmonary disease, preoperative posteroanterior and lateral chest radiography is mandatory, because findings often direct modification of the anesthetic technique used during surgery. Arterial blood gas (ABG) testing on room air is also indicated. Patients with an arterial oxygen tension less than 60 mm Hg or an arterial carbon dioxide tension greater than 50 mm Hg are more likely to have postoperative pulmonary complications. Serial ABG determinations can also be used to assess the overall efficacy of preoperative medical and respiratory therapy. As with chest radiography, preoperative ABG levels also provide a baseline for postoperative comparison.

Preoperative pulmonary function tests such as spirometry and flow-volume loops are quite helpful. A quantitative measure of ventilatory function can also be used to assess the efficacy of both preoperative and surgical interventions. Spirometry can be used to differentiate restrictive from obstructive lung disease, as well as to predict perioperative morbidity from pulmonary complications. Generally, a forced expiratory volume in 1 second/forced vital capacity ratio of less than 75% is considered abnormal, whereas a ratio of less than 50% carries a significant risk of perioperative pulmonary complications. Preoperative flow-volume loops can distinguish among fixed (e.g., goiter), variable extrathoracic (e.g., unilateral vocal cord paralysis), and variable intrathoracic (e.g., tracheal mass) airway obstructions.

The preoperative management of otolaryngology patients with significant pulmonary disease is vital and should follow the recommendations of a pulmonologist. Smokers are advised to cease smoking for at least a week before surgery. Chest physiotherapy aimed at increasing lung volumes and clearing secretions is instituted. This includes coughing and deep breathing exercises, incentive spirometry, and chest percussion with postural drainage. It is not advisable to operate on a patient with an acute exacerbation of pulmonary disease or with an acute pulmonary infection. Acute infections should be cleared with antibiotics and chest physiotherapy before elective surgery. Prophylactic antibiotics in noninfected patients are not recommended for fear of selecting out resistant organisms. Finally, the medical regimen, including the use of inhaled beta-adrenergic agonists, cromolyn, and steroids (inhaled or systemic), must be optimized. Serum levels of theophylline, if used, should be therapeutic.

Renal

The preoperative identification and evaluation of renal problems is also imperative. Any significant electrolyte abnormalities uncovered during the routine screening of healthy patients should be corrected preoperatively, and surgery should be delayed if additional medical evaluation is warranted. Preexisting renal disease is a major risk factor for the development of acute tubular necrosis both during and after surgery. Renal failure, whether acute or chronic, influences the types, dosages, and intervals of perioperative drugs and anesthetics. An oliguric or anuric condition requires judicious fluid management, especially in patients with cardiorespiratory compromise. Furthermore, chronic renal failure (CRF) is often associated with anemia, platelet dysfunction, and coagulopathy. Electrolyte abnormalities, particularly hyperkalemia, can lead to arrhythmias, especially in the setting of the chronic metabolic acidosis that often accompanies CRF. Hypertension and accelerated atherosclerosis resulting from CRF are risk factors for developing myocardial ischemia intraoperatively. Blunted sympathetic responses may predispose to hypotensive episodes during administration of anesthesia. The otolaryngologist must also be wary of the potential for injury to demineralized bones during patient positioning. An impaired immune system can contribute to poor wound healing and postoperative infection. Finally, because patients with CRF have often received blood transfusions, they are at increased risk of carrying blood-borne pathogens such as hepatitis B and C.

The possible causes of renal disease, including hypertension, diabetes, nephrolithiasis, glomerulonephritis, polycystic disease, lupus, polyarteritis nodosa, Goodpasture's or Wegener's syndrome, trauma, or previous surgical or anesthetic insults, should be elicited. The symptoms of polyuria, polydipsia, fatigue, dyspnea, dysuria, hematuria, oliguria or anuria, and peripheral edema are recorded, as is a complete listing of all medications taken by the patient.

In dialyzed patients, it is important to document the dialysis schedule. A nephrologist should assist with the preoperative evaluation and should optimize the patient's fluid status and electrolytes before surgery. A nephrologist should also be available to help manage these issues postoperatively, especially when major head and neck, skull-base, or neurotologic surgery—which may require large volumes of fluids or blood transfusions intraoperatively—is planned.

Preoperative testing on patients with significant renal disease routinely includes ECG, chest radiography, electrolytes and chemistry panel, CBC, PT/PTT, platelet counts, and bleeding times. In addition to a nephrologic consultation, patients with significant renal disease should also receive a preoperative anesthesiology consultation, and, if indicated, further evaluation by a cardiologist.

A history of benign prostatic hypertrophy or prostate cancer, with or without surgery, may predict a difficult urinary tract catheterization intraoperatively. Finally, elective surgery should not be performed on patients with acute genitourinary tract infections because the potential for urosepsis can be increased by the transient immunosuppression associated with general anesthesia.

Hepatic Disorders

Preoperative evaluation of patients with suspected or clinically evident liver failure should begin with a history detailing hepatotoxic drug

therapy, jaundice, blood transfusion, upper gastrointestinal bleeding, and previous surgery and anesthesia. The physical should include examination for hepatomegaly, splenomegaly, ascites, jaundice, asterixis, and encephalopathy. The list of blood tests is fairly extensive and includes hematocrit, platelet count, bilirubin, electrolytes, creatinine, BUN, serum protein, PT/PTT, serum aminotransferases, alkaline phosphatase, and lactate dehydrogenase. A viral hepatitis screen can be obtained as well. Of note, patients with moderate to severe chronic alcoholic hepatitis may present with relatively normal-appearing liver function tests and coagulation parameters; these patients are at risk for perioperative liver failure.

Cirrhosis and portal hypertension have wide-ranging systemic manifestations. Arterial vasodilation and collateralization leads to decreased peripheral vascular resistance and an increased cardiac output. This hyperdynamic state can occur even in the face of alcoholic cardiomyopathy. The responsiveness of the cardiovascular system to sympathetic discharge and administration of catechols is also reduced, likely secondary to increased serum glucagon levels. Cardiac output can be reduced by the use of propranolol, which has been advocated by some as a treatment for esophageal varices. By decreasing cardiac output, flow through the portal system and the esophageal variceal collaterals is diminished. Additionally, there is likely a selective splanchnic vasoconstriction. Once initiated, beta-blockade cannot be stopped easily because of a significant rebound effect.

Renal sequelae vary with the severity of liver disease from mild sodium retention to acute failure associated with the hepatorenal syndrome. Diuretics given to decrease ascites can often lead to intravascular hypovolemia, azotemia, hyponatremia, and encephalopathy. Fluid management in the perioperative period should be followed closely and dialysis instituted as needed for acute renal failure.

From a hematologic standpoint, patients with cirrhosis often have an increased 2,3-diphosphoglycerate level in their erythrocytes, causing a shift to the right of the oxyhemoglobin dissociation curve. Clinically, this results in a lower oxygen saturation. This situation is further compounded by the frequent finding of anemia. Additionally, significant thrombocytopenia and coagulopathy may be encountered. The preoperative use of appropriate blood products can lead to short-term correction of hematologic abnormalities, but the prognosis in these patients remains poor.

Encephalopathy stems from insufficient hepatic elimination of nitrogenous compounds. Although measurements of BUN and serum ammonia levels are useful, they do not always correlate with the degree of encephalopathy. Treatment includes hemostasis, antibiotics, meticulous fluid management, low-protein diet, and lactulose.

Endocrine Disorders

Thyroid

Symptoms of hyperthyroidism include weight loss, diarrhea, skeletal muscle weakness, warm, moist skin, heat intolerance, and nervousness. Laboratory test results may demonstrate hypercalcemia, thrombocytopenia, and mild anemia. Elderly patients also can present with heart failure, atrial fibrillation, or other dysrhythmias. The term *thyroid storm* refers to a life-threatening exacerbation of hyperthyroidism that results in severe tachycardia and hypertension.

Treatment of hyperthyroidism attempts to establish a euthyroid state and to ameliorate systemic symptoms. Propylthiouracil inhibits both thyroid hormone synthesis and the peripheral conversion of T4 to T3. Complete clinical response may take up to 8 weeks, during which the dosage may need to be tailored to prevent hypothyroidism. Potassium iodide (Lugol's solution), which works by inhibiting iodide organification, can be added to the medical regimen. In patients with sympathetic hyperactivity, beta-blockers have been used effectively. Propranolol has the added benefit of decreasing T4-to-T3 conversion. It should not be used in patients with CHF secondary to poor left ventricular function or bronchospasm because it will exacerbate both of these conditions. Ideally, medical therapy should prepare a mildly thyrotoxic patient for surgery within 7 to 14 days. If the need for emergency surgery arises, intravenous propranolol or esmolol can be administered and titrated to keep the heart rate below 90 bpm. Other medications that can be used include reserpine and guanethidine, which deplete catechol stores, and glucocorticoids, which decrease both thyroid hormone secretion and T4-to-T3 conversion. Radioactive iodine also can be used effectively to obliterate thyroid function but should not be given to women of childbearing years.

The symptoms of hypothyroidism result from inadequate circulating levels of T4 and T3 and include lethargy, cognitive impairment, and cold intolerance. Clinical findings may include bradycardia, hypotension, hypothermia, hypoventilation, and hyponatremia. There is no evidence to suggest that patients with mild to moderate hypothyroidism are at increased risk for anesthetic complications, but all elective surgery patients should be treated with thyroid hormone replacement before surgery. Severe hypothyroidism resulting in myxedema coma is a medical emergency and is associated with a high mortality rate. Intravenous infusion of T3 or T4 and glucocorticoids should be combined with ventilatory support and temperature control as needed.

Parathyroid

The prevalence of primary hyperparathyroidism increases with age. Of patients with primary hyperparathyroidism, 60% to 70% present initially with nephrolithiasis secondary to hypercalcemia, and 90% are found to have benign parathyroid adenomas. Hyperparathyroidism secondary to hyperplasia occurs in association with medullary thyroid cancer and pheochromocytoma in multiple endocrine neoplasia type IIA and, more rarely, with malignancy. In humoral hypercalcemia of malignancy, nonendocrine tumors have been demonstrated to secrete a parathyroid hormone-like protein. Secondary hyperparathyroidism usually results from chronic renal disease. The hypocalcemia and hyperphosphatemia associated with this condition lead to increased parathyroid hormone production and, over time, to parathyroid hyperplasia. Tertiary hyperparathyroidism occurs when the CRF is rapidly corrected as occurs in renal transplantation.

In addition to nephrolithiasis, signs and symptoms of hypercalcemia include polyuria, polydipsia, skeletal muscle weakness, epigastric discomfort, peptic ulceration, and constipation. Radiographs may show significant bone resorption in 10% to 15% of patients. Depression, confusion, and psychosis also may be associated with marked elevations in serum calcium levels.

Immediate treatment of hypercalcemia usually combines sodium diuresis with a loop diuretic and rehydration with normal saline as needed. This becomes urgent once the serum calcium levels rise above 15 g/dL. Several medications can be used to decrease serum calcium levels. Etidronate inhibits abnormal bone resorption. The cytotoxic agent mithramycin inhibits parathyroid hormone–induced osteoclastic activity but is associated with significant side effects, and calcitonin works transiently again by direct inhibition of osteoclast activity. Hemodialysis can also be used in the appropriate patient population.

The most common cause of hypoparathyroidism is iatrogenic. Thyroid and parathyroid surgery occasionally results in the inadvertent removal of all parathyroid tissue. Ablation of parathyroid tissue can also occur after major head and neck surgery and postoperative radiation therapy. Symptoms include tetany, perioral and digital paresthesias, muscle spasm, and seizures. Chvostek's sign (facial nerve hyperactivity elicited by tapping over the common trunk of the nerve as it passes through the parotid gland) and Trousseau's sign (finger and wrist spasm after inflation of a blood pressure cuff for several minutes) are clinically important indicators of latent hypocalcemia. Treatment is with calcium supplementation and vitamin D analogs.

Adrenal

Adrenal gland hyperactivity can result from a pituitary adenoma, a corticotropin hormone (ACTH)-producing nonendocrine tumor, or a primary adrenal neoplasm. Symptoms include truncal obesity, proximal muscle wasting, "moon" facies, and changes in behavior that vary from emotional lability to frank psychosis. Diagnosis is made through the dexamethasone suppression test, and treatment is adrenalectomy or hypophysectomy. It is important to regulate blood pressure and serum glucose levels and to normalize intravascular volume and electrolytes. Primary aldosteronism (Conn's syndrome) results in increased renal tubular exchange of sodium for potassium and hydrogen ions. This

leads to hypokalemia, skeletal muscle weakness, fatigue, and acidosis. The aldosterone antagonist spironolactone should be used if the patient requires diuresis.

Idiopathic primary adrenal insufficiency (Addison's disease) results in both glucocorticoid and mineralocorticoid deficiencies. Symptoms include asthenia, weight loss, anorexia, abdominal pain, nausea, vomiting, diarrhea, constipation, hypotension, and hyperpigmentation. Hyperpigmentation is caused by overproduction of ACTH and beta-lipotropin, which leads to melanocyte proliferation. Measurement of plasma cortisol levels 30 and 60 minutes after intravenous administration of ACTH (250 mg) aids in diagnosis. Patients with primary adrenal insufficiency demonstrate no response. Glucocorticoid replacement is required on a twice-daily basis and should be increased with stress. Mineralocorticoid therapy can be given once daily. Of note, patients treated for more than 3 weeks with exogenous glucocorticoids for any medical condition should be assumed to have suppression of their adrenal-pituitary axis and should be treated with stress-dose steroids perioperatively.

Pheochromocytoma is a tumor of the adrenal medulla that secretes both epinephrine and norepinephrine. Of these tumors, 5% are inherited in an autosomal dominant fashion as part of a multiple endocrine neoplasia syndrome. Symptoms include hypertension (which is often episodic), headache, palpitations, tremor, and profuse sweating. Preoperative treatment begins with phenoxybenzamine (a long-acting alpha-blocker) or prazosin at least 10 days before surgery. A beta-blocker is added only after the establishment of alpha-blockade to avoid unopposed beta-mediated vasoconstriction. Acute hypertensive crises can be managed with nitroprusside or phentolamine.

Diabetes Mellitus

Diabetes is a disorder of carbohydrate metabolism that results in a wide range of systemic manifestations. It is the most common endocrine abnormality found in surgical patients and can be characterized as either insulin-dependent (type I or juvenile onset) or non–insulin-dependent (type II). Hyperglycemia may result from a variety of etiologies that affect insulin production and function. Management techniques seek to avoid hypoglycemia and maintain high-normal serum glucose levels throughout the perioperative period. These goals are often difficult to maintain, however, because infection, stress, exogenous steroids, and variations in carbohydrate intake can all cause wide fluctuations in serum glucose levels. Close monitoring is mandatory with correction of hyperglycemia, using a sliding scale for insulin dosage or continuous intravenous infusion in more severe cases. Fluid management should focus on maintaining hydration and electrolyte balance.

Hematologic Disorders

A history of easy bruising or excessive bleeding with prior surgery should raise suspicion of a possible hematologic diathesis. A significant number of patients will also present on anticoagulative therapy for coexisting medical conditions. After a careful history, the physician should obtain laboratory studies. PT, PTT, and platelet count are included in the routine preoperative screen. PT evaluates both the extrinsic and the final common pathways. Included in the extrinsic pathway are the vitamin K–dependent factors II, VII, IX, and X, which are inhibited by warfarin. Conversely, heparin inhibits thrombin and factors IXa, Xa, and XIa, elements of the intrinsic clotting pathway. PTT measures the effectiveness of the intrinsic and final common pathways. Relative to the normal population, some patients may demonstrate significant variation in the quantitative levels of certain factors in the absence of clinically relevant clotting abnormalities. Thrombocytopenia or platelet dysfunction can also lead to derangements in coagulation. A standard CBC includes a platelet count, which should be greater than 50,000 to 70,000 before surgery. The ivy bleeding time, a clinical test of platelet function, should be between 3 and 8 minutes. Fibrin split products may also be measured to help determine the diagnosis of disseminated intravascular coagulation.

Congenital

Congenital deficiencies of hemostasis affect up to 1% of the population. The majority of these deficiencies are clinically mild. Two of the more serious deficiencies involve factor VIII, which is a complex of two subunits, factor VIII:C and factor VIII:von Willebrand's factor. Gender-linked recessive transmission of defects in the quantity and quality of factor VIII:C leads to hemophilia A. Because of its short half-life, perioperative management of factor VIII:C requires infusion of cryoprecipitate every 8 hours. The disease that has a milder presentation than hemophilia A is von Willebrand's disease, in which bleeding tends to be mucosal rather than visceral.

This disease is categorized into three subtypes. Types I and II represent quantitative and qualitative deficiencies, respectively. These deficiencies are passed by autosomal dominant transmission. Type I von Willebrand's also is characterized by low levels of factor VIII:C. Type III von Willebrand's disease is much rarer and presents with symptoms similar to those of hemophilia A. Because of the longer half-life of factor VIII:von Willebrand's factor, patients with type II von Willebrand's disease can be transfused with cryoprecipitate up to 24 hours before surgery, with repeat infusions every 24 to 48 hours. Patients with type I von Willebrand's disease require additional transfusion just before surgery to boost factor VIII:C levels and normalize bleeding time.

Patients with hemophilia, von Willebrand's disease, and other less common congenital hemostatic anomalies should be followed perioperatively by a hematologist. Correction of factor deficiencies should be instituted in a timely fashion, and patients should be monitored closely for any evidence of bleeding.

Anticoagulants

Warfarin, heparin, and aspirin have become commonly used medications in the medical arsenal. Conditions such as atrial fibrillation, deep vein thrombosis, pulmonary embolism, and heart valve replacement are routinely treated initially with heparin, followed by warfarin on an outpatient basis. This therapy markedly decreases the incidence of thromboembolic events and, when appropriately monitored, only slightly increases the risk of hemorrhagic complications. Aspirin is widely used both as an analgesic and as prophylaxis for coronary artery disease. Patients taking any of these medications need careful evaluation to assess the severity of the condition necessitating anticoagulation. The benefit of surgery relative to the risk of normalizing coagulation should be clearly established with both the patient and the physician prescribing the anticoagulant.

Warfarin should be stopped at least 3 days before surgery, depending on liver function. Patients who have been determined to be at high risk for thromboembolism should be admitted for heparinization before surgery. The infusion rate can then be adjusted to maintain the PTT in a therapeutic range. Discontinuation of heparin approximately 6 hours before surgery should provide adequate time for reversal of anticoagulation. In emergency situations, warfarin can be reversed with vitamin K in approximately 6 hours and more quickly with the infusion of fresh frozen plasma (FFP). Heparin effects can be reversed with protamine or FFP. Of note, a heparin rebound phenomenon in which anticoagulative effects are reestablished can occur up to 24 hours after the use of protamine. Anticoagulative therapy can be reinstituted soon after surgery if necessary. Most surgeons, however, prefer to wait several days unless contraindicated. The surgeon may often find it helpful to discuss the timing of postoperative therapy with the hematologist before surgery.

Aspirin, an irreversible inhibitor of platelet function, leads to prolonged bleeding time. No strong evidence links aspirin therapy with excessive intraoperative bleeding. However, the theoretical risk that aspirin and other nonsteroidal anti-inflammatory medications present leads most surgeons to request that their patients stop taking these medications up to 2 weeks before surgery to allow the platelet population to turn over.

Liver Failure

Patients with liver failure can present with several hematologic abnormalities. Bleeding from esophageal varices secondary to portal hypertension can lead to anemia. Hypersplenism and alcoholic bone marrow suppression can result in serious thrombocytopenia. An elevated PT may indicate a deficiency in the vitamin K–dependent factors of the

extrinsic clotting pathway, as well as factors I, V, and XI, which are also produced in the liver. Last, as liver failure progresses, excessive fibrinolysis may occur. All of these hematologic sequelae of hepatic failure increase the risk of operative morbidity and mortality. Preoperative management should attempt to correct anemia and thrombocytopenia as indicated and replenish deficient clotting factors with FFP. Fluid management may prove to be a difficult issue.

Another less common cause of PT elevation is the intestinal sterilization syndrome in which intestinal flora, a major source of vitamin K, are eradicated by prolonged doses of antibiotics in patients unable to obtain vitamin K from other sources. Reversal occurs rapidly with vitamin K therapy.

Thrombocytopenia

A decrease in platelet count can occur as a result of a variety of medical conditions, including massive transfusion, liver failure, disseminated intravascular coagulation, aplastic anemia, hematologic malignancy, and idiopathic thrombocytopenic purpura. With the increasing use of chemotherapeutics for a variety of malignancies, the prevalence of iatrogenic thrombocytopenia has risen. Preoperatively, the platelet count should be greater than 50,000; at levels below 20,000, spontaneous bleeding may occur. Additionally, any indication of platelet dysfunction should be evaluated with a bleeding time. Severe azotemia secondary to renal failure may lead to platelet dysfunction (uremic platelet syndrome). Dialysis should be performed as necessary.

Correction of thrombocytopenia with platelet transfusion should preferably come from human leukocyte antigen–matched donors, particularly in patients who have received prior platelet transfusions and may be sensitized. One unit of platelets contains approximately 5.5×10^{11} platelets. One unit per 10 kg of body weight is a good initial dose. The platelets should be infused rapidly just before surgery.

Hemoglobinopathies

Of the more than 300 hemoglobinopathies, sickle cell disease and thalassemia are by far the most common. Approximately 10% of blacks in the United States carry the gene for sickle cell anemia. The heterozygous state imparts no real anesthetic risk. There are significant clinical manifestations to the 1 in 400 blacks who are homozygous for hemoglobin S. The genetic mutation results in the substitution of valine for glutamic acid in the sixth position of the beta-chain of the hemoglobin molecule, leading to alterations in the shape of erythrocytes when the hemoglobin deoxygenates. The propensity for sickling directly relates to the quantity of hemoglobin S. Clinical findings include anemia and chronic hemolysis. Infarction of multiple organ systems can occur secondary to vessel occlusion. Treatment consists of preventive measures. Oxygenation and hydration help maintain tissue perfusion. Transfusion before surgical procedures decreases the concentration of erythrocytes carrying hemoglobin S, thereby lowering the chance of sickling.

Multiple types of thalassemia exist, each caused by genetic mutations in one of the subunits of the hemoglobin molecule. Symptoms vary on the severity of the mutation. Patients with the most severe form, beta-thalassemia major, are transfusion-dependent, which often leads to iron toxicity. Other thalassemias cause only mild hemolytic anemia. If transfusion dependency exists, the patient should be screened carefully for hepatic and cardiac sequelae of iron toxicity.

Neurologic

For medicolegal reasons, it is critical to document all neurologic abnormalities. The surgeon should distinguish peripheral from central lesions, and CT or MRI is often helpful in this regard. Frequently, neurologic consultation is sought in the setting of subtle findings or confusing or paradoxic findings and for evaluation of possible nonotolaryngologic etiologies of certain complaints, such as headache and dysequilibrium. During preoperative patient counseling, the surgeon must be aware of the potential for nerve injury or sacrifice and must communicate the possible sequelae of these actions to the patient.

If the patient has a history of seizures, the surgeon needs to find out the type, pattern, and frequency of the epilepsy, as well as the current anticonvulsant medications in use and their side effects. Phenytoin therapy can lead to poor dentition and anemia, whereas treatment with carbamazepine can cause hepatic dysfunction, hyponatremia, thrombocytopenia, and leukopenia, all of which represent concerns for the surgeon and anesthesiologist. Preoperative CBC, liver function tests, and coagulation studies are thus advised. Anesthetic agents such as enflurane, propofol, and lidocaine have the potential to precipitate convulsant activity, depending on their doses. In general, antiseizure medications must be at therapeutic serum levels and should be continued up to and including the day of surgery.

Symptomatic autonomic dysfunction can contribute to intraoperative hypotension. It may be necessary to augment intravascular volume preoperatively through increasing dietary salt intake, maximizing hydration, and administering fludrocortisone.

Additional considerations must be taken into account in patients with upper motor neuron diseases, such as amyotrophic lateral sclerosis, or lower motor neuron processes affecting cranial nerve nuclei in the brainstem. In either case, the otolaryngologist may be confronted with bulbar symptoms such as dysphagia, dysphonia, and inefficient mastication. As bulbar impairment progresses, the risk of aspiration increases significantly. When respiratory muscles are affected, the patient is likely to have dyspnea, intolerance to lying flat, and an ineffective cough. Coupled with aspiration, these factors put the patient at considerable surgical risk for pulmonary complications. Hence, if surgery is necessary for these patients, preoperative evaluation should include a pulmonary workup (including chest radiography, pulmonary function tests, ABG analysis) and consultation. A video study of swallowing function may also be indicated. Finally, the patient's neurologist should be closely involved in the decision making (i.e., whether to proceed with surgery).

Parkinsonism presents the challenges of excessive salivation and bronchial secretions, gastroesophageal reflux, obstructive and central sleep apnea, and autonomic insufficiency, all of which predispose to difficult airway and blood pressure management in the perioperative period. Dopaminergic medications should be administered up to the time of surgery to avoid the potentially fatal neuroleptic malignant syndrome. Medications such as phenothiazines, metoclopramide, and other antidopaminergics should be avoided. Preoperatively, the patient's pulmonary function and autonomic stability should be investigated.

If clinically indicated, patients with multiple sclerosis should also undergo full pulmonary evaluation preoperatively, because these patients can present with poor respiratory and bulbar function. The presence of contractures can limit patient positioning on the operating table. In addition, before surgery, the patient must be free of infection because pyrexia can exacerbate the conduction block in demyelinated neurons.

Older Patients

Of all surgeries currently performed, 25% to 33% are performed on people older than 65 years of age. This percentage is likely to increase as the population ages. A greater likelihood of comorbid conditions exists with increasing age. In addition, physiologic reserve is often compromised. Preoperative assessment in this population should take these considerations into account and weigh the benefit of the procedure against the often increased risks in this population. Consultation with the anesthesia service facilitates planning for high-risk older patients.

Approximately 50% of all postoperative deaths in older adults occur secondary to cardiovascular events. Severe cardiac disease should be treated before any elective procedure and should be weighed against the benefit of any more urgent procedure. If surgery is required, cardiac precautions should be instituted. Patients with physical evidence or a history of peripheral vascular disease should be evaluated for carotid artery stenosis. If a critical stenosis is identified, carotid endarterectomy should be performed before any elective procedure that requires a general anesthetic. The risk of a cerebrovascular accident should be considered when evaluating patients for more urgent procedures. From a respiratory standpoint, increasing age leads to loss of lung compliance, stiffening of the chest wall, and atrophy of respiratory muscles. In many otolaryngology procedures, the surgeon should consider the risk of intraoperative or postoperative aspiration and postobstructive pulmonary edema. Patients with borderline pulmonary function may not

tolerate even mild respiratory complications. The function of all the organ systems diminishes with age, necessitating a thorough preoperative evaluation to maximize older patient safety.

Conclusion

This chapter provides a brief overview of the importance for the surgeon to gather a patient's history and complete a physical examination and preoperative evaluation. Disturbances in one organ system often have repercussions for other systems, so an interdisciplinary approach involving the otolaryngologist, anesthesiologist, internist, and specialized consultants is often warranted. This chapter emphasizes the physiologic aspects of the evaluation, without intending to overshadow the importance of gaining insight into a patient's psychosocial preparedness, which often requires the help of family members, social workers, psychiatrists, and support groups, as well as a keen sense of intuition on the part of the surgeon. Furthermore, the surgeon's preoperative discussions with the patient provide a means to reinforce the patient's postoperative expectations and coping mechanisms. Finally, the responsibility of ensuring an appropriate preoperative evaluation lies with the surgeon and the expediency of this process should be in keeping with the best interests of the patient.

CHAPTER NINE

General Considerations of Anesthesia and Management of the Difficult Airway

Lynette Mark

Kurt Herzer

Seth Akst

James Michelson

Key Points

- Preoperative patient evaluation by the anesthesiologist identifies a patient with a potentially difficult airway/intubation.
- Basic anesthetic techniques are undertaken with specific attention to implications of anesthetics in airway management.
- Indications and limitations of airway techniques primarily used by anesthesiologist and emergency physicians are discussed.
- The American Society of Anesthesiology (ASA) Guidelines for Management of the Difficult Airway and the role of the otolaryngology—head and neck (OLHN) surgeon in using these guidelines are reviewed.
- The Johns Hopkins Medical Institutions Departments of Anesthesiology and Critical Care Medicine (ACCM) and OLHN Airway Management Initiative are outlined.
- Mechanisms for communicating patient airway information to other health care providers and patients are discussed.
- Case presentations are focused on the use of the ASA Difficult Airway Algorithm.
- Case presentations are focused on catastrophic events and the role of the OLHN surgeon.

Airway management is the essence of clinical anesthesiology. Complex airway management of the patient with an anticipated difficult airway/intubation or the patient with an unanticipated difficult airway/intubation is a multispecialty process that involves anesthesiologists, surgeons, pulmonologists, critical care physicians, emergency physicians, and nursing/technician staff support.

The OLHN surgeon with expertise in rigid laryngoscopy and bronchoscopy, flexible fiberoptic bronchoscopy, and surgical approaches to the airway is uniquely qualified to take the lead surgical role in a team approach with the anesthesiologist to safely manage difficult airway/intubation patients. The goal of airway management is simple: to provide the most expeditious form of management that has the lowest potential for injury and the greatest potential for control of the airway.[1]

The approach to the patient with a difficult airway varies, depending on whether management is elective or urgent and whether the health care setting is an operating room or a non–operating room environment.

This chapter presents the anesthetic component of complex airway management in a manner that OLHN surgeons can incorporate into their practice. The focus of this chapter is on clinical airway algorithms and the decisions that must be made by the anesthesiologist together with the OLHN surgeon to safely provide anesthesia and airway management for their patient or for a non-OLHN patient seen in joint consultation for airway management. In-depth discussions about the pharmacology and physiology of anesthesiology are beyond the scope of this chapter but can be found in any number of authoritative textbooks of anesthesiology.[2,3]

Difficult Airway/Intubation: A Multispecialty Problem

Complex airway management is a multifaceted problem involving health care providers in a variety of clinical settings. The consequences of failed airway maintenance, endotracheal intubation, or both, can be devastating to the patient, the practitioner, and the health care system. Critical issues include identification of difficult airway/intubation patients, mobilization of physician and support staff, mobilization of airway management equipment, preparation of the patient, implementation of appropriate airway algorithms, documentation of airway management techniques, dissemination of critical airway information to future health care providers, and quality improvement/medicolegal considerations.

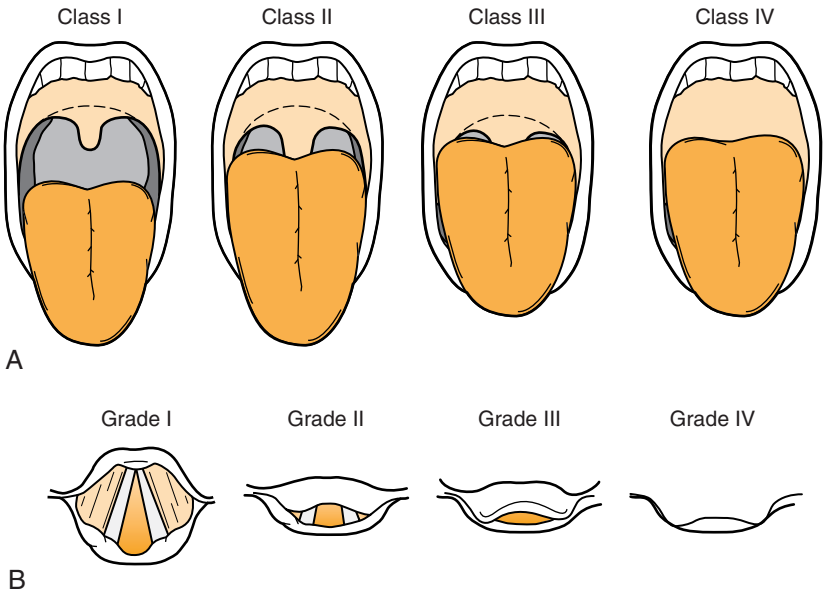

Figure 9-1. Mallampati, Cormach, and Lehand oral **(A)** and laryngoscopic **(B)** views.

Figure 9-2. Anesthesia resident with thick neck, 5′8,″ 95 kg, viewed by colleagues as "anticipated difficult" airway. Mallampati class I oral view. Airway algorithm for elective surgery: mask ventilation easy; direct laryngoscopy times one with MAC No. 4 with full grade I laryngoscopic view.

Figure 9-3. Patient evaluated to have a Mallampati class II airway with a tongue blade and anticipated easy intubation with conventional laryngoscopy. Airway algorithm for elective surgery: mask ventilation easy; unsuccessful direct laryngoscopy with MAC No. 3/4 Miller No. 2/3 times 4; successful asleep oral fiberoptic intubation with No. 7.0 ETT with view of complete glottic opening.

Patient Identification

Controversy regarding predictors and definitions of "difficult" exists in both intraspecialty and interspecialty, dependent and independent of practitioner skill, related to specific techniques, and complicated by changing patient pathophysiology.[4] Some patients may be anticipated to be difficult to intubate on the basis of a history of difficulty intubation or clinical predictors of difficult intubation. The ASA Practice Guidelines for Management of the Difficult Airway[5] reviews some of the historical or physical examination findings possibly suggestive of a difficult intubation. Some of these predictors of anticipated difficulty with conventional direct laryngoscopy (MAC/Miller) include a large overbite, large tongue, narrow mouth opening, or short chin. Various prediction models, such as correlation with Mallampati oral view I to IV to the Cormack and Lehand laryngoscopic view grades I to IV have been proposed, but none offer 100% sensitivity for prediction of a difficult airway (Figs. 9-1 to 9-4).[6] Historically, anesthesiology literature cites an incidence of 1% to 3% for unanticipated difficult airway/intubation in patients undergoing general endotracheal anesthesia.[5-7] The airway management technique used to define "difficult" in this literature was conventional rigid laryngoscopy (Macintosh or Miller blades).

Despite advances in airway management techniques and refinement of difficulty predictors, the cited 1% to 3% incidence of unanticipated difficulty has not changed and is still defined by conventional laryngoscopy.[6-9] In an institution where approximately 25,000 general endotracheal anesthetic procedures are done annually, there are potentially 250 to 750 unanticipated difficult airway/intubations per year. Assuming that a full-time practicing anesthesiologist would encounter one unanticipated difficult airway/intubation per year, then, based on ASA membership (which represents 90% of practicing anesthesiologists), there are potentially 30,000 to 90,000 unanticipated difficult airway/intubations annually in the United States. However, these numbers may underestimate the true incidence, because anesthesiologists may not recall the more common "near misses" as vividly as they recall the smaller number of actual difficult airway/intubations in which the outcome was suboptimal. On a national and international level, the scope of this problem and its impact on patients, practitioners, and the health care system is sufficient to warrant vigorous efforts to identify and implement solutions.

In addition to those patients who have unanticipated difficult airway/intubations on initial presentation, there are cohorts of patients

Figure 9-4. Postoperative evaluation of patient in Figure 9-3. Note that without the tongue blade, the patient has a Mallampati class IV airway and should have been considered to be anticipated difficult intubation with conventional laryngoscopy.

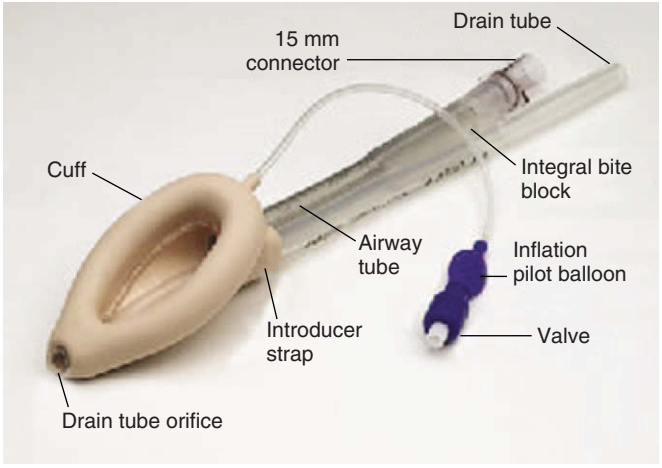

Figure 9-5. Laryngeal mask. *(Courtesy of LMA, North America Inc.)*

who have anticipated complex airway management; these patients can be successfully managed by a variety of innovative and specialty-specific techniques. Some of these techniques (laryngeal mask airway [LMA][10] and Combitube)[11] are readily available (Figs. 9-5 and 9-6), require minimal practitioner education or training, and are inexpensive; other techniques (fiberoptic bronchoscope, surgical airway, specialized rigid laryngoscopes, and fluoroscopic-assisted intubation) are available primarily in specialty centers, may require extensive practitioner skill, and may be relatively expensive. For patients who have undergone head and neck surgery and have visible or hidden implants (e.g., laryngeal stents, thyroplasties), specific considerations for airway management may be unknown to future providers (e.g., thyroplasty patients might require smaller endotracheal tubes than anticipated), thus compromising patient safety and increasing practitioner risk for adverse events.

Successful future management of previously unanticipated difficult airway/intubation patients depends on identification of those patients, and documentation and dissemination of information detailing successful and unsuccessful airway management techniques and primary difficulties encountered. These patients then become anticipated difficult airway/intubations, and the availability of this information promotes quality and safety of care.

Consequences of Difficult Airway Management

The consequences of difficult airway/intubation (with or without an adverse outcome) may be as unsettling as the event itself. The patient may perceive this as a threat to future anesthetic safety or may lack understanding as to the significance of the difficulty. There may be

Figure 9-6. Diagram of usage of a Combitube.

practitioner-perceived threat to professional security. The impact of complex airway management-related events in direct and indirect costs to the health care system is far reaching.

Three studies specifically demonstrated the consequences of difficult airway/intubation management on liability exposure.[12-14] An analysis of approximately 5000 claims filed in the Maryland legal system over a 15-year period in which one or more anesthesiologists were named as defendants revealed that insertion of an endotracheal tube was the sixth most common medical procedure leading to a liability claim. Most of these claims also included other members of the operating room team (e.g., otolaryngologists, general surgeons, nurse anesthetists, orthopedic surgeons, plastic surgeons, cardiac surgeons, dentists, or nurses) as defendants. One claim (in 1994) resulted in a jury award of $5 million.[15] In a 1992 loss analysis study conducted by the Physicians Insurers Association of America (PIAA), files from 43 physician-owned malpractice insurance companies (representing approximately 2000 anesthesiologists nationally) ranked "intubation problems" as the third most prevalent misadventure (behind "tooth injury" and "no medical misadventures"). The average paid indemnity for 175 of 339 files was $196,958.[15] The ASA Committee on Professional Liability closed claims study found that respiratory events were the most common cause of brain damage and death during anesthesia, with difficult intubation being the likeliest category for risk reduction. The median payment for respiratory claims was $200,000.[12]

To put these statistics in perspective, the following must be considered.

1. The number of malpractice claims reported represents only a small fraction (one eighth) of all adverse outcomes, with one malpractice claim filed for every 7.5 patient injuries from difficult airway/intubation events and adverse outcomes.[12]

2. Claims may often be aborted by good physician-patient communication.

3. Claims are often initiated against physicians because of poor communication and inadequate records.[16]

Routine Anesthetic Care of the Patient with the Nondifficult Airway

Before discussing management of the difficult airway, this section will discuss the routine provision of anesthesia to provide a framework for

the discussion that follows. The three main tasks of the anesthesiology team are (1) to keep the patient safe, (2) to keep the patient comfortable, and (3) to provide for good operating conditions during the preoperative, intraoperative, and immediate postoperative periods. The component qualities of an anesthetic are loss of consciousness, amnesia, analgesia, and muscle relaxation/paralysis. Anesthesia can be general, regional, or local; general anesthesia is provided for most head and neck surgeries, thus the need for airway management.

In a routine setting, the patient receives a general anesthetic, and the anesthetic "take-off" follows after a thorough preoperative history and physical. The patient is then brought into the operating room and positioned supine. Standard monitors are placed, as described later in this section. Preoxygenation occurs with 100% inspired oxygen to denitrogenate the patient's functional residual capacity. At that point, anesthesia is induced and the airway is managed appropriately. After intubation or other airway control, invasive monitors or additional intravenous access may be placed, and the surgery is allowed to commence.

Advances in Monitoring

As a previous section made clear, there are serious legal and financial consequences of failed airway management. Fortunately, adverse outcomes related to poor airway management have decreased in frequency with the standardization of anesthetic monitoring. The American Society of Anesthesiology Standards for Basic Anesthetic Monitoring statement was first released in 1986 and further amended in 1998 and 2005.[17] These standards call for continual evaluation of the patient's oxygenation, ventilation, circulation, and temperature during all administered anesthetics. Practically speaking, the standard mandates continuous oxygen analysis of the anesthetic circuit, pulse oximetry, end-tidal capnometry, tidal volume measurement, electrocardiography, and temperature, as well as intermittent (no less frequent than every 5 minutes) measurement of arterial blood pressure and heart rate. In addition, the routine use of the neuromuscular blockade (NMB) monitor (also called the "twitch" monitor) to assess degree of muscle paralysis and return of muscle strength after pharmacological reversal of paralyzing agents significantly contributed to improved patient safety. Compared with earlier eras, this document made the important leap of elevating pulse oximetry and capnometry to standards of care, thus allowing more rapid, accurate recognition of oxygen desaturation and rapid recognition of previously unrecognized esophageal intubation.

The consequences of this change were staggering. Respiratory system adverse events (including airway mishaps) accounted for 36% of claims in the ASA Closed Claims Project data set for the 1970s, but this percentage decreased to 14% of claims in the 1990s after implementation of the routine use of capnometry and pulse oximetry.[18] Claims related to death or brain injury likewise had a similar drop in the percentage that was attributable to respiratory adverse outcomes. Caused in part by continuous pulse oximetry and capnometry, anesthesiology has been a leader in the patient safety movement in the past decade.

Standard Anesthetic Pharmacology

This section provides a brief introduction to the array of drugs used by anesthesiologists to facilitate anesthesia and maintain control of the airway. An in-depth discussion of these agents is not within the scope of this chapter; however, certain features of these drugs that are particularly applicable to airway management are highlighted.

Induction Agents and Volatile Anesthetics

In most adult patients, a peripheral intravenous line is started preoperatively to administer fluid and drugs. Therefore, most adult patients receive an intravenous induction of anesthesia. The most commonly used intravenous induction agents are thiopental, propofol, etomidate, and ketamine. Each of the intravenous induction agents has the advantage of quick onset, producing unconsciousness within 1 to 2 minutes when given in standard induction doses. Of note, thiopental and propofol are both associated with negative inotropic effects and a related drop in blood pressure when used for induction of general anesthesia. Etomidate's effects are considered to be more hemodynamically stable, but this drug has the drawbacks of potential adrenal suppression and myoclonic activity. Thiopental, propofol, and etomidate all produce apnea along with unconsciousness. In contrast to the other three agents, ketamine is notable for not producing apnea with administration. The maintenance of spontaneous ventilation with ketamine is an important consideration in the management of patients with potentially difficult airways and other subsets of patients presenting for surgery. In addition, ketamine has the advantage of being able to be given intramuscularly in patients without intravenous access. The major disadvantages of ketamine include emergence delirium and the sympathomimetic effects of the drug, and thus can cause tachycardia and hypertension, which limit its role in the treatment of patients with cardiovascular disease. Additionally, ketamine produces exaggerated secretions, and an antisialogue such as glycopyrrolate should be coadministered if the airway is not secured immediately after induction.

For most adults, the volatile anesthetic agents (e.g., halothane, isoflurane, sevoflurane, and desflurane) are used for maintenance of anesthesia rather than induction. Their role in induction of anesthesia is limited by slower onset of activity and patient inability to tolerate the scent of the anesthetic gas. However, in pediatric anesthesia, wherein most patients are intolerant of intravenous placement before coming to the operating room, "mask inductions" with volatile agents is common. Sevoflurane is typically the agent used for mask induction because it is considered less noxious than the other agents. All of the volatile agents have the significant advantage of maintaining spontaneous respiration while producing unconsciousness.

Adjuncts to Induction: Sedatives and Opioids

Benzodiazepines are also commonly given in the immediate preoperative period for their anxiolytic and amnestic effects. Midazolam is the most commonly used benzodiazepine, because it has onset of activity in 2 to 4 minutes. In larger doses, benzodiazepines can also be used as induction agents themselves. In sedative doses, the benzodiazepines do not typically produce significant respiratory depression. However, in combination with opioids, the respiratory depression can be synergistic. Furthermore, the response to benzodiazepines can be idiosyncratic, and a sedative dose can produce unconsciousness and apnea in sensitive patients.

Opioids are used intraoperatively to provide analgesia and a balanced anesthetic. When given as part of anesthetic induction, they are useful in blunting the sympathetic response to laryngoscopy and intubation. They also have a role during sedation of patients, because they can produce a sense of well-being, with decreased responsiveness to noxious stimuli. Commonly used opioids are fentanyl, sufentanil, remifentanil, morphine, and hydromorphone. Opioids produce a dose-dependent central respiratory depression with increased $Paco_2$ and diminished respiratory drive. This respiratory depression can often be offset in the awake patient by asking the patient to consciously breathe deeply. However, the combination of opioids with benzodiazepines can result in a patient with central apnea who is unresponsive to instructions to breathe. Both opioids and benzodiazepines can be antagonized at the receptor level by naloxone and flumazenil, respectively.

Lidocaine is sometimes used as adjunct during anesthetic induction, although not in doses large enough to be an induction agent itself. Propofol can cause venous irritation during administration, and pretreatment with lidocaine into the same vein may decrease patient discomfort. In addition, lidocaine does have its own anesthetic effects and may decrease sympathetic response to laryngoscopy and intubation. Doses are kept to 1 to 1.5 mg/kg to avoid potential toxicity of local anesthetics, which are described later.

Paralytic Agents

Paralysis of the patient eases endotracheal intubation by relaxing the jaw and stopping vocal cord motion. Furthermore, paralysis is often necessary for the surgical procedure itself. There are two classes of paralytics, depolarizing agents and nondepolarizing neuromuscular blockers.

The depolarizing agent used in the United States is succinylcholine. Succinylcholine acts at the acetylcholine receptor in the neuromuscular junction, activating the receptor but then occupying it and therefore prolonging the refractory period before the muscle can contract again. The drug eventually diffuses away from the receptor and is

metabolized and deactivated by pseudocholinesterase. Succinylcholine does produce fasciculation of the muscle, which can cause postoperative myalgia. In addition, the original opening of the receptor causes potassium efflux from the muscle, which raises the serum potassium transiently by approximately 0.5 mEq/L. This increase in potassium is exaggerated in patients with up-regulated amounts of acetylcholine receptors, such as after differentiation caused by stroke or other central nervous system injury. In patients with already elevated serum potassium levels, succinylcholine can precipitate ventricular dysrhythmias.

The major advantage of succinylcholine is its very fast onset of action. Paralysis sufficient for endotracheal intubation can be reliably produced within 45 to 60 seconds. Another advantage is its short duration of action, because clinical paralysis usually dissipates within 5 minutes of an intubating dose. It has been thought that this quick return of strength would allow resumption of spontaneous respirations if positive-pressure ventilation were not successful. However, a past study shows that deleterious oxygen desaturation may occur before resumption of spontaneous respirations.[19] In addition, the small percentage of patients who are pseudocholinesterase deficient will have prolonged paralysis after administration of succinylcholine. Vigilant use of the NMB monitor has led to increased diagnosis of patients with atypical cholinesterase activity, which varies with the population but is cited to be 1 : 2800 in the general population in the United States, with a 1 : 1 male/female ratio.[3] Confirmatory blood laboratory diagnosis is made by determining the patient's dibucaine number. Succinylcholine has also been identified as the most common muscle relaxant trigger for malignant hyperthermia (MH).[20] Primary contraindications for the use of succinylcholine include known or suspected MH, increased intracranial pressure, increased intraocular pressure, and elevated potassium. Although not contraindicated in patients with pseudocholinesterase deficiency, administration should be monitored with the NMB monitor to verify full return of strength before extubation.

The other group of paralytics is the nondepolarizing neuromuscular blockers. These drugs work in the neuromuscular junction by preventing the binding of acetylcholine to its receptor and subsequent muscle contraction. There are many different nondepolarizing agents, clinically distinct because of their different times of onset, durations of action, and different routes of metabolism. None of these agents work as quickly as succinylcholine. In the patient in whom there is a contradiction to the use of succinylcholine, the nondepolarizer of choice for rapid sequence intubation is rocuronium, which has an onset of action between 60 and 75 seconds. However, when given in doses sufficient for intubating conditions, the effects of rocuronium persist for 30 to 40 minutes (and cannot be pharmacologically reversed for 20 to 30 minutes), which can be a major problem if the initial attempts to intubate the trachea are unsuccessful. Establishment of mask ventilation is then essential, and although the risk of aspiration is now greater, there are no other options available to the practitioner.

Local Anesthetics

Local anesthetics are discussed here because of their use surgically as an adjunct for analgesia, and because of their use for topical and regional anesthesia of the airway in awake patients. Lidocaine and bupivacaine are the most commonly used local anesthetics for local infiltration or nerve blocks at our institution. The surgeon must be aware of the maximum dose allowable, given the risk of local anesthetic toxicity, manifested first by central nervous depression and seizures, followed by cardiovascular dysrhythmias, and potentially ventricular fibrillation. The maximum dose of lidocaine is 5 mg/kg and up to 7 mg/kg can be given safely if epinephrine is used in the solution to slow uptake through subcutaneous tissues into the central circulation. A 2% lidocaine solution contains 20 mg/mL of lidocaine, so a 70-kg patient should receive no more than 17.5 mL of this solution. The effects of intravenous lidocaine administered during induction are additive to the amount of lidocaine absorbed from local infiltration, topical application, or regional block, so communication between the anesthesiology and surgical teams is crucial to avoid potentially toxic overdoses. The maximum dose of bupivacaine is 2 to 3 mg/kg, with the upper end of the range reflecting the addition of epinephrine to the solution during local infiltration. As a word of caution, toxic effects are seen with much lower doses of local anesthetics administered directly into the circulation, so careful aspiration must be done before injection of these drugs during infiltration or regional blocks. Injection into the carotid artery during extraoral glossopharyngeal block can produce immediate seizures and loss of consciousness.

Cocaine is also used for topicalization of the airway during head and neck surgery. The advantage of cocaine applied to the nasal mucosa is its vasoconstrictive properties in addition to its anesthetic properties. However, the side effects of cocaine include tachycardia and hypertension, which can be particularly deleterious in patients with coronary artery or other cardiovascular disease. The addition of phenylephrine to lidocaine jelly offers similar vasoconstrictive properties with fewer risks than cocaine. In addition, cocaine has significant addictive properties, so its use during surgery must be intensively monitored.

Antihypertensives

Airway management in the last decade has been radically advanced by the increased understanding of the pathophysiology of ischemia and the judicious perioperative use of antihypertensives for patients at increased risk of ischemic events. Intraoperative hypertension and tachycardia can be a direct response to agents used in topicalization of the airway for awake airway management techniques, specifically cocaine, epinephrine in lidocaine mixtures, and phenylephrine in lidocaine mixtures. In the asleep patient, translaryngeal intubation of the trachea stimulates laryngeal and tracheal receptors, resulting in marked increase in the elaboration of sympathomimetic amines. This sympathetic stimulation results in tachycardia and an increase in blood pressure. In normotensive patients, this increase is approximately 20 to 25 mm Hg; it is much greater in hypertensive patients. This increase in blood pressure results from vasoconstriction, owing to unopposed alpha stimulation in hypertensive patients taking β-blocking agents.

The most commonly used antihypertensives for intraoperative control of hypertension and tachycardia related to airway management include the β-blockers esmolol and metoprolol, and the α- and β-blocker labetalol. Most blood pressure and heart rate changes occur about 15 seconds after the start of direct laryngoscopy and become maximal after 30 to 45 seconds. Esmolol is especially effective in blunting these responses because of its almost immediate onset of action, ease in titration, and short action of duration with half-life of 9 minutes. Labetalol is comparable in attenuating hemodynamic effects, but is less immediate in onset of action and has a half-life of 5 hours.

Standard Induction versus Rapid Sequence Induction

After the patient with an expected routine airway is monitored and anesthesia is induced, the next step is appropriate management of the airway.

An important question to ask before this point is whether the patient is at risk for aspiration of gastric contents into the airway, an event that can be potentially catastrophic. The patient's risk of aspiration of gastric contents helps determine whether the patient should be managed with rapid-sequence induction (RSI) and intubation or with a nonrapid sequence of events. The increased risk of aspiration is due to the presence of gastric contents and is the reason anesthesiologists are concerned about the length of time patients have been without food or drink before surgery. The ASA has published guidelines for preoperative fasting that are based on the time required for gastric emptying in healthy patients.[21] As surgeons, your familiarity with these guidelines can prevent the delay or cancellation of elective surgery.

The summary of fasting recommendations is 2 hours for clear liquids, 4 hours for breast milk, and 6 hours for other food or beverage, including infant formula and milk. In patients with delayed gastric emptying, such as diabetic gastroparesis, further fasting may be necessary for reduced risk of aspiration. In addition to adherence to fasting guidelines, pharmacologic agents given preoperatively may reduce risk of aspiration and include clear antacids (30 mL of 0.3 M sodium citrate), anticholinergic agents (atropine or glycopyrrolate), metoclopramide (to stimulate gastric emptying and to increase lower esophageal sphincter tone), and H_2-receptor antagonists (cimetidine or ranitidine) to decrease further secretion of additional acid.

Figure 9-7. Establishing mask ventilation with Anesthesia Attending L. Mark, MD.

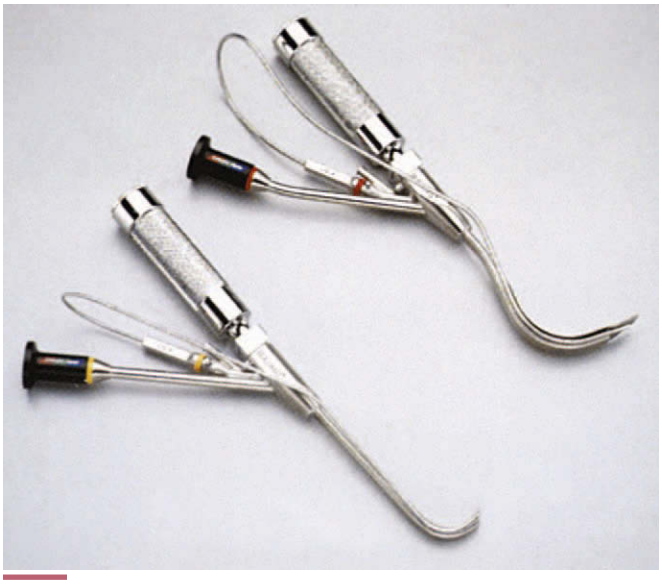

Figure 9-8. Rigid bronchoscopes.

In patients without increased risk of aspiration, a controlled and stepwise approach is taken with induction and intubation. After monitoring and preoxygenation, general anesthesia is induced. Once the patient is unconscious, positive-pressure mask ventilation is performed (Fig. 9-7). Only after successful mask ventilation is established is a paralyzing agent given. This stepwise approach to the airway increases patient safety because, even if intubation cannot be performed successfully, it is known that the patient can be mask ventilated and oxygenated while the paralytic wears off or alternative intubation techniques are readied. The ability to ventilate a patient is more crucial than the ability to intubate a patient, and bag-valve-mask ventilation is a lifesaving skill that every anesthesiologist must master. After successful mask ventilation, the paralytic is given, and intubation is performed after the paralytic takes effect.

RSI and intubation are done for patients with an increased risk of aspiration, such as a patient with a full stomach or a patient with a significant history of gastroesophageal reflux. During an RSI technique, mask ventilation is not done, because it can fill the stomach with air and increase the risk of aspiration even further. Instead, the paralytic agent is given immediately after the induction agent. Cricoid pressure is held throughout, and the patient is not ventilated for the time it takes the paralysis to take effect.

Proper preoxygenation allows most apneic patients to maintain oxygen saturation during this minute. The patient is intubated once paralysis is achieved, usually by means of direct laryngoscopy. After confirmation of proper endotracheal tube placement by end-tidal CO_2 and auscultation of bilateral breath sounds, the endotracheal tube cuff is inflated, and cricoid pressure can be released.

The risk of an RSI is that intubation may not be successful and the ability to mask ventilate the patient has not been previously established. The most dangerous result of failed RSI could be a paralyzed patient who cannot be ventilated or intubated (see Case 8).

Therefore, the stepwise approach to the induction of anesthesia and establishment of mask ventilation before paralysis is the safer and preferred technique for a patient without increased risk of aspiration and without an expected difficult airway. The stepwise approach for a patient with risk for aspiration and with an expected difficult airway requiring general anesthesia is awake versus RSI, with immediate backup in the event of failed intubation.

Difficult Airway/Intubation: Advances in Airway Devices and Techniques

In parallel with organizational responses to difficult airway management, individual practitioners responded with inventions of new airway devices and with innovative combinations of existing techniques. In Table 9-1, a brief review of many of these devices is presented, with identification of primary use by anesthesiology and of OLHN. For a more in-depth discussion of the devices and appropriate techniques, refer to *Airway Management: Principles and Practice*[22] and references identified in Table 9-1.

To appreciate the scope and magnitude of these efforts, consider that in the early 1990s, most anesthesiologists in the United States had the following airway management techniques: awake blind nasal, awake nasal fiberoptic intubation, and awake and asleep conventional laryngoscopy. Select difficult patients would undergo spontaneous ventilation "breathe-down" inductions without paralysis to facilitate optimal conditions for the OLHN surgeon to attempt to secure the patient's airway with either rigid laryngoscopy or bronchoscopy. Complications of this technique included laryngospasm, aspiration, lost airway because of inability to maintain spontaneous ventilation, or difficult positive pressure mask ventilation, and inability to intubate by the OLHN surgeon.

In the early 1990s, OLHN surgeons had the following airway management techniques: awake and asleep surgical airway, awake fiberoptic bronchoscopy, and asleep rigid laryngoscopy and bronchoscopy (Fig. 9-8).

Indisputably, the most significant invention in the recent history of airway management was the LMA (see Fig. 9-5).[10] Although introduced into the United States in the early 1990s as an alternative to elective face mask ventilation (Fig. 9-9) in general anesthetics not requiring intubation, the value of the LMA as a rescue device for the most devastating situation "cannot intubate/cannot ventilate" quickly became realized. In the 1993 ASA Practice Guidelines for Management of the Difficult Airway, the LMA was the airway device that routed the Difficult Airway Algorithm into the significant branch points. In the 2003 amended Guidelines, the LMA was promoted as a first choice device for cannot-ventilate rescue options.[23]

In the past decade, for elective difficult airway management, the "family" of LMAs (Classic, ProSeal, Flexible, and Fastrach) has had a major impact on the decision branches with the Difficult Airway Algorithm. Specifically, many practitioners decide that if they can mask the patient with an LMA, definitive placement of an endotracheal tube (ETT) can be achieved with either fiberoptic bronchoscopy or ETT exchanger assistance. Backup plans, however, must be in place, because these techniques can be difficult and unsuccessful, as described in Case 7.

Table 9-1 briefly presents many of the advances in airway management devices discussed previously and throughout this chapter. References, including links to more comprehensive websites, are provided

The Johns Hopkins Departments of Anesthesiology and Critical Care Medicine and Otolaryngology—Head and Neck Surgery Airway Management Initiative and Formation of a Hospital-Wide Airway Service

The following section briefly outlines ongoing efforts of the Departments of ACCM and OLHN Surgery Airway Management Initiative and formation of a hospital-wide Airway Service.

Conceptual Framework

The Johns Hopkins Medical Institutions Departments of ACCM and OLHN Surgery responded to the release of the ASA guidelines by developing an Airway Management Initiative that has evolved over the past 15 years into the present-day Airway Management Service, education program, and hospital-wide difficult airway management response system. For the first 6 years, both departments provided financial support. However, in 1999, the Legal Department issued the following statement regarding the Airway Management Initiative and multidisciplinary Airway Service that resulted in full financial support by The Johns Hopkins Medical Institutions[24]:

> The institution will be well served by supporting a coordinated team approach dealing with patients with difficult airways. Being able to call upon such a team would assist us in preventing claims and would help with management of claims that do arise because of the assurance of excellence of care and good documentation.
>
> We were fortunate enough to have a lawsuit dismissed in which we allegedly did not render appropriate care for a patient with a difficult airway. The dismissal was a direct result of involvement of members of the multidisciplinary airway service team and their review of the case and their expert opinions.
>
> With appropriate funding and education about the multidisciplinary airway service team, we may have been able to avoid an incident that led us to settling a case in which a patient's compromised airway led to an arrest and her death.
>
> Based on even these two examples, it will be prudent for the Hospital to fund the multidisciplinary airway service and to make sure that it remains functional. We would also need to make sure that the medical staff is aware of the existence and expertise of the service.

Multispecialty Service and Joint Clinical Faculty Appointment

To facilitate familiarity between faculty from each department and to support the academic careers of individuals, joint faculty appointments were/are awarded to physicians interested in becoming active members of the Airway Management Service. At any given time, there are two to three members from each department with such appointments. These individuals have the primary responsibility for teaching other faculty, residents, nursing, and support staff within an organized educational program that includes a month-long elective for senior anesthesiology residents. They are the physicians who provide consultation electively and urgently for patients requiring difficult airway management. They are encouraged to be members of Society of Airway Management (SAM) and to participate in the annual meeting.

Preoperative Evaluation and Identification of "Airway Alert"

Approximately 50% of patients seen for surgery are evaluated in our Preoperative Evaluation Center (PEC) several days or weeks before their scheduled procedure by the PEC staff, which consists of an attending anesthesiologist, anesthesiology resident, and nurse practitioner. The PEC anesthesiologist identifies the difficult airway/intubation patient on the basis of prior documented history, physical examination, or specific surgical needs. If consultation with an otolaryngologist or other specialist is needed to facilitate airway management, this is arranged. On the basis of the PEC staff evaluation, the patient is identified as an "Airway Alert" on the Preanesthesia Assessment Form and entered into the hospital's operating room scheduling system (ORSCIS) with "Airway Alert" identified in the free text field associated with the surgical procedure. Whenever possible, an anesthesia attending is identified who will be available for assistance with airway management on the day of surgery and who has experience with the specific condition or airway difficulty the patient has and the recommended technique. However, the designated anesthesiologist and surgeon caring for the patient during the surgical procedure determine the final airway management plan. When appropriate, postoperative intensive care unit beds are requested to facilitate extubation management. The PEC anesthesiologist, and Airway Service members if consulted, discuss with the patient overall concerns and probable airway management plans A, B, and C. Discussions include any potential for the procedure to be aborted if issues arise during airway management that are not appropriately planned for. Written informed consent is obtained, including for elective tracheotomy if considered part of the airway management plans. For select patients, recommendations are made for enrollment into Medic Alert.

Before surgery, the anesthesiologist reviews the Preanesthesia Assessment Form to specifically identify the following information: surgical procedure, airway requirements (e.g., nasal/oral ETT, jaw wired at end of procedure, tracheotomy as part of procedure), patient's yes/no response to the presence of gastroesophageal reflux/hiatal hernia (to assess aspiration risk and potential for awake vs. RSI technique), previous anesthesia experiences/airway difficulties, height and weight, and attempted-standardized airway examination (oral excursion in fingerbreadths [scale of 1 to 4], temporomandibular distance in fingerbreadths [scale of 1 to 4], upper and lower dentition [normal, dentures, caps, decayed], Mallampati I to IV, neck extension/flexion [scale of normal to decreased by 1 to 2]). The final patient interview and examination are conducted, and the anesthesiologist and surgeon (with assistance from Airway Service, as requested) formulate their actual plans A, B, and C.

Formulation of Intraoperative and Postoperative Plans A, B, and C

Members of the Airway Service are familiar with the ASA difficult airway/intubation algorithm and our institutional experience with rigid

laryngoscopy as a primary otolaryngology technique within the ASA algorithm.

The first question the Airway Service asks is, "What is the surgical expectation at the end of the procedure?" Specific answers need to be provided for questions about if and at what stage of the procedure the patient might have a tracheotomy done, if the jaw will be wired closed, whether direct manipulation of the airway will result in edema or significant bleeding, whether positioning could cause airway edema, what will total fluid management entail, and what other considerations might suggest continued intubation at the end of the procedure. For these patients, precise extubation strategies are planned to include the location of extubation (intensive care unit vs. returning to the operating room for extubation) and physicians, staff, and equipment resources that must be available.

Next, the Airway Service explores the concept of "difficult." Although the ASA attempts to distinguish between difficult mask and difficult intubation, when the patient does not have a documented prior airway history and is assessed to be difficult for either mask or intubation, considerations for awake intubation techniques are discussed. Obvious limitations to awake techniques are severe mental status issues (e.g., intoxication, noncooperative, mental retardation), severe respiratory/hemodynamic compromise, and unstable trauma. In our experience, patient refusal of an awake intubation has rarely been an issue, primarily because of the positive approach to awake intubation taken by the anesthesiologist during the discussion with the patient.

The next question that the Airway Service asks is, "Should the intubation be awake, oral, nasal, or surgical?" followed by, "What is the surgical preference for the ETT (cuffed or uncuffed, smaller-than-expected size, right-angle endotracheal (RAE) or nasal RAE tube, reinforced, laser, double lumen, microlaryngeal, or other specialty ETT)?"

Finally, the Airway Service addresses the issue of the patient's surgical attending airway management expertise and comfort with specific airway management techniques. Specifically, if the situation deteriorates and an emergency surgical airway becomes necessary, who will do it: the patient's surgical attending or OLHN member of the Airway Service?

Based on this knowledge, plans A, B, and C are developed by the Airway Service and communicated to the surgeon, patient, and nursing and support staff. Modifications to the plans are made jointly, before the initiation of any airway management.

Operating Room Preparation

In the early years of the Airway Management Initiative, the Airway Service had as resources four designated OLHN operating rooms (in a single operating room suite) and a small work room to house and clean airway equipment. As the Airway Service expanded coverage to non-OLHN patient consultations in multiple operating room suites within the institution, and responded to emergency responses in nonoperating room locations, the need for duplicate central locations, and numerous mobile sites became apparent. In addition, the standard airway equipment in each operating room was expanded and upgraded to facilitate more efficient operating room preparation for both elective and emergency airway management.

Equipment: Standard Anesthesia Equipment and Airway Service Resources

Standard anesthesia equipment in all adult anesthetizing locations includes the following airway management equipment: Eschmann stylet; LMA sizes 3, 4, and 5; conventional laryngoscopes (MAC No. 2, 3, and 4; Miller No. 2 and 3); Sanders jet ventilator; and AMBU bag.

Airway Service resources include a wall poster listing contact numbers for the surgical airway support individuals who are in the hospital daily (elective and on call), the airway equipment specialist support staff contact numbers, and a copy of The Johns Hopkins Adult Airway Management Card. There is specific identification of which services are available and when (24 hours a day, electively, or emergently). The Airway Management Card includes the following information: the contents of the anesthesia fiberoptic cart, the contents of the adult emergency airway cart, information on local anesthesia toxicity, techniques for topical anesthesia, airway blocks, techniques for fiberoptic intubation, information on size issues with the LMA, techniques for changing from LMA to ETT, techniques for changing from a double-lumen ET to a single-lumen ETT, information about size issues with the light wand, lung isolation techniques, techniques for jet ventilation and cricothyrotomy, and information about airway fires, surgical airways, challenging situations, and difficult airway telephone numbers.

Carts: Anesthesia Fiberoptic Cart and Adult Emergency Airway Cart

Two airway carts were created to address specific airway management situations: the Anesthesia Fiberoptic Cart and the Adult Emergency Airway Cart. Both are available with and without a monitor. Both carts include airway alert wristbands and information on how to enroll patients in the in-hospital registry, enter an airway note into the Electronic Patient Record (EPR), and enroll into Medic Alert. The complete contents for each cart are listed on the Adult Airway Management Card.

The Anesthesia Fiberoptic Cart is specifically set up for elective fiberoptic intubations or for fiberoptic verification of double-lumen ETT placement. It has both an LF 1/2 Olympus (3.5/4.0 mm) bronchoscope and adult bronchoscope, Olympus (5.0/6.0 mm) assorted airway management equipment, and topical anesthesia supplies. This cart is specifically designed to be used by anesthesiologists in the operating room.

The Adult Emergency Airway Cart is specifically set up for elective procedures in the operating room in which the following techniques are part of the airway management plan and for which the otolaryngologist has primary involvement: fiberoptic bronchoscopy, rigid laryngoscopy, rigid bronchoscopy, jet ventilation, and surgical airway. Adult Emergency Airway Carts are also located in all intensive care units and the Emergency Department. To note, monitors are included with these carts.

For an emergency in the operating room, our otolaryngologists prefer to use the Adult Emergency Airway Cart without the monitor and organized on a single flat-surface cart without numerous drawers. It has the same equipment as the preceding Adult Emergency Airway Cart, but the critical equipment, rigid laryngoscopes and adult fiberoptic bronchoscope, is already assembled for immediate use.

Staff: Anesthesiologist, Specialty Nursing Staff, Surgical Technologists, and Airway Equipment Specialist

For years, anesthesiologists were taught to believe that all aspects of airway management were the responsibility of the anesthesiologist, without specified assistance from nursing or support staff. At The Johns Hopkins Medical Institutions, it was the practice of otolaryngologists and pulmonologists to schedule patients with complex airway pathology to have a diagnostic fiberoptic bronchoscopy in the operating room, with monitored sedation by an anesthesiologist. It became increasingly apparent that successful management of these patients required a team of four professionals: an anesthesiologist to monitor and provide sedation, a surgeon or pulmonologist to perform the bronchoscopy, a nurse to assist with the bronchoscopy, and an equipment specialist to set up the equipment. We found that if any one of the team members failed to perform these duties, the patient's airway management was compromised. We realized that it was not reasonable to expect that an anesthesiologist (or other physician with airway expertise) working alone could provide all the components of complex airway management in a timely and successful manner. When the OLHN surgeon was not immediately required, the Airway Service provided an additional anesthesiologist to provide patient monitoring and sedation while the airway management was being accomplished by the Airway Service and/or operating room anesthesiologist facile with complex airway management. The goals were successful airway management, patient safety, patient satisfaction, and efficient use of operating room resources.

The Airway Service currently has support staff from the Departments of ACCM, Surgery, and Nursing, including specialty operating room nurses, airway equipment specialists, certified surgical technologists (CST), and critical care technicians. Their primary responsibilities are to assist physicians in difficult airway management, maintain and

upgrade airway equipment, and ensure that the organizational process of a functional airway team is maintained. They are also responsible for the education other operating room staff, specifically as to their roles in airway emergencies.

Operating Room Setup

There are three standard operating room bed positions that we use, depending on the surgeon, anesthesiologist, and procedure to be performed. These are (1) the classic position with the patient's head in alignment with the anesthesiologist; (2) the patient's head rotated 90 degrees from the anesthesiologist; and (3) the patient's head rotated 180 degrees from the anesthesiologist. Decisions regarding positioning are determined by specific operating room equipment issues, the choice of airway algorithm, and the comfort of the anesthesiologist and/or support anesthesia staff (when staff is needed) with having the patient's head rotated away from the classic position and the anesthesia machine. For example, if the clinical algorithm has plan A as conventional laryngoscopy and plan B as rigid laryngoscopy, and if the anesthesia team includes an attending and resident, then an optimal position to facilitate the rigid laryngoscopy setup is with the patient's head/operating room table rotated 90 degrees from the classic position. One member of the anesthesia team has the designated role of monitoring the anesthesia, while the other member is responsible for the airway; the otolaryngologist and nurse are set up to immediately assist, if required.

Advanced Monitoring in the Operating Room and Postoperative Considerations

In efforts to optimize the surgical positioning, as described previously, careful planning of advanced monitoring—specifically arterial and central venous monitoring—must be communicated between the anesthesia and surgery teams. In procedures in which the positioning involves both patient's arms tucked by the sides and the bed rotated 180 degrees from the anesthesiologist, placement of a radial, dorsal pedal, or femoral arterial catheter facilitates more precise management of blood pressure and ability to easily obtain laboratory values as required. Considerations for central venous access include limitations of adequate peripheral venous access (either difficult peripheral venous access or request by surgeon not to access the patient's arms for flap procedures), potential for large blood loss, or patient cardiac issues that suggest monitoring of central venous pressures for optimal management. Communication with the surgical staff facilitates placement of internal/external jugular, subclavian, or femoral venous cannulation. Specific indications for use of pulmonary artery catheters and/or invasive cardiac pacing catheters can be limited by surgical request for femoral venous only and must be carefully considered for relative risk/benefit and issues of difficulty with successful placement from the femoral venous site.

Difficult airway management includes algorithms for difficult extubation management.[25] Specific considerations include when, where, and how to extubate, and the safe disposition of the patient postoperatively. Preoperative discussions between anesthesiologists, surgeons, and patients should always include the extubation strategy. Issues can occur in the event that a relief anesthesia teams takes over the patient's care, but extubation strategies are not clearly communicated by the original team. In an attempt to avoid the potential for adverse airway events, it is our practice to clearly communicate the entire airway management plan to the operating room nursing, recovery, and intensive care unit staff when possible. When a team decision is made to extubate a complex airway patient, techniques to optimize successful extubation include the following: (1) elevation of the head to at least 45 degrees; (2) careful suctioning of the trachea and oropharynx; (3) nebulizations with bronchodilators; (4) suctioning of the stomach and administration of an antiemetic drug; (5) verification of the reversal of muscle relaxants; (6) verification of appropriate respiratory parameters (head lift of 5 seconds, tidal volume approximately 10 mL/kg, negative inspiratory effort of −20 mm Hg, oxygenation of greater than 90%, appropriate level of CO_2); (7) appropriate volume status (nonedematous); (8) hemodynamic stability, and (9) normal laboratory values, if indicated. Considerations for extubation over an Eschmann or ventilating ETT changer, the use of heliox,[26,27] or a "trial extubation" should be clearly communicated to all appropriate physician, nursing, and technician support staff. Emergency airway equipment should be immediately available. The final algorithm for a potentially difficult extubation poses the question, "Who does the emergency tracheotomy?" If the answer is uncertain and the appropriate physicians are not immediately available, it might be prudent to leave the patient intubated and transport to the recovery room or to an intensive care unit.

Extubation Locations

In The Johns Hopkins Medical Institutions, extubations of known difficult airway/intubation patients are done in the recovery room or intensive care units but treated as if they were in the operating room in that the patient's condition must be optimized for a successful extubation, emergency airway equipment must be immediately available and/or set up, a physician who can create a surgical airway must be present, and a physician must be present who can monitor the patient and administer anesthesia or resuscitation medications, if needed. Depending on the complexity of the airway management, some patients are returned to the operating room for extubation and airway management as required.

Nursing Critical Pathway for Difficult Airway/Intubation Patients

Once the care of the patient is transferred to the recovery room or intensive care unit, the patient is entered into a nursing critical pathway, a key element of which is education and Medic Alert enrollment of the patient with a difficult airway/intubation. The pathway prompts nursing personnel to specifically query difficult airway/intubation preoperatively and again on arrival in the recovery room. If difficult airway/intubation is present, the pathway initiates implementation of a specific protocol that includes in-hospital identification, patient-family teaching, enrollment into the in-hospital registry, and a quality improvement system.

In-Hospital Difficult Airway/Intubation Alert Wristbands and Chart Labels

Difficult airway/intubation patient identification also includes a green identification wristband and a patient chart airway alert label. This facilitates transition from a temporary in-hospital registry to the permanent Medic Alert Registry. Similar in appearance to an allergy alert wristband, the green difficult airway/intubation wristband provides continued patient identification and safety during hospitalization. The Joint Committee on Clinical Investigations at The Johns Hopkins Medical Institutions issued a waiver on the need to obtain written informed consent before placing green wristbands on identified patients with a difficult airway/intubation. Health care personnel and patients recognize that the tremendous implications to patient safety outweigh the concern for breach of confidentiality, as already modeled in existing in-hospital allergy alert temporary wristbands and out-of-hospital permanent medical alert bracelets.[28]

Education

The educational component of the Airway Initiative and Airway Service is divided into directed efforts toward family and patient, physicians and health care providers within the institution, administrators of The Johns Hopkins Medical Institutions, and health care providers at large.

Patient and Family

At numerous times during a patient's hospitalization, effective communication with the patient and family is accomplished in preoperative consultation, immediately preoperatively, during the procedure (as requested), immediately postoperatively, and during the postoperative course. Discharge follow-up consists of a letter from the Department of ACCM with an enclosed brochure for enrollment into Medic Alert, as previously discussed with the patient.

Physicians

Physicians at The Johns Hopkins Medical Institutions are invited to participate in the Airway Rotation as appropriate. During this rotation,

in addition to exposure to airway devices identified in the ASA Difficult Airway Guidelines, senior anesthesia residents receive training in the elective use of the OLHN Hollinger and Dedo rigid laryngoscopes. Before elective use in the operating room, the anesthesia resident completes an in-service and mannequin practice under OLHN attending guidance.

Physicians are also invited to attend monthly airway management multidisciplinary case conferences, attend quarterly mandatory risk management seminars in which airway events are highlighted, and participate in monthly equipment workshops and optional cadaver laboratories. Arrangements can be made to observe airway management in the operating room, intensive care units, or emergency department as appropriate.

Institutional Systems Approach

All operating room personnel participate in yearly disaster drills in which difficult airway management is highlighted and protocols are reviewed. The use of simulation has been a component of the educational program for the past 4 years, with acute airway management being the most recent component. Effective education in difficult airway management encompasses much more than simple task training. The high-level components of learning difficult airway management skills include (1) task training (different techniques of airway management), (2) decision making (learning to recognize and react appropriately to an evolving critical situation), and (3) team building (who needs to be present and what their roles are). Classically, this process has taken place in the setting of delivering patient care, under conditions that may not be particularly conducive to education.

Ongoing Education and CME: Workshops, Role of Simulator, and SAM Annual Meeting

Ongoing education includes a series of annual workshops organized by the Airway Service and offered to all members of the medical institution. They include cadaver surgical airway techniques; mannequin rigid laryngoscopy, fiberoptic bronchoscopy, light wands and a variety of other specialty scopes; and mannequin percutaneous cricothyrotomy and jet ventilation. All are case-based to facilitate discussion and are staffed by at least one attending anesthesiologist, otolaryngologist, nursing specialist, and airway equipment specialist.

In recent years, technology has been developed that can realistically simulate a myriad of critical airway scenarios by use of computerized mannequins. Depending on the verisimilitude required, such mannequins can cost between $30,000 and $300,000, with operating costs ranging from negligible to $60,000 per year. Despite the apparent high cost, the use of simulation in airway management education ultimately should be cost-effective with respect to the improved outcomes that would be expected from better-educated clinicians.

The implementation of simulation is occurring in the context of the "competency-based" education movement that is underway in medical education as a whole. The advantages of simulation over the classic methods of patient-based education are fourfold. First, by using simulation, the trainees can get unlimited experience in critical airway situations that are not very common, thereby having an opportunity to practice and improve their skills until a level of proficiency is achieved. Every time an adverse outcome results, the student can review it, learn from it, and hit the reset button to revive the mannequin to try again. Second, the mannequin is programmed to respond to the interventions of the student, whether correct or not. In either case, the student is forced to reassess the situation and make alternative plans. This decision-making process is essential to learn if one is to be capable of managing the difficult airway. The entire process is recorded and compared with instructor-developed objective standards, which permits focused learning. Third, critical airway management is a team game and requires an understanding of the roles of each team member. This is easily simulated using the mannequins while in an environment that is less pressured than if a real critical airway event was taking place. This facilitates better communication between team members, so that everyone has a common understanding of the overall process. Last, the use of simulation ensures that all the clinicians have educational exposure to a set of clinical situations that are standardized with respect to the specific conditions and the specific learning objectives to be achieved. This is not possible in the patient-based educational model.

Individuals interested in participating in a formal continuing medical educational, multidisciplinary, comprehensive, airway course, complete with simulation technology are encouraged to attend the annual SAM Meeting.

Difficult Airway/Intubation: Documentation and Dissemination of Critical Airway Information to Patients

Written documentation of airway events is institution-specific and specialty variable. No standardized, uniform, readily available document exists to precisely record airway events and summarize salient issues.

Issues with Conveying Information Verbally to Difficult Airway/Intubation Patients

When complex airway management patients are discharged, information about critical airway events may be inadvertently not communicated or miscommunicated. Verbal communication of difficult airway information by the provider to the patient is unreliable. Communication may be hindered by patient intubation, sedation, or both. The patient may be expeditiously discharged from the health care facility or discharged by personnel other than the primary health care provider before airway events have been fully communicated. Miscommunication may arise because of the patient's lack of medical knowledge or because of overriding anxiety related to the medical condition. In addition, providers may underrepresent the severity of difficulty, attempting to allay the patient's anxiety or because they themselves fear liability exposure. Written communication of difficult airway/intubation information by the provider to the patient may be a more effective strategy, but the patient may fail to accurately and comprehensively convey this information to future health care providers. Patients may lose the anesthesiologist's letter or memo or fail to give a copy of it to their primary care provider. Then, in an emergency situation, the information will most likely be inaccessible.

When difficult airway/intubation patients re-enter the health care system electively or emergently, they may relate vague verbal histories, deny any difficult airway/intubation history, or be physically unable to communicate.

Issues with Obtaining Information from Previous Medical Records

Attempts to retrieve prior anesthesia records and documentation should be initiated but may be unsuccessful because of time constraints or unavailability. Even when available, written documentation may be incomplete and difficult for other health care providers to decipher. These situations create confusion as to the exact nature of the airway difficulty encountered and airway management used, thus potentially delaying or compromising patient care.

Even when written documentation is complete and adequate, the information is contained in the patient's original medical record. Subsequent elective or emergent retrieval of records by future health care providers, who are separated by geography or time from the original event, may prove to be untimely or impossible.

Electronic Patient Record: Airway Notes and Anesthesiology Consultant Report

Building the electronic patient record (EPR) at Johns Hopkins, we developed and implemented two templates that can be used by the anesthesiologist for either dictating or typing a note on a patient with a difficult airway/intubation. The first template, the Airway Note, is a brief, free-text dictated entry that specifically summarizes airway management. The second, more complete template, the Anesthesiology Consultant Report (ACR), is a one-page to two-page summary that includes airway information in addition to more comprehensive anesthesia concerns.[29]

"Difficult Airway/Intubation" is placed as a "problem" in the patient's PAM (problem, allergy, medication) list in the overview of

the medical record, so that subsequent health care providers will be aware of this specific issue. Because many providers may not read the specific notes on a patient, this PAM alert, similar to an allergy alert, is immediately highlighted whenever the medical record is accessed.

As electronic anesthesia intraoperative records begin to appear in hospitals, it is imperative that they be integrated into the hospital EPR, so that the anesthesiologist only needs to enter relevant difficult airway/intubation information one time. Finally, to close the loop from the surgical side, all surgeons, particularly OLHN surgeons who understand the nuances of difficult airway management, should be encouraged to include in their operative dictation an accurate description of whatever difficult or unanticipated airway events occurred.

Finally, a letter regarding the airway management is sent from the Department of ACCM to the patient, along with a brochure for enrollment into the Medic Alert Foundation.

Case-Based Learning: Case Presentations of Difficult Airway/Intubation Patients

The following cases are available on the book website. Major teaching points for each case are included below.

Case 1: Consultation with the Airway Service for Future Airway Management

- Despite major advances in airway techniques, anesthetic agents, and monitoring, there remain instances when an elective tracheotomy is the airway management technique of choice.

Case 2: Anticipated from Physical Examination: Awake Nasal Intubation

- Patient's upper airway anatomical considerations and presence of a pedunculated lesion in the glottic opening made the first choice of an awake nasal intubation the safest technique.

Case 3: Anticipated from Surgical Procedure: Three Staged Surgeries for Temporomandibular Joint (TMJ) Surgery

- This case illustrates the concept that, for each patient, the airway algorithm used is on the basis of these concepts: full stomach (yes/no), oral or nasal intubation (or neck/surgical), and awake or asleep intubation. In each case, the anesthesia team chose a technique that they had expertise with, that suited the surgical needs, and that was agreed on with the patient.

Case 4: Anticipated Difficult Intubation and Extubation: Trismus versus Fused TMJ

- The diagnosis of trismus presents practitioners with at least two major challenges: (1) distinguishing between masseter muscle spasm/pain and TMJ limited opening, and (2) having multiple airway techniques immediately available, and limited by (1).

Case 5: Anticipated Difficult Intubation: Asleep Oral Intubation

- A multidisciplinary approach to airway management and immediate mobilization to equipment facilitated successful intubation on a patient with a known difficult airway.

Case 6: Unanticipated Difficult Intubation, Difficult Mask Ventilation with LMA, Can Wake Up

- This was a case of difficult mask ventilation in which the LMA proved invaluable as a "bail out" device.

- Until it becomes standard to have anesthesia documentation within electronic medical records, surgeons should be encouraged to briefly document the airway management of their patient in their dictated operative note.

Case 7: Unanticipated Difficult Intubation, Maskable, Cannot Wake Up Because of Long-Acting Paralysis

- In the hands of an experienced practitioner, the Hollinger laryngoscope has a significant role in the management of difficult airway/intubations, as detailed in The ASA Difficult Airway Management Algorithm.[8]

Case 8: Unanticipated Difficult Intubation, Failed RSI, Respiratory Compromise

- Although anesthesiologists assume that most surgeons are facile with surgical airways, this is not always the reality in an emergency situation. Although the introduction of percutaneous cricothyrotomy into anesthesiologists' difficult airway algorithms was thought to address this issue, there are many complications related to its emergency use.

Case 9: Known Difficult Intubation Patient: Consequences of Failed Regional Anesthesia

- The authors strongly advocate for immediate availability of appropriate airway management equipment and support staff for any patient with a difficult airway/intubation receiving regional anesthesia throughout the entire operative period.

Case 10: "Fast Track Evaluation": Preoperative Evaluation and Airway Management of a Patient with Prader-Willi Syndrome

- The optimal evaluation of this patient would have been to be seen by members of the Airway Service before the day of surgery, as had been originally planned by the attending surgeon.

Case-Based Learning: Case Presentations of Catastrophic Events In The Operating Room and the Role of the OLHN Surgeon

The following cases are available electronically. Major teaching points for each case are included below.

Case A: Fire in the Airway

- The best treatment for fire in the airway is prevention.

- In the event of an airway fire, the following steps should be taken:
  1. Stop the flow of O_2 to the ETT.
  2. Remove the ETT.
  3. Flood the field with fluids, if appropriate.
  4. Mask ventilate with 100% O_2.
  5. Reintubate as soon as possible.
  6. Consider positive end-expiratory pressure (PEEP), continued ventilatory support, and high-dose steroids.
  7. Call for immediate consultation with an otolaryngologist to evaluate the extent of the airway burn.

Case B: Postobstructive Pulmonary Edema

- With the relief of the obstruction, either with a surgical airway or oral/nasal ETT, the pulmonary edema becomes evident but can be delayed for some time after the episode of obstruction. Prompt recognition and treatment are essential and include reintubation/surgical airway, oxygenation, PEEP, and diuretics as indicated.

Case C: Rule Out Tension Pneumothorax versus Anaphylactic Reaction

- Rule out latex anaphylaxis has increasingly become the number one differential diagnosis when faced with acute respiratory and cardiovascular compromise that appears anaphylactic in presentation. Many hospitals are latex-safe with the goal of becoming latex-free.

Case D: Rule out MH

- Treatment includes immediate notification to the surgeon, discontinuation of any potential triggering agents, administration of dantrolene, and cardiovascular support of the patient. Temperature increases can be a late sign, and meticulous measurement of temperature and appropriate treatment are critical.

Case E: Rule Out Pheochromocytoma

- Although pheochromocytomas only account for 0.1% of cases of hypertension, when first identified unexpectedly under general anesthesia, the physiologic effects of released catecholamines can be catastrophic and life threatening.[31]

- While this patient does not have known MEA, practitioners must be vigilant in the evaluation of patients in risk populations for MEA, specifically to diagnose pheochromocytoma before the diagnosis is made under general anesthesia.[31]

Conclusion

Difficult airway management, anticipated or unanticipated, is multidisciplinary. Although there is an obvious interactive role for the OLHN surgeon and the anesthesiologist in the "airway" of the ABCs of patient management, successful management depends on joint preoperative evaluation, precise discussions of airway plans, and discussion of immediate plans of action in the event of failed airway management or patient compromise for nonairway issues.

Effective communications, verbal and written, regarding critical airway information is essential to the future safety of patients and facilitates efficient and appropriate future airway management. Practitioners are encouraged to incorporate any/all of the documents presented in this chapter into their practice. Enrollment into Medic Alert should be encouraged for all patients who might benefit from the immediate identification of critical medical information (e.g., difficult airway and anaphylaxis).

Development of an institutional Airway Service can be significant in the delivery of quality patient care. Familiarity with medical, societal, and institutional airway algorithms is a key in the success of an Airway Service.

Finally, all physicians must remain current in basic and advanced resuscitation protocols if they are to actively practice in environments that administer sedation or general anesthesia to patients, because unexpected catastrophic events cannot be predicted and occur when one least expects them or is inadequately prepared to immediately respond to the emergency.

Acknowledgments

We wish to acknowledge Mr. Matthew Logan for photodocumentation presented in this chapter and Ms. Susan Turley for her assistance with medical editing.

CHAPTER TEN

Surgical Management of the Difficult Adult Airway

Nasir Islam Bhatti

Key Points

- The difficult airway must be considered as involving at least one of the following: difficult laryngoscopy and difficult mask ventilation (DMV), and/or difficult tracheal intubation.
- It is important to realize that identification of the difficult airway before manipulation is the first step in preparing for optimal patient care and a safe outcome.
- The otolaryngologist with her or his training and expertise in endoscopic techniques, such as rigid and flexible laryngoscopy, bronchoscopy, and the ability to provide open surgical access to the airway, is an essential member of the difficult airway response team (DART).
- Techniques commonly used in management of the difficult airway include awake fiberoptic laryngoscopy, intubation through a laryngeal mask airway (LMA) with or without fiberoptic laryngoscopy, intubation by direct laryngoscopy with an anterior commissure laryngoscope, and the surgical airway.
- Awake fiberoptic intubation should be considered in the obese patient with obstructive sleep apnea (OSA), in conditions resulting in supraglottic obstruction (e.g., edema, supraglottic tumor), and in patients with history of difficult intubation by other techniques.
- Lack of training and experience in fiberoptic bronchoscopy is a common cause of failure in awake fiberoptic intubation.
- Once the "can't intubate, can't ventilate" situation has been identified, immediate consideration should be given to surgical airway access.

Failure to maintain a patent airway may result in catastrophic events for the patient, including brain damage or death. In 1990, more than 85% of all respiratory event–related closed malpractice claims involved an anoxic brain injury or death.[1] Difficulties with intubation and emergent airway issues remain the leading causes of serious intraoperative complications.[2] As many as 30% of deaths attributable to anesthesia involve failure to manage the difficult airway.[3] In any given patient, the risk of anoxic injury or death increases in direct proportion to the degree of difficulty in maintaining a patent airway.[4] Any scientific or clinical description of the difficult airway must include clearly defined terminology. In this chapter, the difficult airway must be considered as involving three distinct but often clinically related scenarios.

The first of these is difficult tracheal intubation. This condition exists when multiple attempts are needed in the presence or absence of tracheal disease. An infinitely difficult intubation means the trachea cannot be intubated under direct vision, despite full paralysis, optimal head and neck positioning, cricoid pressure, forceful anterior elevation of the laryngoscope blade, and attempts by multiple operators with a variety of laryngoscope blades.[4] The incidence of failed endotracheal intubation ranges from 5 to 35 in 10,000 patients.[5,6]

The second difficult airway scenario is the difficult laryngoscopy. Difficult laryngoscopy is described as not being able to visualize any portion of the larynx, vocal folds, or glottic aperture after multiple attempts at conventional laryngoscopy. Many investigators include grades III and IV or grade IV alone, according to the Cormack-Lehane original grading of the rigid laryngoscopic view.[7] For studies of difficult laryngoscopy to be reliable and for the preceding laryngoscopic grading system to be helpful, the reported grades must describe the best view that was obtained, which in turn depends on the best performance of laryngoscopy.[4] The technical components that optimize laryngoscopy include optimal position, complete muscle relaxation, firm forward and upward traction on the laryngoscope, and, if necessary, firm external laryngeal manipulation with cricoid pressure. External laryngeal pressure, for example, may reduce the incidence of grade III view from 9% to 1.3%.[8] Theoretically, if the preceding technical components of laryngoscopy are used and the pitfalls avoided, all laryngoscopists (novice and expert) should have close to the same laryngoscopic view. Difficult laryngoscopy is synonymous with difficult intubation in most patients. A grade II or III laryngoscopic view requiring multiple attempts with different blades, or both, is relatively common, occurring in 100 to 1800 of 10,000 patients.[9] The incidence of a higher grade III laryngoscopic view ranges from 100 to 400 of 10,000 patients.[10,11]

The third difficult airway scenario is difficult mask ventilation (DMV), which is a condition in which it is not possible to provide adequate face mask ventilation as a result of inadequate mask seal, or excessive resistance due to inadequate patency of airway.[4] Langeron and colleagues compiled a list of predictors of difficult mask ventilation based on a survey of anesthesiologists asking them to rate difficulty of face mask ventilation.[12] This difficulty was based on whether it was clinically relevant and could have led to potential problems if mask ventilation had to be maintained for a longer time. Six reasons for DMV were identified: (1) inability of the unassisted anesthesiologist to

Box 10-1

Differences Between 1993 and 2003 ASA Management of the Difficult Airway Algorithms

1. Difficult ventilation is now listed first under assessment of the likelihood and clinical impact of basic management problems. Also, in the same category, difficult tracheostomy was added.
2. To pursue actively opportunities to deliver supplemental oxygen throughout the process of difficult airway management was added.
3. When considering the relative merits and feasibility of basic management choices, awake intubation versus intubation attempts after induction of anesthesia should now be considered first before nonsurgical techniques as the initial approach to intubation.
4. The use of laryngeal mask airway (LMA) is incorporated into the algorithm in awake limb and after induction of general anesthesia limb in both emergency and nonemergency pathways (either as a ventilator device or as a conduit for tracheal intubation).
5. One more intubation attempt was removed.
6. Rigid bronchoscope was added as an option for emergency noninvasive ventilation.

From Hagberg CA, Benumof JL. The American Society of Anesthesiologists management of the difficult airway algorithm and explanation—analysis of the algorithm. In: Hagberg CA, ed. *Benumof's Airway Management*. 2nd ed. Philadelphia: Mosby Elsevier; 2006:236-251.

maintain oxygen saturation to greater than 92% using 100% oxygen and positive-pressure mask ventilation, (2) significant gas flow leak by the face mask, (3) necessity to increase the gas flow to greater than 15 L/min and to use the oxygen flush valve more than twice, (4) no perceptible gas movement, (5) necessity to perform a two-handed mask-ventilation technique, and (6) change of operator required.

The incidence of DMV is difficult to estimate in that there has not been a standard definition used universally by researchers, so each study needs to be carefully read to determine the definition used. Langeron and colleagues reported a 5% incidence of DMV with 1 in 1502 patients being impossible to ventilate with a face mask.[13] A very significant finding from this study is that DMV conferred a fourfold increased risk for difficult intubation and 12-fold increase in the risk for an impossible intubation.

The incidence of the ultimately critical failed airway, the "can't intubate, can't ventilate" situation, can be estimated because it frequently results in anoxic brain injury or death, ranging from 0.01 to 2 of 10,000 patients.[14,15] Although the cause of this dire apneic or obstructive state may be completely or partially related to the patient's disease, there is often an identifiable iatrogenic component. The clinicians caring for the patient in this urgently life-threatening state must be prepared to act swiftly and decisively in order to sustain or recover oxygen saturation and ensure ventilation.

With these definitions in mind, it is important to realize that identification of the difficult airway before manipulation is crucial, and the key step in preparing for optimal patient care and a safe outcome.[16] Selection of airway equipment or devices, techniques, and procedures all pivot on airway evaluation. The literature provides strong evidence that specific strategies and communication of these strategies with the airway team facilitate management of the difficult airway. The American Society of Anesthesiologists' (ASA) algorithm on the management of the difficult airway is an example of such collaborative effort and should act as a foundation for locally developed institution-specific action strategies.[17] Refer to the differences between 1993 and 2003 versions of the ASA algorithm (Box 10-1).

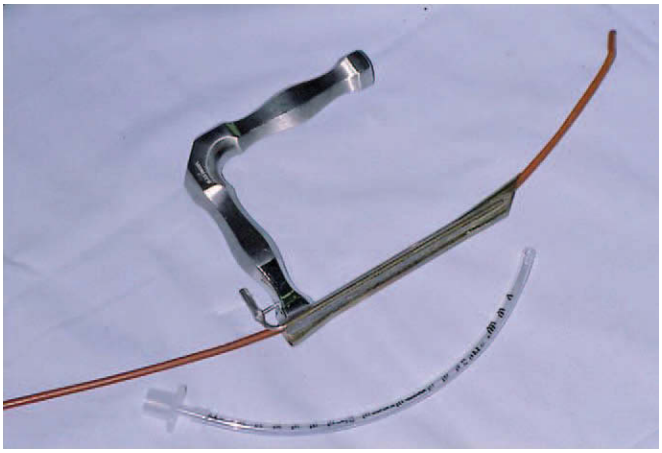

Figure 10-1. Hollinger laryngoscope is the most dependable scope for direct laryngoscopy in management of the difficult airway. Both cuffed and cuffless tubes may be passed through the scope, although size is limited to 5.0 cuffed endotracheal tube. If a larger tube is required, intubation over an Eschmann stylette is possible.

When considering management options for the difficult airway situation, the anesthesiologist and surgeon must give consideration to aborting the planned procedure, waking the patient, and reassessing airway management options before proceeding. When this is not an option, the team must consider alternative techniques for laryngoscopy such as the video-assisted Glidoscope, placement of a laryngeal mask airway (LMA) and intubation by fiberoptic laryngoscopy with or without an Aintree catheter, or direct laryngoscopy with an anterior commissure (Hollinger) laryngoscope and intubation through the laryngoscope.

Use of the LMA in the difficult airway situation has increased as equipment has evolved to facilitate intubation through the LMA. The success of this device led to the introduction of the intubating LMA (LMA Fastrach) into clinical practice.[18,19] Intubation may be accomplished by passing the endotracheal tube (ETT) alone through the LMA (blind technique), or by intubation over a fiberoptic bronchoscope with or without an Aintree catheter placed over the bronchoscope. This technique provides visualization of the intubation and may be combined with videoendoscopy. The addition of the Aintree catheter facilitates intubation after removal of the LMA if this is required to proceed with surgery.

The Hollinger anterior commissure laryngoscope is the otolaryngologist's most useful tool in difficult airway management, and should be considered when all other techniques have failed. This is particularly true for fixed laryngeal and subglottic lesions where a small cuffless ETT may be passed under direct visualization. The Hollinger scope will accommodate a 5.0 or smaller cuffed ETT, although the insufflation port may become lodged in the barrel of the scope. This should be determined before intubation. An Eschmann stylette may also be passed through the laryngoscope and the ETT passed over the stylette, allowing placement of a larger sized ETT (Figs. 10-1).

Awake fiberoptic intubation should always be considered as a viable option, especially in the anticipated difficult airway situation. This technique is discussed in more detail in following sections.

Surgical procedures such as open cricothyroidotomy, tracheostomy, and transtracheal jet ventilation must be considered when faced with the "can't intubate, can't ventilate" situation. The role an otolaryngologist can play in such situations is critical, providing expertise in endoscopic techniques with the ability to provide open surgical access to the airway. The indications, contraindications, technique, and strategies to optimize success with these techniques are discussed herein in detail.

Awake Fiberoptic Nasotracheal Intubation

Awake fiberoptic nasotracheal intubation is now a common technique employed in the management of the difficult airway in both the operating room and intensive care unit settings.

Box 10-2

Indications for Fiberoptic Intubation

I. Difficult intubation
   A. Known or anticipated
   B. Unanticipated failed intubation
II. Compromised airway
   A. Upper airway
   B. Lower airway (tracheal compression)
III. Intubation of the conscious patient preferred
   A. High risk of aspiration
   B. Movement of neck not desirable
   C. Known difficult mask ventilation
   D. Morbid obesity
   E. Self-positioning
IV. High risk of dental damage

Figure 10-2. Cart for anesthesia for the difficult airway demonstrating organization of ancillary items used for fiberoptic intubation.

Historical Perspective

Flexible fiberoptic technology has provided the vehicle for developing and perfecting these intubation techniques. A flexible fiberoptic choledochoscope was first used for nasotracheal intubation on a patient with Stills' disease as early as 1967.[29] Five years later, nasotracheal intubation was successfully carried out in a patient with severe rheumatoid arthritis using a fiberoptic bronchoscope (FOB).[30] Stiles and colleagues subsequently reported the first series of 100 fiberoptic endotracheal intubations.[31] These intubations were performed both orally and nasally, and the authors suggested that with experience, fiberoptic intubation could be performed in less than 1 minute.

Davis and colleagues described the use of FOB for checking the ETT position in relation to carina.[32] Use of FOB in assessing ETT position was shown to be as good as chest radiography in both adults and children.[33,34] Many other uses of FOB technique were also described, especially in critically ill patients, to evaluate the upper and lower airway.[35-38] Several authors cited advantages of the technique, including the ability to perform diagnostic and therapeutic procedures at the bedside without general anesthesia and without interruption of ongoing mechanical ventilation. Another advantage cited was the ability to perform the procedure orally, nasally, or through an in situ ETT or tracheostomy tube. One main disadvantage reported by many authors was the increased airway resistance particularly in pediatric patients because the FOB may occupy a significant portion of the lumen of the tube. FOB was not originally developed for the management of the difficult intubation.[39] However, as technology was advanced and visualization improved, anesthesiologists soon appreciated the value of the FOB in the management of the difficult airway.[40-43] Use of the FOB has been described for airway management in Ludwig's angina,[44] rheumatoid arthritis,[45] trauma,[46] unstable cervical spine,[47] disruptive injuries of the soft tissue of the neck,[48] acromegaly,[49] and Pierre Robin syndrome,[50] among other conditions. Several authors have reported successful use of the FOB in securing the airway in awake patients with increased risk of aspiration.[51-54] As a result, the teaching of fiberoptic airway endoscopy is now an integral part of training for otolaryngology head and neck surgery (OHNS), anesthesiology, and emergency medicine.

Indications

When the airway is compromised or a difficult airway is anticipated, awake fiberoptic intubation (FOI) with or without sedation should be considered (Box 10-2). Awake fiberoptic intubation is an ideal procedure for patients with morbid obesity, supraglottic mass, or edema with the ability to visualize the glottic aperture, risk of aspiration, history of known DMV, patients with limited mandible excursion or trismus, and history of prior difficulty with transoral intubation using other techniques. Contraindications to awake fiberoptic intubation include fixed stenotic lesions at all levels that will not allow passage of an ETT without dilatation, active bleeding obscuring visualization, and acute obstructing supraglottitis, as well as in patients unable to cooperate during the examination. In general, many patients who might be denied general anesthesia or receive a tracheostomy can be safely intubated using the FOB. To intubate patients safely and quickly, certain preparatory steps should be taken.

Bronchoscopy Cart

Proper functioning equipment is essential to a successful outcome. A fully equipped videobronchoscopy cart should be available for use in the intensive care units, emergency department, critical care wards (e.g., otolaryngology patient floor) as well as in the operating room. All equipment and supplies for administration of anesthesia, resuscitation, and monitoring should be available and should be checked following a standard protocol before beginning a nonemergent fiberoptic intubation (Fig. 10-2). For awake intubations, the cart is placed on the left side at the head of the bed while a right-handed operator stands on the right side facing the patient. The light source should be checked for integrity and the necessary supplies are laid out on top of the fiberoptic cart, and suction is connected and at hand. The cart should contain ancillary equipment including nasopharyngeal airway and endotracheal tubes (standard and MLT long tubes), among other items.

Fiberoptic Intubation of the Conscious Patient

The advantages of awake fiberoptic intubation include maintenance of spontaneous ventilation and the ability to position the tip of the ETT precisely beyond the obstruction/compression. It is easiest in the awake near upright patient because the tongue does not fall back in the pharynx, and breathing tends to keep the airway open. In addition, with deep inspiration, the patient can assist the operator in locating the glottis when airway anatomy is distorted. Box 10-3 lists the factors that are crucial for successful completion of an awake fiberoptic intubation. These include training and preparation of the airway team, psychological and pharmacologic preparation of the patient, appropriate monitoring and delivery of oxygen during preparation of the patient and the procedure, expertise of the operator, and a well-functioning bronchoscopy cart.

Preparing the Patient

Psychological Preparation

A successful outcome is more likely to occur with a relaxed and cooperative patient. The preparation starts with an informative, reassuring

Box 10-3

Keys to Successful Awake Fiberoptic Intubation

I. Expert endoscopist
II. Functioning fiberoptic bronchoscope and supplies
III. Preparation of the patient
  A. Psychological preparation: informative, reassuring preoperative visit
  B. Pharmacologic preparation
    1. Premedication
      a. Light or no sedation for calm patients
      b. Heavy sedation for anxious patients
      c. Narcotics when pain is present
      d. Specific drugs for habitual drug users
      e. Anti-sialagogue unless contraindicated
    2. Intravenous sedation
      a. No sedation for patients with severely compromised airway
      b. Conscious sedation for most patients
      c. Heavy sedation for uncooperative patients
    3. Topical anesthesia
      a. Oral intubation: oropharynx, laryngotracheal
      b. Nasal intubation: nasal mucosa, laryngotracheal
      c. Monitoring and oxygen

Modified from Wheeler M, Ovassapian A. Fiberoptic endoscopy–aided techniques. In: Hagberg CA, ed. *Benumof's Airway Management*. 2nd ed. Philadelphia: Mosby Elsevier; 2006:399-438.

preoperative visit with the patient. The process is explained in detail and all the questions are answered. If intubation is going to be performed without any sedation, the reason (which is almost always patient safety) is explained. The patient's active participation is requested, which may include maintaining head position, taking deep breaths, or clearing secretions when requested. When minimal or no sedation is used, the patient should be informed that recall of the procedure is possible.

Pharmacologic

There are three components to the pharmacologic preparation of the patient for awake fiberoptic intubation. These include premedication, limited sedation at the time of intubation, and application of topical anesthesia. The goals of premedication include sedation that augments the psychological preparation and provision of an anti-sialogogue to reduce secretions. Midazolam 1 to 3 mg intramuscularly or 10 to 20 mg by mouth provides adequate sedation in most patients. If the patient's airway or physical condition is compromised, no sedative or opioid should be given before the patient's arrival at a monitored setting where the airway team including an anesthesiologist is in attendance. An anti-sialogogue agent is essential for establishing good topical anesthesia and to optimize conditions for fiberoptic visualization of the glottis.[55] Glycopyrrolate is considered the agent of choice in that it does not cross the blood-brain barrier and causes less tachycardia.

Monitoring

Standard monitoring is applied to all patients undergoing FOB, whether the procedure is performed in the operating room suite, intensive care unit, or any other location. Oxygen is provided by nasal cannula at a flow rate of 3 L/min to all adult patients undergoing FOI unless contraindicated.

Conscious Sedation

When possible, conscious sedation is administered in immediate preparation for intubation. The goal of conscious sedation is to have a calm and cooperative patient who can follow verbal commands and maintain adequate oxygenation and ventilation. Depending on the indication for FOI, an opioid, a sedative, or a combination of both is used. A combination of fentanyl (1.5 μ/kg) and midazolam (30 μ/kg) has been used successfully for these procedures. Remifentanil infusion may also be used for sedation for fiberoptic intubation.[56,57] This approach may not be indicated in the obese patient with obstructive sleep apnea, because it may precipitate an airway crisis. Use of sedation should be discussed with the anesthesiologist before initiating the procedure.

Topical Anesthesia

Instrumentation of the airway without using topical anesthesia is uncomfortable and distressing to an awake patient. Pharmacologic preparation should, therefore, include application of topical anesthesia. Adequate topical anesthesia eliminates pharyngeal, laryngeal, and tracheobronchial reflexes. Presence of excess secretions dilutes the local anesthetic solution, creates a barrier between the drug and the mucosa, and carries the local anesthetic away from the site of action.[58,59] Using an effective antisialogogue is therefore necessary. Furthermore, the absorption rate and amount of topical anesthetic vary according to the site of application, the dose of the drug, and the general condition of the patient.[60-62] The agents are absorbed more rapidly from alveoli than from the tracheobronchial tree. The rate and amount absorbed from the pharynx is even lower. The dosage for topical agents should be halved when applying them to the respiratory mucosa because the plasma levels rise more rapidly than do injections into the tissues.[54]

Nasotracheal Intubation of the Awake Patient

Topical Anesthesia

The more patent nostril is selected and sprayed with 2 mL of oxymetazoline (Afrin). This should be determined in clinic if possible or just before the procedure by direct examination. The cotton-tipped applicators are then soaked in 4% cocaine (4 mL) and gently pasted over the septum and the inferior turbinates. Alternatively, a combination of 4% lidocaine with 1% phenylephrine may be used instead. It is advisable to wait at least 5 minutes, allowing maximal vasoconstriction and topical anesthesia. Using cotton-tipped applicators helps evaluate the patency of the nostril as well as predict the angle of the nasal floor, which slopes downward from front to back. Laryngotracheal anesthesia is achieved by transtracheal injection of 1% lidocaine or by spraying through the FOB during intubation. The oropharynx should also be anesthetized as the gag reflex is stimulated by the nasal route. Using nebulized lidocaine during set-up before the procedure is a useful technique.

Technique

Intubating fiberoptically via the nasal route is easier than the oral approach because the scope is usually pointed straight at the vocal cords as it enters the oropharynx and is generally better tolerated by the patient.[63] Our preferred method is to prepare the nose as described above while setting up the equipment and supplies. The ET tube is placed in warm saline to soften the tube. The cuff is tested by inflation, and to minimize resistance, when deflated the cuff is retracted back so that it is flush with the outer wall of the tube. The nasal passages are first dilated to appropriate diameter with increasingly larger nasal trumpets, which are generously lubricated with lidocaine gel and epinephrine solution (Fig. 10-3). The ET tube is then placed into the nostril, directed downward as it is advanced toward the nasopharynx. If the tube does not make the bend toward the oropharynx, it is pulled back and rotated 90 degrees to the right or left and then reintroduced.

The FOB, which is connected to a videoendoscopy unit, is then passed through the ETT and used to visualize the airway (Fig. 10-4). It is preferable to have the patient's head elevated and if possible to be sitting near upright to minimize airway collapse; the operator faces the patient and video monitor (Fig. 10-5). The video-assisted FOI provides feedback to those assisting with the procedure and facilitates intubation. In 80% to 85% of patients, the epiglottis and vocal folds are seen

Figure 10-3. Nasal trumpet placed for dilatation is lubricated with Xylocaine gel.

Figure 10-4. After placement of the endotracheal tube into the nasal cavity, the fiberoptic bronchoscope is passed through the tube for visualization of the airway.

with minimal or no manipulation of the tip of the scope. In patients who are not breathing spontaneously or are older, the tongue and pharyngeal tissue may fall back and block the exposure of the larynx. A few maneuvers, including extending the head, applying jaw thrust, or gently pulling the tongue forward, help visualize the cords. Once visualized, application of 3-mL aliquots of 2% lidocaine instilled through the scope should be performed at the level of the vocal folds before intubation and time should be allowed for effect. Patience is extremely helpful at this point and continuous communication with the patient, letting him or her know that all is proceeding as planned, helps minimize anxiety. It is also helpful to have multiple syringes with "slip-tip" preloaded with lidocaine, because repeated injections may be necessary until the patient no longer coughs in response to stimulation. The scope is then advanced through the vocal folds. Timing the entry of the scope with the breathing cycle is a useful trick. Once adequate visualization is achieved, the scope is then advanced into the cervical trachea and additional lidocaine in instilled. The scope is then advanced to a level just above the carina and the ET tube is passed over the scope into position. If there is resistance during this maneuver, it is helpful to rotate the ETT 90 degrees clockwise, changing the orientation of the bevel.[64]

Figure 10-5. Optimal setup for fiberoptic intubation includes patient with head elevated to minimize airway collapse, operator facing patient, and entire team observing the procedure on the video monitor.

Avoiding Failure in Fiberoptic Awake Intubation

Causes of Failure

Lack of training and expertise in the use of FOB is the single most common cause of failure in awake fiberoptic intubations. Other causes may be considered under the categories of team factors, patient factors, and equipment issues. These are outlined in Box 10-4.

Pearls to Ensure Successful Awake Fiberoptic Intubation

The training and expertise of the operator and the team is most critical (see Box 10-3 for a list of keys for successful awake intubation). There is no substitute for structured training during residency or fellowship.[65,66] Preparing the team and keeping the communication lines open during the entire process helps ensure successful intubation. Maintaining a fully stocked, easily transportable, and functioning FOB cart at hand is highly desirable as well.

Psychological and pharmacologic preparation of the patient increases likelihood of successful outcome. It is essential to administer an adequate dose of anti-sialogogue, sedative if indicated, and topical anesthesia. The value of proper suctioning before an intubation attempt cannot be overemphasized. The conscious patient can be asked to swallow and cough to clear secretions. In some patients, the tip of the epiglottis may fall against the posterior pharyngeal wall, interfering with the navigation of the scope into the larynx. Application of jaw thrust or gentle but firm pull on the tongue moves the epiglottis away from the posterior pharyngeal wall and corrects the problem.

Advancing the ET tube into the trachea is not possible when the FOB is passed through the Murphy eye of the ET tube rather than the distal opening.[67] Withdrawal of the FOB may be difficult or impossible without damaging the instrument. The scope and the tube should be withdrawn as a unit, the scope disengaged, and the procedure repeated. It is also necessary to use lubrication on the scope to facilitate movement of the tube into and out of the ET tube.[68]

Operative Surgical Airway Options

Historical Perspectives

The role of surgical airway as a lifesaving procedure has been appreciated for thousands of years.[20] Egyptian tablets dating back to 3600 BCE depict surgical tracheostomy.[21] Galen in the second century CE described a tracheostomy using a vertical incision as an emergency measure for airway obstruction.[22] The first detailed description of tracheostomy was published in the sixteenth century by Vesalius, who proposed using the procedure to ventilate the lungs. The Spanish

Inquisition, however, condemned his alleged resuscitation of a Spanish nobleman.[23]

The first recording of a successful tracheostomy in the United States was in 1852. The patient later died of airway stenosis, which remained a common complication of the procedure for decades to follow. A mortality rate of 50% was quoted for tracheostomy in an 1886 paper with many of these deaths attributed to a high incidence of stenosis.[24] A landmark paper by Chevalier Jackson in 1909 described a safe surgical technique and principles that are still applicable.[25] He described many factors that he considered to contribute to a lower mortality rate (3%) at the time. These included optimal securing of the airway before the procedure, the use of local anesthesia instead of sedation, using a specifically designed tube, and meticulous surgical technique and postoperative care. In the same paper, Jackson condemned the technique of high tracheostomy, which was the term used for cricothyrotomy at the time. In a later paper in 1921, Jackson described his series of 200 patients with postcricothyrotomy stenosis in patients referred to him. In addition to the obvious referral bias, the primary indication at the time (inflammatory lesions of the upper airway) might have accounted for high incidence of subglottic stenosis.[26]

After Jackson's criticism, cricothyrotomy continued to be condemned for more than half a century. It was not until Brantigan and Grow published a series of 655 patients undergoing cricothyrotomy for chronic airway management.[27] They described a procedure that was faster, simpler, and less likely to cause bleeding than tracheostomy. The stenosis rate was 0.01% and there were no major complication. Many subsequent studies support their conclusion that cricothyrotomy is a safe and effective surgical procedure and in fact preferable to tracheostomy for emergent airway control.[28]

Cricothyrotomy

Definition

Cricothyrotomy is the establishment of a surgical opening into the airway through the cricothyroid membrane (CTM) and placement of a tube for ventilation.[20] It differs from tracheostomy in the anatomic location of entry into the airway.

Anatomic Considerations

In emergent situations, cricothyrotomy is preferable to tracheostomy because of relative simplicity, speed, and lower perioperative complication rate. The airway at the level of CTM is separated from the skin only by the subcutaneous fat, anterior cervical fascia, and strap muscles laterally. The trachea moves progressively deeper in the neck as it moves caudally. This makes anterior access more difficult. Additionally, the thyroid isthmus overlies the second to fourth tracheal rings, acting as an additional structure to negotiate when performing a tracheostomy.

Box 10-5

Cricoid hook (single curved hook)
Scissors
Tracheal dilator

Cricothyroid Membrane

The CTM stretches between the thyroid cartilage and the cricoid ring and consists of fibroelastic tissue. In an average adult male it is 1 cm high and 2 to 3 cm wide, and located in the midline approximately 1 fingerbreadth below the laryngeal prominence. The vocal folds are approximately 1 cm above the CTM and therefore prone to injury during a cricothyrotomy. The ligament does not calcify with age. It has no overlying muscles, major vessels, or nerves; however, the anterior jugular veins border the membrane laterally and bleeding from these vessels may be substantial.

The right and left cricothyroid arteries are branches of the right and left superior thyroid arteries. In most patients these vessels cross the superior aspect of the CTM to anastomose in the midline.[69] Although at risk for injury during cricothyrotomy, the resulting bleeding is usually self-limiting and easily controlled with gauze packing.

The CTM lies a fingerbreadth below the laryngeal prominence. Its location can also be estimated to be 3 to 4 fingerbreadths above the suprasternal notch with the neck in neutral position, although this may be quite variable depending on body habitus. Identification of the landmarks may be difficult or impossible in the edematous or traumatized neck, and in obese patients.

Surgical Cricothyrotomy

Indications

The primary indication for cricothyrotomy is failure to intubate by oral or nasal means in the presence of an immediate need for definitive airway management and inability to mask-ventilate the patient.

The American Society of Anesthesiologists (ASA) Difficult Airway algorithm recommends a surgical airway as the final endpoint for the unsuccessful arm of the emergency pathway.[70] Despite the introduction of numerous rescue devices for failed airway, the most common errors in the management of the difficult airway result from repeated unsuccessful attempts at intubation in these situations.[71] *Once the "can't intubate, can't ventilate" situation has been identified, immediate consideration should be given to a surgical airway.* Failure to pursue this approach when unable to ventilate will most likely result in delay in achieving airway control, placing the patient at risk for subsequent hypoxic brain injury and/or death. Often the main obstacle is lack of experience or timely recognition of the need to perform this procedure. Adequate training in the laboratory, planning based on an algorithm and availability of equipment, as well as trained personnel, are the keys to successful performance of the procedure. Availability of necessary equipment, preferably packaged as a preassembled kit, prevents wasting crucial minutes gathering supplies in the emergency situation (Box 10-5).

Relative contraindications for cricothyrotomy include age younger than 10 years of age, severe neck trauma with inability to palpate the landmarks, and expanding neck hematoma. Preexisting laryngeal disease with subglottic extension (e.g., malignancy) is another relative

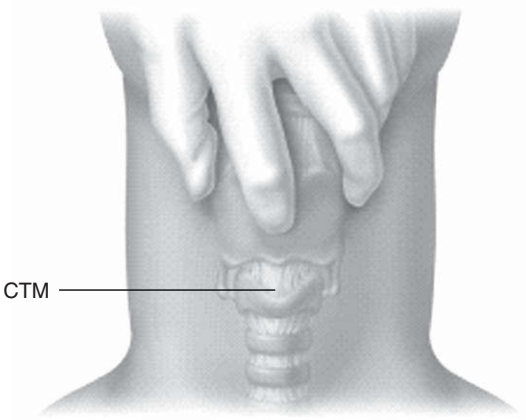

Figure 10-6. With the superior cornu of the larynx firmly immobilized by the thumb and long finger of the nondominant hand, the index finger is free to palpate and locate the cricothyroid membrane (CTM). *(From Walls RM, Murphy MF, Luten RC.* Manual of Emergency Airway Management*. 2nd ed. Philadelphia: Lippincott Williams & Wilkins; 2004.)*

Figure 10-7. A vertical skin incision is made down to, but not through, the airway. *(From Walls RM, Murphy MF, Luten RC, et al.* Manual of Emergency Airway Management*. 2nd ed. Philadelphia: Lippincott Williams & Wilkins; 2004.)*

contraindication. A planned urgent awake tracheostomy is preferred in this situation. Emergency or "slash" tracheostomy is a procedure that carries a very high risk of complications (up to 5 times that of elective procedure).[72]

Surgical Procedure

Identification and palpation of the sternal notch, thyroid cartilage (especially the superior thyroid notch), and cricoid cartilage (felt as an indentation below the thyroid cartilage) is the critical first step (Fig. 10-6). Stabilizing the upper airway with the nondominant hand of the operator during the rest of the procedure is the single most important factor determining successful outcome.[73] This technique pins the larynx in the midline, facilitating dissection by maintaining anatomic positioning of the airway.

A midline vertical skin incision over the cricoid cartilage avoids the often engorged anterior jugular veins and minimizes the risk of injury to the carotid arteries and jugular veins (Fig. 10-7). The membrane is palpated through the incision (Fig. 10-8) and entered with a horizontal incision at the lower edge of the cricothyroid space (Fig. 10-9). This incision is then dilated with a hemostat or Kelly clamp placed in the airway and opened horizontally while lifting upward to expose the opening (Fig. 10-10). A cricoid hook may be placed at the

Figure 10-8. The index finger is used to directly palpate and relocate the cricothyroid membrane. *(From Walls RM, Murphy MF, Luten RC.* Manual of Emergency Airway Management*. 2nd ed. Philadelphia: Lippincott Williams & Wilkins; 2004.)*

inferior edge of the thyroid cartilage (Fig. 10-11) to facilitate elevating and opening the airway. A small (5.0) endotracheal tube or a tracheostomy tube is then placed and secured in position (Fig. 10-12). After stabilizing the patient, the cricothyrotomy should be converted to a formal tracheostomy preferably in the operating room if long-term intubation is anticipated. If early extubation is anticipated, the cricothyrotomy may be used until extubation. See reference 74 for basic technique of cricothyrotomy.

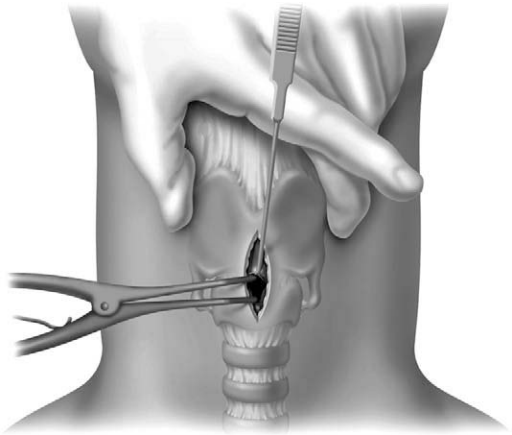

Figure 10-10. The Trousseau dilator is used to enlarge the vertical dimension of the membrane, the aspect providing the most resistance to insertion of the tube. *(From Hagberg CA, ed.* Benumof's Airway Management. *2nd ed. Philadelphia: Mosby Elsevier; 2006.)*

Rapid Five-Step Technique

A rapid four-step technique has been described and reported to be simple to learn and faster in obtaining a surgical airway.[75] This technique has many advantages, including (1) the need for less equipment, (2) the need for only one operator without assistance, (3) the positioning is such that the operator stands at the head end of the patient.[76] The authors prefer a slight modification and use a five-step rule.

1. Identify landmarks and stabilize the airway.
2. Make vertical skin incision.
3. Make horizontal incision through the cricothyroid membrane.
4. Insert clamp to spread and elevate the airway.
5. Insert tracheostomy tube or small endotracheal tube.

The incidence of complications reported after cricothyrotomy varies from 6% to 39% depending on whether the procedure was done semielectively or as an emergent procedure. Reported complications include bleeding, trauma, or injury to the laryngeal framework and/or vocal folds (Fig. 10-13), mediastinal emphysema, pneumothorax, false passage with the tube placed in the mediastinum, esophageal laceration, and failure to secure the airway.

Percutaneous Cricothyrotomy

Primarily based on modified Seldinger technique, many commercially available kits and systems can help place a tracheal airway with limited surgical dissection beyond the skin incision. Although deemed simpler than surgical technique by many nonsurgeons, the procedure increases complexity and requires execution of more than five steps to secure an airway. Although no significant differences in performance times between open surgical cricothyrotomy and the percutaneous procedure have been noted in cadaver and dog models, as with the open cricothyrotomy, severe complications are more likely to occur in the emergent situation.[77,78] One of the limitations of percutaneous cricothyrotomy, especially with the commercially available kits, is the relatively small lumen of the cannula.[76]

In general, percutaneous tracheotomy is considered an elective procedure and should not be considered for emergency airway scenarios. More information and links to demonstrate this technique are available in the online version of this textbook.

Transtracheal Needle Ventilation

This technique can be used as a great option to buy time in an emergency. Access to the equipment, including 100% oxygen at 50 psi, a

large-bore needle and cannula (14 G), and a Luer-Lok connector is all that is required. The airway is accessed by puncturing the trachea or the CTM with a small saline-filled syringe attached to the needle-cannula combination. It is advanced through the skin in the midline in a 30-degree caudal direction. Upon confirming entrance into the airway by the presence of bubbles in the saline-filled syringe, the cannula is advanced while withdrawing the needle. The cannula is then connected to the oxygen with the Luer-Lok connector and a manual interrupter switch. The patient can only be oxygenated with this technique for 30 minutes to 2 hours because this type of ventilation is suboptimal.

Complications associated with this procedure are similar to those in cricothyrotomy and include improperly placed catheter and mediastinal emphysema, pneumothorax, hematoma, and kinking of the catheter with inability to adequately oxygenate or ventilate the patient. Similar to percutaneous cricothyrotomy, the author prefers to use this technique in elective or semiurgent situations only.

Conclusion

It is our belief that difficult airway management is an emerging subspecialty within otolaryngology head and neck surgery. The nature of these situations demands a multidisciplinary effort to standardize institutional action plans and strategies for training, and day-to-day management of these patients, capitalizing on the skills provided by experienced anesthesiologists, otolaryngology head and neck surgeons, general surgeons, emergency department physicians, respiratory therapists, and nursing staff.

Acknowledgments

The author wishes to thank Dr. Kulsoom Laeeq, MD, for her help with editing the manuscript for this chapter.

CHAPTER ELEVEN

Overview of Diagnostic Imaging of the Head and Neck

Nafi Aygun

S. James Zinreich

Key Points

- The choice of imaging modality varies depending on the location and nature of the disease process.
- CT is fast and widely available and can be employed as the first and often the only imaging modality in the majority of the disease processes affecting the neck.
- CT excels in demonstrating bone detail.
- IV contrast administration for CT examinations improves the quantity and quality of information provided.
- Radiation exposure from CT examination is substantial and should be taken into account particularly in young patients who require repeat examinations.
- MRI provides excellent soft tissue contrast and is the modality of choice in most aggressive processes.
- Appropriate use of fat suppression and IV contrast are essential for most MRI examinations of the head and neck.
- The accuracy of PET increases when it is used in conjunction with CT.
- Successful primary staging of most malignant lesions in the neck can be accomplished with CT or MRI and clinical examination.
- PET/CT is superior in identifying distant metastases and postoperative follow-up.
- Image interpretation should always be made in conjunction with clinical information.
- To provide a practical differential diagnosis for neck mass lesions, an approach based on neck spaces that are defined by the cervical fascia is advised.

Diagnostic medical imaging has changed medical and surgical diagnosis in ways never imagined. Every area of clinical medicine has been affected in a profound way. Radiologists are able, through their consultations, to assist the otolaryngologist in a variety of ways, including providing primary diagnosis, confirming a clinical impression, evaluating regional anatomy and extent of disease, assessing response to treatment, and assisting in definitive treatment of patients.

Neuroradiologists are subspecialty trained radiologists who specialize in the imaging of the head and neck, skull base, temporal bone, brain, and spine. They are the primary imaging consultants for otolaryngologists.

This chapter provides an introduction and overview of head and neck imaging for the otolaryngologist. The various available imaging modalities are discussed. Imaging strategies for various regions and clinical questions are reviewed. The basic approach to the radiologist's image acquisition and interpretation are described so that the referring physician will gain a measure of understanding of this field. This is intended to maximize the usefulness of diagnostic imaging in the care of patients.

The scope of head and neck imaging is too broad a topic to be covered in one chapter. The authors provide the clinician with an outline and brief synopsis of the field. Definitive textbooks for each area of head and neck imaging are available.[1-4]

Available Imaging Modalities

Conventional Radiography

Since the discovery of the x-ray, conventional radiography (CR) has been used in imaging the head and neck region. CR in the head and neck imaging has been largely replaced by computed tomography (CT). The traditional projections obtained with CR that are applicable to head and neck imaging are described here.

Views of the Facial Bones and Sinuses

Lateral, Caldwell, Waters, and submentovertex (SMV or base) views are attainable. The lateral view shows the frontal, maxillary, and sphenoid sinus. It is best obtained 5 degrees off the true lateral position to avoid superimposition of the posterior walls of the maxillary sinuses. The Caldwell view displays the frontal sinuses and posterior ethmoid air cells. It is obtained in the posteroanterior (PA) projection with 15 degrees of caudal angulation of the x-ray beam. The Waters view can show the maxillary sinuses, anterior ethmoid air cells, and orbital floors. It is obtained in the PA projection with the neck in 33 degrees of extension. The SMV view can show the sphenoid sinuses and the anterior and posterior walls of the frontal sinuses. It is obtained in the anteroposterior (AP) projection with the head in 90 degrees of extension.

Views of the Neck

AP and lateral views of the neck exposed for soft tissue detail are useful for the evaluation of the overall contour of the soft tissues of the neck. These views are essentially the same projections used in the evaluation of cervical trauma, but they are not exposed for bone detail.

Temporal Bone Views

Several projections are acceptable for visualizing portions of the temporal bone, including the Schüller projection, a lateral view of the mastoid obtained with 30 degrees of cephalocaudad angulation. The Stenvers projection is an oblique projection of the petrous bone obtained with the patient's head slightly flexed and rotated 45 degrees toward the side opposite the one under study. The beam is angulated 14 degrees. The transorbital projection is a frontal projection of the mastoids and petrous bones. Conventional imaging of the temporal bone has largely been replaced by CT scanning.

Computed Tomography

CT was developed for clinical use in the mid-1970s by Hounsfield. CT scanners have evolved over time such that the most advanced scanners now scan in a "helical" fashion, in which the scanner uses a slip-ring technique. This allows the table to move as the scan is performed, resulting in complete volumes of tissue being imaged without skipping tissue between slices. The ratio of the speed at which the table moves to the time it takes for a complete rotation of the CT tube is called the pitch. Multidetector CT allows scanning of multiple slices during one rotation of the CT tube which significantly increases the speed of examination, which in turn makes it possible to obtain much thinner slices in a short time. At present, CT scanners can obtain slices 0.5 mm thick. A neck examination from skull base to the mediastinum can be performed in less than 30 seconds. More importantly, enhanced computer technology permits real-time manipulation of these data, allowing multiplanar and various forms of three-dimensional reconstructions without image degradation. Images can be reconstructed in any desired plane regardless of the plane at which they are acquired.

CT uses a tightly collimated x-ray beam that is differentially absorbed by the various body tissues to generate highly detailed cross-sectional images. The degree of attenuation of the x-ray photons for each voxel (smallest imaging unit) is assigned a numeric readout. These units of attenuation are known as Hounsfield units (HU) and generally range from −1000 HU to +1000 HU. Water is assigned a value of 0 HU. Fat is approximately −80 to −100 HU. Calcium and bone are in the 100 to 400 HU range, and most fluids are in the 0 to 30 HU range.

To create images from the attenuation values, CT uses complex mathematical reconstruction algorithms. Bone disease and bone trauma are best visualized with a bone detail algorithm whereas a soft tissue algorithm is used to evaluate soft tissue structures (Fig. 11-1).

Computed Tomography Image Display

Images from a given reconstruction algorithm can be displayed in various ways to highlight differences in attenuation of different structures. The window width refers to the range of attenuation values in HU that make up the gray scale for a given image. The window level refers to the center HU value for that given window width. A narrow window width of 80 HU and a level of 40 HU is frequently used for brain imaging because it centers the density at the common density of brain tissue, and displays only those densities 40 HU greater than and 40 HU less than the window level. Thus any density greater than 80 HU will be displayed as white, and any density less than 0 will be displayed as black on the gray scale. Any intermediate density will be spread out evenly along the gray scale. For imaging of the soft tissues of the head and neck, a window level of approximately 40 to 70 HU is usually chosen, at a midpoint approximately equal to the density of muscle. The window width frequently is in the 250 to 400 HU range, thus displaying a wider range of densities including calcification, intra-

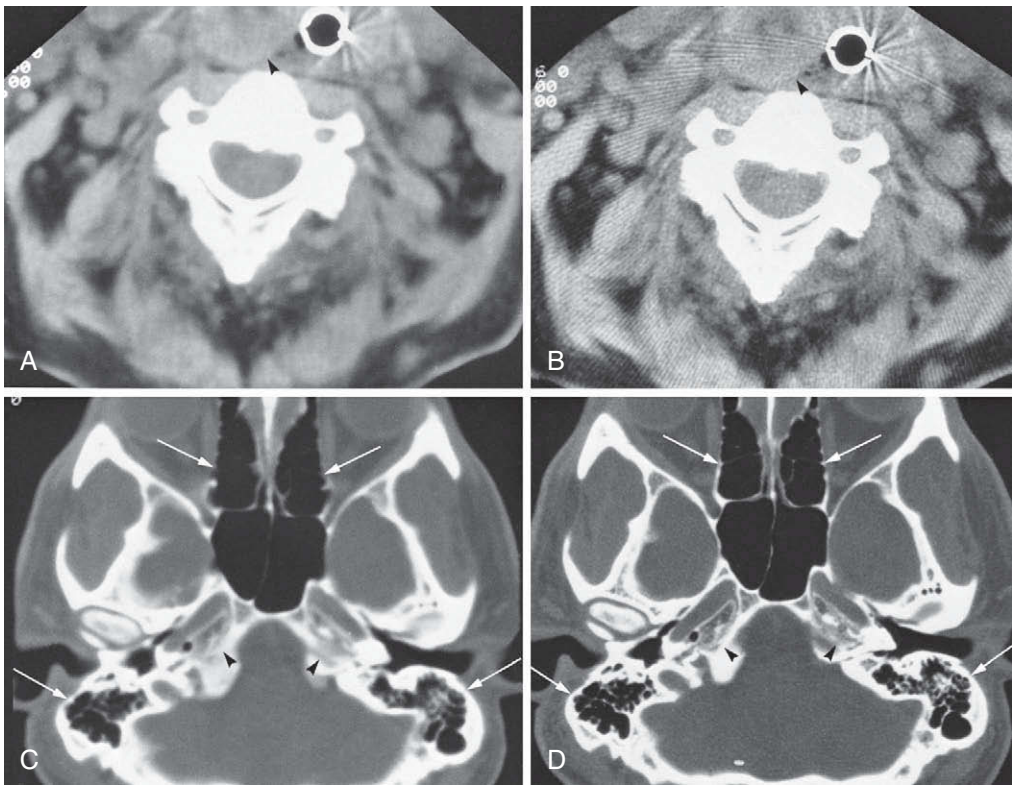

Figure 11-1. Comparison of various computed tomography algorithms and windows. **A,** Soft tissue algorithm and **B,** bone algorithm images of a laryngeal hematoma *(arrowheads)* using soft tissue windows (350 HU width). The bone algorithm image has a grainier appearance, whereas the standard algorithm gives a smoothed image. Soft tissue algorithm **(C)** and bone algorithm **(D)** images of the skull base using bone windows (4000 HU width). Note the improved sharpness of the petrous apex trabeculae *(arrowheads)* and bony walls of the mastoid and ethmoid sinus air cells *(arrows)*.

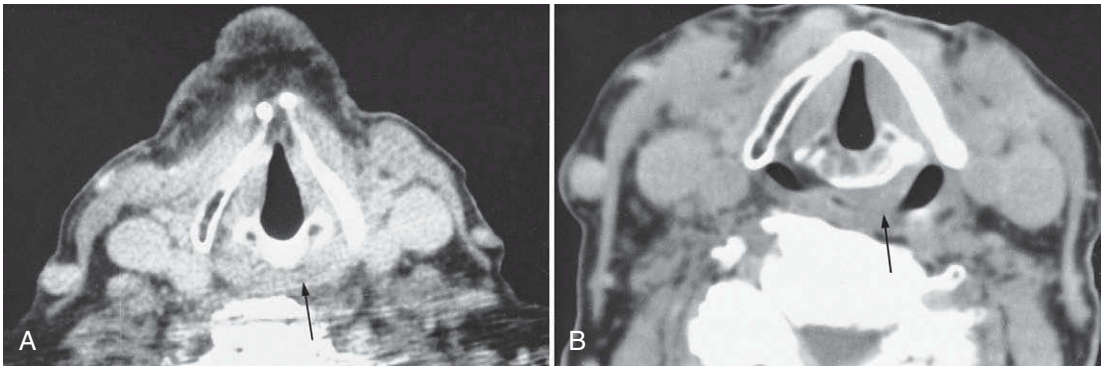

Figure 11-2. Larynx without and with modified Valsalva maneuver. **A,** Axial contrast-enhanced computed tomography (CECT) performed during quiet breathing does not allow discrimination of the retrocricoid carcinoma *(arrow)* because the posterior pharyngeal wall is collapsed against the mass. **B,** Axial CECT in the same patient (a few minutes later) obtained with a modified Valsalva maneuver causes distention of the now air-filled hypopharynx, permitting tumor detection *(arrow)*.

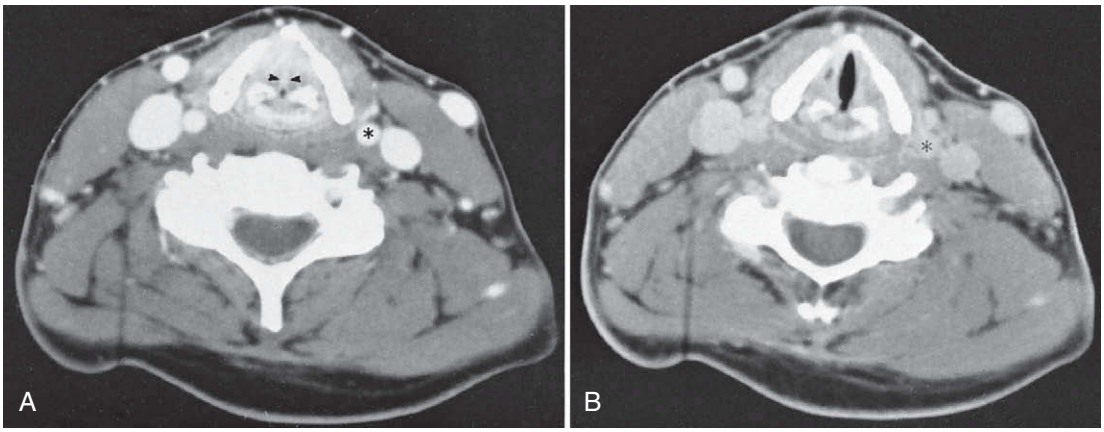

Figure 11-3. Axial contrast-enhancing computed tomography during breath holding and while phonating. **A,** This axial computed tomography, obtained during breath holding, shows the true vocal cords adducting and approximating each other *(arrowheads)*. Note the superb high-contrast density in common carotid artery *(asterisk)* and jugular veins. **B,** Phonating "eeee" causes the vocal cords to partially adduct into the paramedian position. Note that the contrast density has significantly decreased in the common carotid artery *(asterisk)* and the jugular veins in this delayed image, obtained well after contrast infusion had finished.

venous contrast, muscle, and fat to best advantage. For imaging bony structures such as paranasal sinuses and temporal bone, window levels from 0 to 400 HU and a wide window width of 2000 to 4000 HU may be chosen. The reason for a wide bone window width is that a wide range of densities ranging from cortical bone (approximately +1000 HU) down to gas (−1000 HU) need to be displayed on the same image. However, structures of intermediate density between bone and gas occupy a narrow range on the gray scale at this window width and are poorly discriminated (appear washed out) on these settings. The terminology commonly used to describe the previously mentioned windows includes soft tissue windows (window width of 250 to 400 HU) and bone windows (2000 to 4000 HU). It is important to understand that these display windows are completely independent of the mathematical imaging algorithm chosen for creation of the image. In other words, an image created by a soft tissue algorithm can be displayed with soft tissue and bone window widths (see Figs. 11-1A and C). Conversely, the image may be computer reconstructed using a bone algorithm and displayed with either soft tissue or bone window width (see Fig. 11-1B and D). To optimize the imaging of the soft tissue lesion and the adjacent bone, a soft tissue and a bone algorithm may be used, generating images with the appropriate soft tissue and bone windows. (See also Figs. 11-12A and C).

Multiple options for displaying the image (adjusting the window level and width parameters on the imaging console) and recording it permanently on radiographic film or other media are available. Picture archiving and communication systems (PACS) are becoming the norm for image display and storage.

Patient Cooperation

Patient cooperation is necessary to obtain optimal image quality. The patient is instructed not to swallow and to stop breathing or to maintain quiet breathing during each slice acquisition to minimize motion artifact from the adjacent airway and pharyngeal structures. Occasionally, provocative maneuvers such as blowing through a small straw or using a cheek-puffing (modified Valsalva) maneuver to distend the hypopharynx, or phonating to assess vocal cord movement, may be necessary (Figs. 11-2 and 11-3).

Contrast enhancement often is used to opacify blood vessels and to identify regions of abnormal tissue as identified by abnormal enhancement patterns (Fig. 11-4). As it relates to head and neck imaging, contrast is particularly useful in CT scans of the neck and orbits. Contrast often is not needed in evaluation of the temporal bones, although it can be necessary on occasion. CT of the facial bones and paranasal sinuses does not require intravenous contrast for most common applications.

Radiation Exposure

As a brief review, the radiation exposure (dose) that a patient receives is known as the *radiation absorbed dose*. This radiation absorbed dose is a measure of the total radiation energy absorbed by the tissues, and

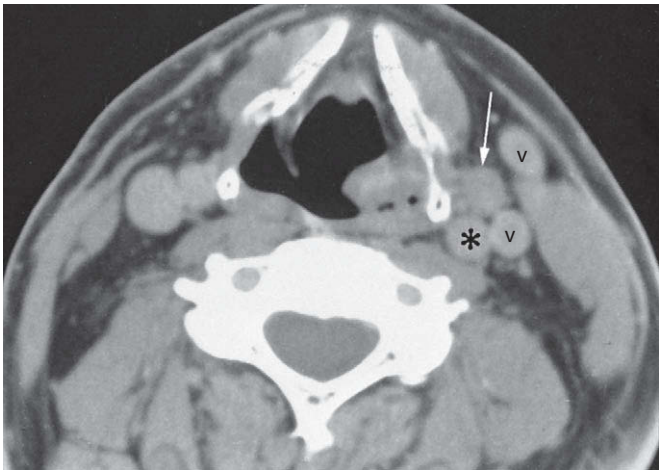

Figure 11-4. Contrast-enhancing computed tomography (CECT) with suboptimal contrast infusion. This axial CECT of a patient with a left piriform sinus tumor was obtained with insufficient contrast infusion, resulting in poor discrimination of the common carotid artery *(asterisk)* and jugular vein (v) from the isodense adjacent metastatic lymph node *(arrow)*. Inadequate contrast infusion also reduces the likelihood of identifying the focal defect in nodal metastasis.

it is expressed in an international system (SI) unit known as the Gray (Gy). One Gy is the amount of radiation needed to deposit the energy of 1 Joule (J) in 1 kg of tissue (1 Gy = 1 J/kg). Formerly, the unit used to express radiation absorbed dose was the rad (1 rad = amount of radiation needed to deposit the energy of 100 ergs in 1 g of tissue). The conversion of rads to Gy is 1 Gy = 100 rad.

Radiation dose equivalent is a more useful term as it considers the "quality factor" (Q) of the radiation involved (radiation dose equivalent = radiation absorbed dose Q). The quality factor considers the varying biologic activity of various types of ionizing radiation. For x-rays, Q = 1. Thus when discussing diagnostic x-rays, the radiation dose equivalent equals the radiation absorbed dose. The SI unit for the radiation dose equivalent is the Sievert (Sv). The former unit was the Roentgen equivalent for man (rem). In summary, 1 Gy = 1 Sv, and 1 Sv = 100 rem.

The radiation dose equivalent depends on the choice of tube voltage and current settings (kVp and mAs), slice thickness, pitch, and gantry cycle time. For a given kVp, the radiation dose equivalent will vary linearly with the mAs. The actual dose will vary slightly among machines. The radiation dose equivalent for a CT examination can be considerably reduced using a low-mAs technique.

The effective dose equivalent was developed as a means of representing the fraction of the total stochastic risk of fatal cancers and chromosomal abnormalities resulting from the irradiation of a particular body part. A system of weighting is used to consider the individual susceptibility of the body's major tissues and organs. A full discussion of this is beyond the scope of this chapter. Suffice to say that, for a given examination, the effective dose to the patient is less than the dose (radiation dose equivalent) received by the area under examination. Table 11-1 lists common radiologic procedures and their effective dose equivalents.

Table 11-1

Estimated Effective Dose Equivalent of Common Examinations

Examination	Effective Dose Equivalent
Chest radiograph	20 mrem
CT, abdomen	1000 mrem
CT, chest	1000 mrem
CT, brain	120 mrem
CT, sinus	70 to 130 mrem

From Nationwide Evaluation of X-Ray Trends (NEXT) 2000 Survey of Computed Tomography. Frankfort, KY: Food and Drug Administration, Center for Devices and Radiological Health; August 2007. CRCPD Publication E-07-2.

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) is an imaging modality that uses the response of biologic tissues to an applied and changing magnetic field to generate images. It is not possible to completely describe the principles of MRI in an introductory chapter of all head and neck imaging. A brief summary of MRI follows.

Two types of magnets are used to perform clinical MRI: permanent and superconducting. Permanent magnets do not require continual input of energy to maintain the magnetic field. They are composed of large magnetic metallic elements set up to generate a uniform magnetic field between components. Superconducting magnets are electromagnets usually composed of niobium-titanium wire. They require input of energy to start them, but once they are up to strength, they are maintained in a superconductive state by means of an encasing system of liquid nitrogen and liquid helium shells.

The earth has a magnetic field strength of 0.5 Gauss (G). The tesla (T) is another unit of magnetic strength that is related to G by the equation 1 T = 10,000 G. Clinical MRI units usually operate at magnetic field strengths of between 0.3 and 3.0 T. Small-bore research scanners of strengths up to 9.0 T are in use.

Many MR pulse sequences are available to generate images. The most common pulse sequences in MRI are the spin-echo and gradient echo techniques.

MRI is one of the most active areas of development and research within diagnostic radiology. MRI derives its signal from hydrogen protons, most abundant in tissue fat and water. When placed in a high magnetic field, the spinning protons are aligned in the direction of the magnetic field. Radio frequency pulses are transmitted into the subject to excite the spinning protons, changing their orientation with respect to the magnetic field. As the protons realign with the magnetic field, they lose energy and give off a signal, which is picked up by coils and reconstructed into an image. The quality of MRI depends on a high signal-to-noise ratio, which is used to improve image contrast and spatial resolution. In general, the higher the field strength of the magnet, the higher the signal-to-noise ratio.

A surface coil is a receiving antenna for the radio frequency signal that is emitted from the imaging subject after the initial radio frequency stimulation. The standard head coil is usually adequate for studying head and neck disease above the angle of the mandible. A head coil allows imaging of the adjacent brain and orbits, an advantage when head and neck lesions extend intracranially. Neck coils cover a larger area from the skull base to the clavicles and come in various configurations, for example, volume neck coil and anterior neck coil. Surface coils significantly improve the quality of head and neck imaging by more effectively collecting the signal hence increasing the signal-to-noise ratio but they are able to collect signal from a smaller body part.

Slice thickness on MRI is most commonly 5 mm, with 3-mm sections used for smaller regions of interest. However, a thinner slice has a smaller signal-to-noise ratio. Occasionally, 1- to 2-mm sections may be needed for small structures (e.g., facial nerve), requiring a volume acquisition technique. The number of slices is limited in MRI (as opposed to CT) by the specific sequence used. Covering the entire neck from skull base to superior mediastinum often requires that two separate acquisitions be obtained.

Magnetic Resonance Imaging Artifacts

Motion artifact, chemical shift artifact, susceptibility artifacts from metallic implants (e.g., amalgam, orthodontic implants), and eyelid mascara degrade MRI (Fig. 11-5). Motion artifact becomes more

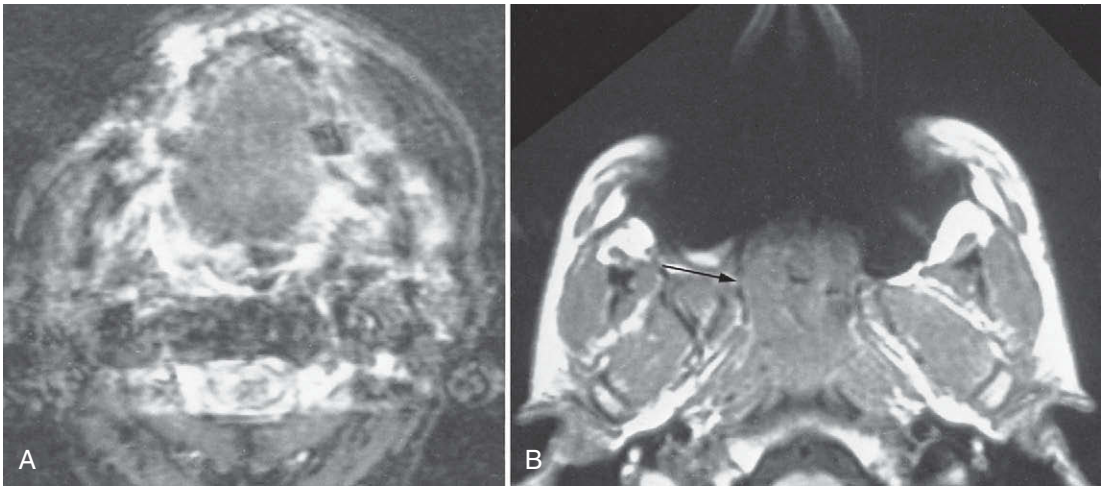

Figure 11-5. Magnetic resonance imaging artifacts. **A,** Motion during axial short T1 inversion recovery sequence caused significant degradation of the image with anatomic distortion and mismapping of the signal intensity. **B,** Metallic dental braces cause artifacts distorting anterior facial structures in this T1-weighted image of a boy with juvenile angiofibroma filling the nasal cavity *(arrow)* and nasopharynx. Anterior maxilla and portion of the nose have been distorted.

prominent with increased field strength, increased length of individual pulse sequences, and the total length of the imaging study. A typical imaging sequence may last from 2 to 8 minutes. To limit motion artifact, sequences fewer than 4 minutes are preferred, and the patient should be instructed not to swallow and to breathe shallowly and quietly.

Chemical shift artifact arises from the differences in resonance frequencies of water and fat protons. The result is an exaggerated interface (spatial misregistration) in areas where fat abuts structures containing predominantly water protons such as the posterior globe or a mass. Chemical shift artifact may produce the appearance of a pseudocapsule around a lesion or cause obscuration of a small-diameter structure such as the optic nerve. Chemical shift artifact may be identified as a bright band on one side of the structure and a black band on the opposite side. This is usually most noticeable on T1-weighted images (T1WIs).

Metallic artifact from dental work varies in severity depending on amount and composition of the metal in the mouth, as well as the pulse sequence and field strength of the MRI scanner. Most dental amalgam causes mild distortion to the local magnetic field, resulting in a mild dropout of signal around the involved teeth. Extensive dental work, metallic implants, and braces may cause more severe distortion of the image, precluding visualization of the maxilla, mandible, and floor of the mouth. Mascara containing metallic compounds can also cause localized signal loss in the anterior orbit and globe.

Magnetic Resonance Imaging Pulse Sequences

Numerous pulse sequences are available on clinical MRI units. The details of the physics of MRI may be found in most radiology and MRI textbooks. Commonly used imaging protocols include T1-weighted, spin (proton) density, T2-weighted, gadolinium-enhanced T1-weighted, fat-suppressed, and gradient echo imaging. Magnetic resonance angiography (MRA) is infrequently obtained (Figs. 11-6 and 11-7). The abbreviations used to identify sequence parameters are repetition time (TR), echo time (TE), and inversion time (TI) and are measured in milliseconds. The following description of pulse sequences is intended to assist the clinician in identifying and understanding the commonly performed sequences and in determining their respective use in the head and neck.

T1-Weighted Images

T1-weighted (short TR) sequences (see Figs. 11-6A and 11-7A) use a short TR (500 to 700 msec) and a short TE (15 to 40 msec). T1-weighted imaging is the fundamental head and neck sequence because it provides excellent soft tissue contrast with a superior display of anatomy, a high signal-to-noise ratio, and a moderate imaging time (4 to 5 min), minimizing motion artifacts. Fat is high signal intensity (bright or white) on T1WIs and provides natural contrast in the head and neck. Air, rapid blood flow, bone, and fluid-filled structures (e.g., vitreous and cerebrospinal fluid [CSF]) are low signal intensity (dark or black) on T1WIs. Muscle is low to intermediate in signal intensity on T1WIs. The inherent high contrast of fat relative to adjacent structures allows excellent delineation of the muscles, globe, blood vessels, and mass lesions that border on fat. The cortical bone is black, and the enclosed bone marrow is bright from fat within the marrow. The aerated paranasal sinuses are black, whereas retained mucous or mass lesions are of low to intermediate signal intensity. Most head and neck mass lesions show a comparable signal to muscles on T1WIs. (To quickly identify a T1WI: fat is white, CSF and vitreous are black, and nasal mucosa is low signal.)

T2-Weighted Images

T2-weighted images (see Fig. 11-6C) use a long TR (2000 to 4000 msec) and a long TE (50 to 90 msec) and are sometimes referred to as long TR/long TE images. Note that spin density and T2WI are acquired simultaneously from a single sequence that produces two sets of images with the same TR but different TEs. For example, spin density = 2000/30 and T2WI = 2000/80. T2WIs are most useful for highlighting pathologic lesions. T2WIs show the vitreous and CSF as high signal intensity (bright) relative to the low to intermediate signal intensity of head and neck fat and muscle. Fat loses signal intensity with increased T2 weighting. Most radiologists use a fast spin-echo (FSE) T2WI for head and neck imaging, which provides a much faster acquisition with improved signal-to-noise. Fat remains bright, however, on FSE images. Most head and neck masses are higher signal intensity on a T2WI compared with their low-to-intermediate signal intensity on T1WI. The combination of the T1WI and T2WI is often useful for characterizing fluid-containing structures, solid components, and hemorrhage. Bone, rapid vascular flow, calcium, hemosiderin, and air-containing sinuses are black. Inflammatory sinus disease and normal airway mucosa appear very bright. (To quickly identify a T2WI: CSF, vitreous, and nasal mucosa are bright. Muscle is low to intermediate in signal.)

Gadolinium Enhancement

Gadolinium-based contrast material is used in conjunction with T1WI sequences (gadolinium shortens the T1) and, with the dose used, it has little effect on T2WI. The advantages of contrast enhancement are increased lesion conspicuity and improved delineation of the margins of a mass relative to the lower signal of muscle, bone, vessel, or globe.[5]

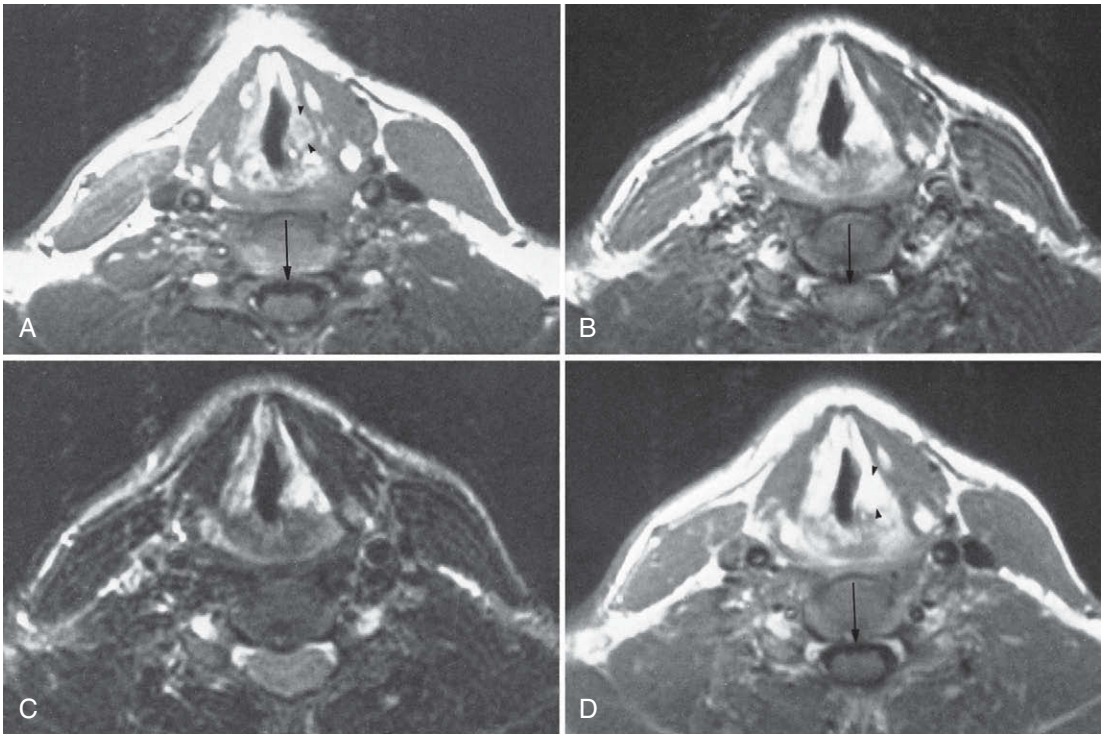

Figure 11-6. Common magnetic resonance imaging pulse sequences without fat suppression. **A,** Axial T1-weighted image (T1WI) of the left glottic tumor *(arrowheads)*, which is intermediate in signal intensity and thickens the true cord. Note that the cerebrospinal fluid (CSF) surrounding the spinal cord *(arrow)* is black, indicating that this is a T1WI. **B,** Spin density-weighted image also reveals high signal intensity (caused by increased water content) of the vocal cord tumor. CSF is now isointense to the spinal cord *(arrow)*, indicating this is a spin density sequence. **C,** T2-weighted image demonstrates a high signal intensity mass clearly demarcated against the dark background of fat and muscle. **D,** Postgadolinium T1WI shows enhancement of the cord tumor *(arrowheads)*. CSF remains black *(arrow)*.

However, gadolinium enhancement (without concomitant fat suppression) has had limited usefulness within the head and neck, as well as in the orbit, because of the large amount of fat present within these regions (see Fig. 11-6D). After gadolinium injection, the signal increases within a lesion, often obscuring the lesion within the adjacent high signal intensity fat.[6] Therefore, for head and neck imaging, gadolinium is optimally used with specific fat suppression techniques that turn fat dark or black. Gadolinium enhances normal structures including nasal and pharyngeal mucosa, lymphoid tissue in Waldeyer's ring, extraocular muscles, and slow-flowing blood in veins, all of which may appear surprisingly bright, especially if combined with fat suppression techniques. (To quickly identify a gadolinium-enhanced T1WI: nasal mucosa is white, fat is white, and CSF and vitreous are black. Also look for Gd-DTPA printed directly on the image or on adhesive study labels.)

Fat Suppression Methods

Several sequences have been developed that suppress fat signal intensity. T2WIs, short TI inversion recovery (STIR), spectral presaturation inversion recovery (SPIR), and chemical shift selective presaturation (fat saturation) are some of the more common clinically available methods of fat suppression. One advantage of fat suppression is reduction or elimination of chemical shift artifacts by removing fat signal from the image while preserving water signal. Additionally, some fat suppression techniques take advantage of gadolinium enhancement by eliminating the surrounding high intensity signal from fat while retaining the high intensity enhancement produced by gadolinium. Most pathologic lesions have increased water content, and gadolinium exerts its paramagnetic effects while in blood vessels and in the increased extracellular fluid of the lesion, but gadolinium does not enhance fat. The fat signal can be manipulated in the following ways:

1. STIR (see Fig. 11-7E) provides reliable fat suppression over large body parts.[7] The inversion time (e.g., TI = 140 msec) is individually "tuned" for each patient to place fat at the null point of signal intensity and thus eliminates fat signal by turning it completely black. STIR images show the mucosa, vitreous, and CSF as very high signal intensity. Most mass lesions in the head and neck have similar high signal intensity on STIR and T2WI. The disadvantages of STIR are image degradation secondary to a decreased signal-to-noise ratio, and increased vulnerability to motion artifacts including the vessel pulsations. Additional disadvantages of STIR, such as increased scan time and fewer slices, are circumvented by the recently available fast sequences. (To quickly identify a STIR image: fat is almost completely black; CSF, vitreous, and mucosa are very bright. A TI is listed with the TR and TE times on the image.)

2. Frequency selective presaturation sequences (see Fig. 11-7B) typically used with a spin-echo technique selectively suppress fat signal. (Note that for the remainder of this chapter, the terms fat suppression and fat saturation are used interchangeably and refer to frequency [chemical shift] selective presaturation techniques). T1-weighted fat saturation sequences take full advantage of gadolinium enhancement. A gadolinium-enhancing lesion within the head and neck retains its high signal intensity and is not obscured, because fat is suppressed to become low to intermediate signal intensity. Enhancing masses within the head and neck and orbit are particularly well imaged with this technique.[8] Frequency selective fat suppression is also complementary for FSE T2WIs (see Figs. 11-7C and D). Fat-saturated T2WIs provide excellent fat suppression, optimizing the high signal from normal structures and lesions that are high in water content contrasted against a black background of fat. The disadvantages of fat saturation sequences are that non–gadolinium-enhancing lesions may be less well discriminated, that these sequences are more susceptible to artifacts, and that nonuniform fat suppression can occur. Also, fewer slices are acquired than with T1WI, unless the TR time is lengthened, which prolongs imaging time. (To quickly identify a gadolinium-enhanced T1WI

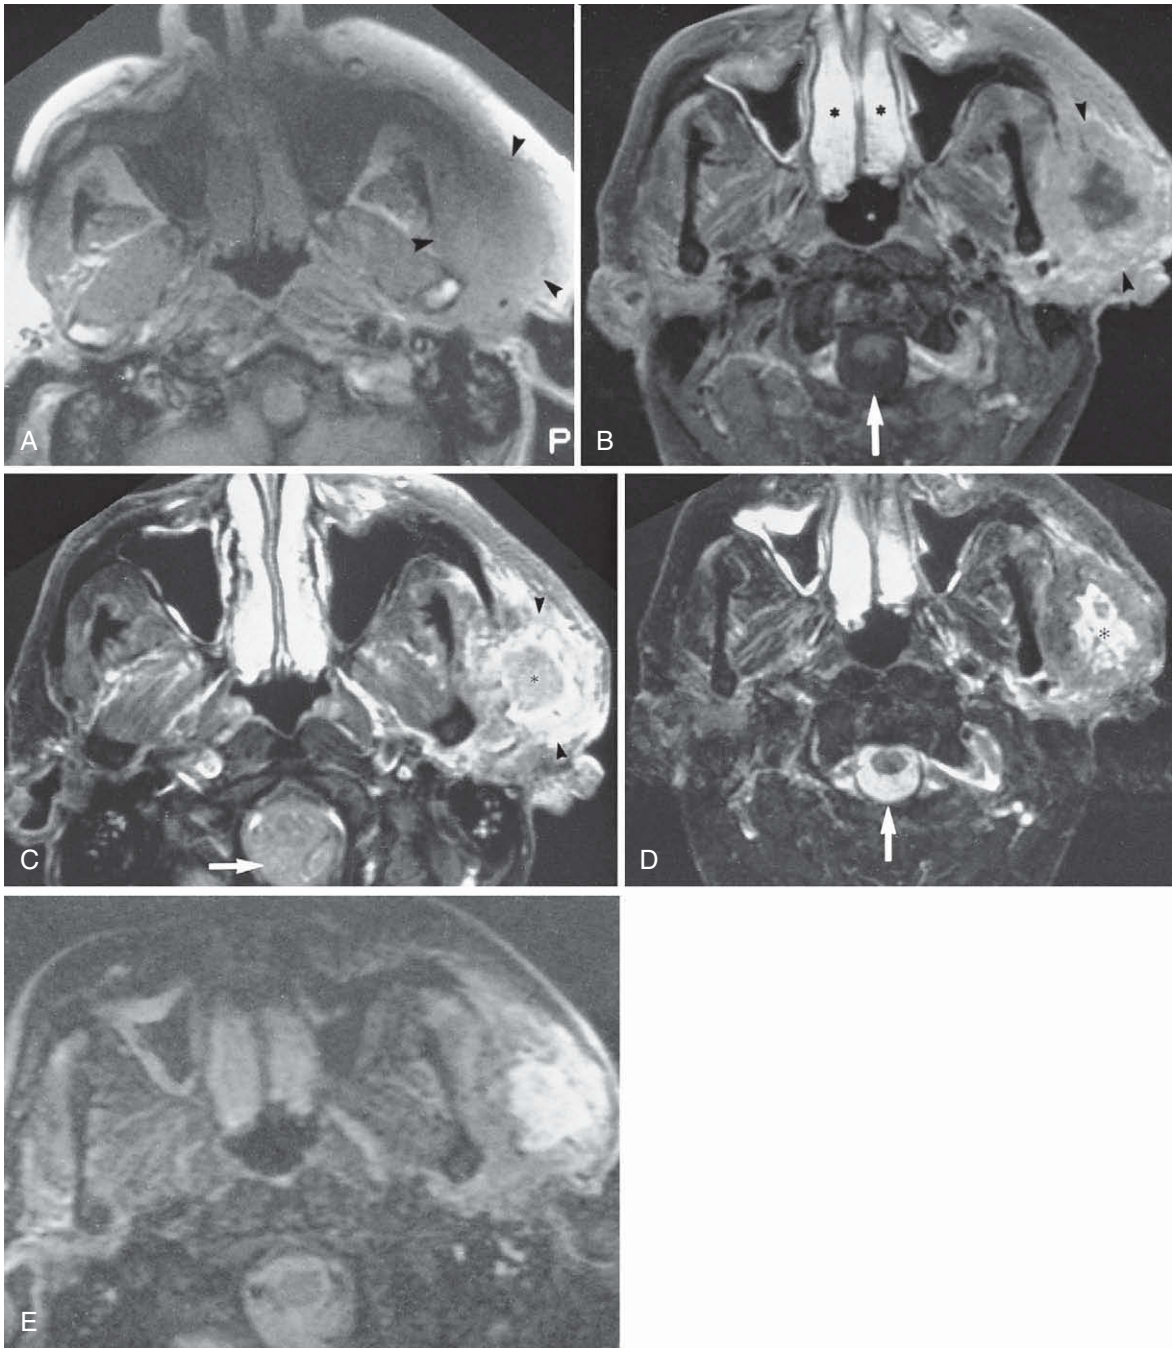

Figure 11-7. Magnetic resonance imaging pulse sequences with fat suppression. **A,** Axial T1-weighted image (T1WI) without contrast in a patient with squamous cell cancer shows a poorly defined mass in the left parotid gland *(arrowheads)*. Suboptimal signal in the image is the result of a signal drop-off at the edge of the anterior neck surface coil. **B,** Axial postgadolinium T1WI with fat saturation has adequate suppression of subcutaneous fat (compared with **A**) and enhancement of the tumor *(arrowheads)*. Center of the mass enhances less and likely is necrotic. Cerebrospinal fluid (CSF) is black *(arrow)*, indicating a T1WI. Note the marked enhancement of the inferior turbinates *(asterisks)* compared with the precontrast T1WI. **C,** Axial postgadolinium spin density image with fat saturation shows a high signal in the mass *(arrowheads)* with a lower-intensity necrotic center *(asterisk)*. Fat signal is suppressed and the image is similar to **B.** CSF is isointense with the spinal cord indicating the use of a spin density sequence. Turbinates are very bright. **D,** Axial T2-weighted image with fat saturation demonstrates nearly ideal fat suppression, almost as good as a short T1 inversion recovery (STIR) sequence. Necrotic or cystic center of the mass *(asterisk)* and CSF *(arrow)* have become very bright. **E,** On this axial STIR image with excellent fat suppression, the margin and center of the mass are bright.

with fat saturation: mucosa and small veins are white, fat is low to intermediate intensity, and CSF and vitreous are black.)

Gradient Echo Techniques

Numerous gradient echo sequences are available that have a variety of applications. Gradient echo scans have a very short TR (30 to 70 msec), a very short TE (5 to 15 msec), and a flip angle of less than 90 degrees. They have a variety of proprietary acronyms, including GRASS, MPGR, SPGR, FLASH, and FISP. Gradient echo sequences take advantage of the phenomenon of flow-related enhancement. That is, any rapidly flowing blood appears extremely bright. These sequences are useful for localizing normal vessels, detecting obstruction of flow in compressed or thrombosed vessels, and showing vascular lesions that have tubular, linear, or tortuous bright signal representing regions of

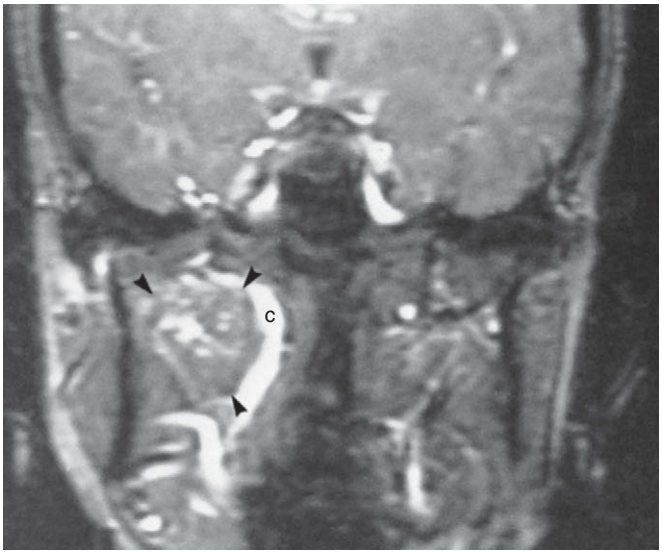

Figure 11-8. Gradient echo sequence in patient with right vagal paraganglioma. Coronal multiplanar gradient echo image demonstrates a mass *(arrowheads)* displacing the internal carotid artery (c) medially. Arterial blood flow is very high in signal intensity in the medially displaced internal carotid artery, as well as within the feeding vessels deep inside mass.

rapid blood flow (Fig. 11-8). Gradient echo sequences may be obtained faster than conventional spin-echo techniques, although their increased susceptibility to motion artifact decreases the benefits of a short scan time. Gradient echo techniques also permit volume, that is, three-dimensional versus two-dimensional acquisition of images, allowing increased spatial resolution and computer workstation reconstruction of any imaging plane at various slice thicknesses. The disadvantage of gradient echo sequences is the increased magnetic susceptibility artifact from bone or air, thus limiting their role near the skull base or paranasal sinuses. (To quickly identify a gradient echo image: arteries and often veins are white; fat, CSF, vitreous, and mucosa may have variable signal intensities depending on the technique used.)

Magnetic Resonance Angiography

MRA is most commonly generated by time-of-flight or phase contrast techniques, which rely on the flowing blood within the vessels as the signal source. Contrast-enhanced MRA uses the enhancement of blood with gadolinium-based contrast as the primary source of signal. MRA can be obtained with two-dimensional and three-dimensional algorithms. At present, MRA provides the most pertinent information in many clinical scenarios but lacks the temporal resolution (ability to image a vessel over time as the contrast material passes through) necessary to evaluate some of the vascular malformations.

Magnetic Resonance Imaging Disadvantages

Several disadvantages of MRI of the head and neck bear consideration. MRI frequently requires 30 to 45 minutes of scanning time, during which time the patient must remain motionless, a process difficult for a sick patient to accomplish. Motion artifacts are more frequently encountered than with CT, although dental artifacts may be less problematic. Although no harmful effects are known to occur during pregnancy, MRI should not be used during the first trimester. Absolute contraindications to MRI include patients with cardiac pacemakers, cochlear implants, and ferromagnetic intracranial aneurysm clips. With the ever-increasing variety of implants with electronic components, one must follow the manufacturer's recommendations as to the safety of MRI. Those patients at risk for metallic orbital foreign bodies should be screened with plain films or CT before MRI. Generally, ocular prostheses and ossicular implants are safe. Unfortunately, MRI is one of the more expensive imaging modalities.

Ultrasound

High-resolution diagnostic ultrasound uses the properties of reflected high-frequency sound waves to produce cross-sectional images, obtainable in almost any plane. The transducer, a high-frequency 5- or 10-MHz probe, scans over the skin surface of the region of interest. Fat has a moderate degree of internal echoes (echogenicity). Skeletal muscle is less echogenic than fat. A solid mass has a variable echogenicity but is usually less echogenic than fat. A cyst has few, if any, internal echoes, a strongly echogenic back wall, and strong through-transmission of sound behind the cyst. Both calcium and bone are strongly echogenic, thus obscuring adjacent structures by an acoustic shadow. Ultrasound has no known harmful effects and no contraindications. High-resolution ultrasound is quick and accurate. Doppler ultrasound provides information on blood vessels and flow patterns. Furthermore, it is relatively inexpensive compared with CT or MRI. Disadvantages include limited field of view, lack of easily identifiable anatomic landmarks, and operator dependence.

Nuclear Medicine

Positron Emission Tomography

As opposed to the imaging modalities already discussed in this chapter, which allow detailed anatomic information, positron emission tomography (PET) imaging provides physiologic and biochemical data. A positron emitting radiopharmaceutical is intravenously injected and its distribution in the body is measured. Positron emitting radiopharmaceuticals can be developed from naturally occurring substances such as 15O water, 11C carbon monoxide, or 13N ammonia, or radioactive analogs of other biologic substances such as 18F fluoro-2-deoxy-2-glucose (FDG). After being emitted from the atom, the positron travels in the tissue for a short distance until it encounters an electron and forms a positronium, which immediately annihilates (converts its mass to energy) forming two 511-keV photons. These annihilation photons travel away from each other at approximately 180 degrees and are picked up by the detectors placed around the patient. Simultaneous detection of these photons relates them to the same annihilation event and allows spatial localization. Annihilation coincidence detection can be accomplished by very expensive dedicated PET scanners, yielding superior spatial resolution and sensitivity. Less costly gamma camera-based hybrid systems allow utilization of PET imaging outside of academic centers.

Attenuation of the photons in tissues they travel through decreases the apparent activity picked up by the detectors. Attenuation correction methods provide improved anatomic detail and better lesion localization but they result in noisier images. The effect of attenuation correction on visual image quality is controversial and, in many centers, the images are generated both with and without attenuation correction. For semiquantitative and quantitative evaluation, however, attenuation correction is necessary.

Depending on the radiopharmaceutical chosen, PET imaging can provide information regarding blood flow, ischemia, deoxyribonucleic acid metabolism, glucose metabolism, protein synthesis, amino acid metabolism, and receptor status. Radiopharmaceutical development requires sophisticated knowledge and equipment which, combined with the very short half-life of most of these substances, limits clinical utility. The relatively long half-life of FDG (110 minutes) accounts for its widespread use. FDG can be delivered to PET imaging facilities through commercial vendors obviating the need for an on-site cyclotron.

Glucose metabolism in growing neoplastic cells is enhanced and accounts for the increased uptake on FDG-PET studies. Molecular studies have revealed that several genetic alterations responsible for tumor development also have direct effects on glycolysis. It has also been shown that increased tumoral FDG uptake is strongly related to the number of viable tumor cells, but not clearly associated with their proliferative rate. The glucose analog 2-deoxy-D-glucose is transported into the cell and metabolized in the glycolytic cycle. After phosphorylation with hexokinase to DG-6-phosphate, the compound is metabolically trapped in the cell. Because of this trapping mechanism, FDG concentration steadily increases in metabolically

active cells, yielding a high contrast between tumor and normal tissue. Bear in mind that increased glucose metabolism is not unique to malignant cells and can be seen in benign tumors, inflammatory or infectious lesions, and even normal tissues. Also, some malignant cells may not have increased glucose metabolism for a variety of reasons.

A typical PET scan is started 30 to 60 minutes after the intravenous administration of approximately 10 mCi of 18F-FDG. A 6- to 12-hour period of fasting is required before injection. Patients are encouraged to drink water before the FDG injection to minimize collection in the urinary system. The patients are told not to speak or chew before PET scanning. Because normal FDG uptake in muscle may mimic tumor, muscle relaxants such as benzodiazepines are used in some centers. Scanning is performed in the supine position at multiple table positions to cover the entire body. Scan time is 30 to 60 minutes.

Qualitative evaluation of FDG-PET images is sufficient for most clinical purposes, but quantitative measurement of FDG concentration is possible. Several approaches of different complexity can be applied for this purpose. Some of these require complex computation, data acquisition, and arterial blood sampling during scanning. The most commonly used method, standardized uptake values (SUV), is simple and confined to the measurement of radioactivity concentrations at a single time point. The activity concentration is normalized to the body weight or body surface area. SUV may allow differentiation of malignant tissue from benign causes of increased uptake and can be used to measure the response to treatment. A downside of SUV calculation in therapy monitoring is that it only allows comparison of two measurements obtained at the same time point after tracer injection.

A major disadvantage of PET is lack of anatomic information, resulting in poor lesion localization. A number of software applications are used to "fuse" PET images with CT or MR images, which are obtained at different time points. Fusion of anatomic and functional images significantly improves lesion localization, but it is still subject to many technical difficulties and errors. Combined PET/CT units permit acquisition of both CT and PET images using a single piece of equipment in the same session without the need to move the patient. Errors in lesion localization are minimized, although they do occur in certain body regions where physiologic or involuntary motion is unavoidable.

Another major limitation of PET is poor spatial resolution. Currently, the maximum spatial resolution of dedicated PET scanners is about 5 to 6 mm. It is substantially inferior for more commonly used hybrid scanners. PET is an evolving technology and improvements in spatial resolution will surely be accomplished. Because of fundamental limitations inherent to the method, however, the maximum achievable spatial resolution is 1 to 2 mm. Therefore PET is incapable of showing microscopic disease.

Radionuclide Imaging

Scintigraphy has several applications in the head and neck. In salivary gland imaging, technetium-99m (99mTc)-pertechnetate imaging may be useful for assessing salivary gland function in autoimmune and inflammatory disease of the salivary glands. If the salivary glands are obstructed, the degree of obstruction, as well as the follow-up of obstruction after treatment, can be assessed. In evaluating neoplasms of the salivary glands, the findings of the 99mTc-pertechnetate scan are almost pathognomonic of Warthin's tumor and oncocytoma. Spatial resolution is limited to approximately 1.5 cm, so accurate localization of the mass within the gland is difficult. Single photon emission computed tomography (SPECT) may be useful in some cases.

Techniques of thyroid imaging and thyroid therapy are described in several textbooks.[9,10] Many centers use I-123 to obtain a thyroid update determination, and 99mTc-pertechnetate is used to obtain whole gland images. It is these images that determine whether thyroid nodules are "hot" or "cold." I-131 is used for therapy of hyperthyroidism and in follow-up to detect and treat residual, recurrent, and metastatic thyroid cancers.

Medullary carcinoma of the thyroid is difficult to visualize, but 99mTc-DmSA has been used. In-111 pentetreotide has been used with some success.

Identification of parathyroid adenomas has been done for several years with a subtraction technique using 99mTc-pertechnetate and Tl-201 (Fig. 11-9). The basis of this test is that thallium is taken up by thyroid tissue and parathyroid tissue. Thyroid tissue is the only tissue that uptakes 99mTc-pertechnetate. Therefore the subtraction of the 99mTc-pertechnetate image from the thallium-201 image should leave only parathyroid tissue. The sensitivity of this technique is believed to be very high for lesions larger than 1 g. Sensitivity decreases for smaller lesions, and the subtraction technique can be hampered by patient motion. 99mTc-sestamibi is now the favored agent in many institutions. A double-phase imaging protocol is employed with improved identification of parathyroid adenomas.

CSF leaks can be detected with In-111 DTPA placed into the subarachnoid space. This technique is described and illustrated in Chapter 44.

Three-Dimensional Reconstruction Techniques

Image data from either CT or MRI can be processed to create three-dimensional reconstructions. The state-of-the-art picture archival and communication systems (PACS) that are now available in most institutions obviate the need for a separate workstation to perform these reconstructions.

CT data are loaded as a stack of contiguous two-dimensional slices that define the scanned volume. Reconstructions are created either by choosing a specific range of densities for display or by manually tracing the outline of the desired structure. Improvements offered by multislice-multirow CT scanners and enhanced computational capacity of imaging workstations have led to a paradigm shift in radiology; volume imaging has replaced axial imaging. CT data from a large body part can be gathered in a very short time as a whole and the obtained "volumetric" data set can be displayed in various planes and as three-dimensional reconstructions.

Magnetic resonance data for image analysis are best acquired using a "volume acquisition" method, in which data are acquired as a complete three-dimensional block rather than as individual slices. Because volume acquisition takes longer, gradient echo techniques are usually required to reduce the imaging time. Once acquired, the data are displayed in any desired plane and, by selecting a range of signal intensities or by tracing specific structures with a cursor, three-dimensional surface models are created.

The utility of three-dimensional reconstruction is best appreciated with craniofacial reconstructions.[11,12] Directly visualizing the three-dimensional relationships of the facial structures aids surgical planning. Instructors find three-dimensional models of the face and orbital structures useful for teaching medical students, residents, and anatomy students. Virtual endoscopy is a computer-generated simulation of endoscopic perspective. The virtual endoscopic images of the trachea, larynx, pharynx, nasal cavity, and paranasal sinuses and ear have demonstrated clinical utility (Fig. 11-10).

At present, the spatial resolution of CT is superior to MRI in the head and neck for displaying bony relationships. However, MRI provides a superior display of transcranial soft tissue structures, such as the entire visual pathway, and has better tissue contrast resolution than CT. Thus CT and MRI will likely have complementary roles in three-dimensional image display.

Applications of CT, MRI, and Ultrasound in the Head and Neck

Each anatomic region requires a different imaging approach to optimize the detection and characterization of the structure or lesion of interest. The following is a description of the indications for using CT, MRI, or ultrasound in specific head and neck regions, plus a general imaging approach relevant to each anatomic region in terms of imaging planes, slice thickness, contrast agents, and pulse sequences. Whenever possible, CT and MRI are performed before biopsy or resection of lesions because the resulting edema may obscure the true margins of a mass.

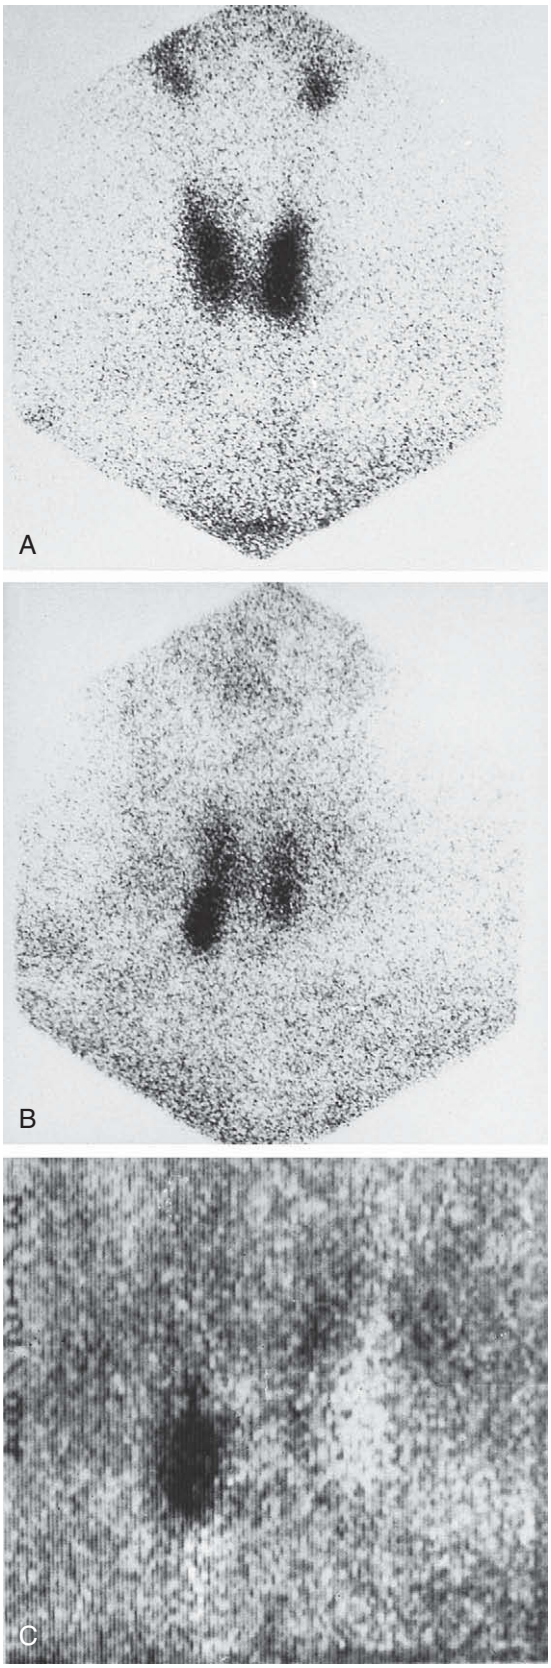

Figure 11-9. **A,** Technetium-99m (99mTc)-pertechnetate scintigraphy in a patient with suspected parathyroid adenoma is essentially normal. **B,** Corresponding T1-201 scintigraphy reveals an apparent area of increased uptake adjacent to the lower pole of the right lobe. **C,** Subtraction of the 99mTc-pertechnetate study from the T1-201 study confirms the presence of a parathyroid adenoma.

Application of Computed Tomography in Head and Neck Region

Multichannel CT scanners revolutionized head and neck imaging. The entire neck can be scanned in less than a minute at a slice thickness of less than 1 mm. These data can then be reconstructed in any plane with a desired slice thickness. This obviated the need for site specific imaging protocols. A typical neck CT using a multidetector scanner employs 1-mm slice thickness and a pitch of approximately 1, with contiguous axial scanning performed from the sella turcica down to the thoracic inlet. Then, typically 3-mm-thick axial, sagittal, and coronal images are reconstructed for view. The use of intravenous contrast is critical for interpretation of the study. Determination of extent of disease and vascular invasion, compression, and discrimination of vessels from nodes and small muscle bundles can be extremely difficult (see Figs. 11-3 and 11-4). Evaluation of the normal mucosa-submucosa interface and mucosal tumors can not be accomplished without contrast enhancement. Optimally, contrast should be present in both arteries and veins during image acquisition. Also, enough contrast should be allowed to diffuse from vessels to the tissue interstitium for tumors to enhance. This is particularly important for high-end multidetector CT scanners, which tend to finish image acquisition before optimal tumor enhancement is achieved, unless a delay between injection of contrast and scanning is employed. To maintain good opacification of vessels after this delay, a biphasic contrast injection scheme is used. The delay time and the rate at which contrast material is injected vary depending on the specifications of the scanner. Contrast is best administered with a mechanical pump infusion although a drip-infusion technique may also be effective. Frequently, image reconstruction using a soft tissue algorithm suffices. If a suspicion of bone erosion or destruction by tumor or inflammation exists, sections of the skull base and mandible need to be reconstructed using a bone algorithm.

Suprahyoid Neck

Suprahyoid neck CT is often performed for simultaneous evaluation of the deep extent of mucosal based tumors and to evaluate associated metastatic disease to the cervical lymph node chains. Because streak artifacts from dental fillings frequently obscure the oropharynx and nasopharynx, it is usually necessary to obtain additional angled sections to assess the pharynx directly posterior to the dental work (Fig. 11-11).

Cervical Lymphadenopathy

Lymph node CT evaluation is concomitantly performed during CT investigation of most suprahyoid and infrahyoid tumors or inflammation. The quality of lymph node assessment depends very much on the success of achieving a high concentration of contrast in the arterial and venous structures of the neck. Otherwise, nodes and vessels may appear remarkably similar.

Salivary Glands

Dental amalgam can cause significant streak artifacts that obscure the parotid or submandibular gland parenchyma. If the dental work is identified on the lateral scout view (scanogram), dental artifacts can usually be avoided if an oblique semiaxial projection is chosen with the scanner gantry angled in a negative direction (between a coronal and an axial plane), thus avoiding the teeth. This plane has the advantage of visualizing both parotid and submandibular glands in the same slice and is parallel to the posterior belly of the digastric muscle.[13] Contrast administration is required for both neoplastic and inflammatory conditions of the salivary glands. Enhancing intraglandular vessels may mimic or obscure small stones, thus a precontrast scan is also advised in cases of suspected sialolithiasis. The CT attenuation of a normal parotid gland is variable depending on the proportion of fat and glandular tissue present, which varies with age. Submandibular glands have a more predictable attenuation that is similar to that of muscle. Any difference in attenuation values of the right and the left submandibular glands should be suspicious for an obstructing lesion such as floor of the mouth cancer.

Sialography and CT-Sialography

Conventional sialography, although rarely needed, remains the best radiographic method for evaluating ductal anatomy in obstructive,

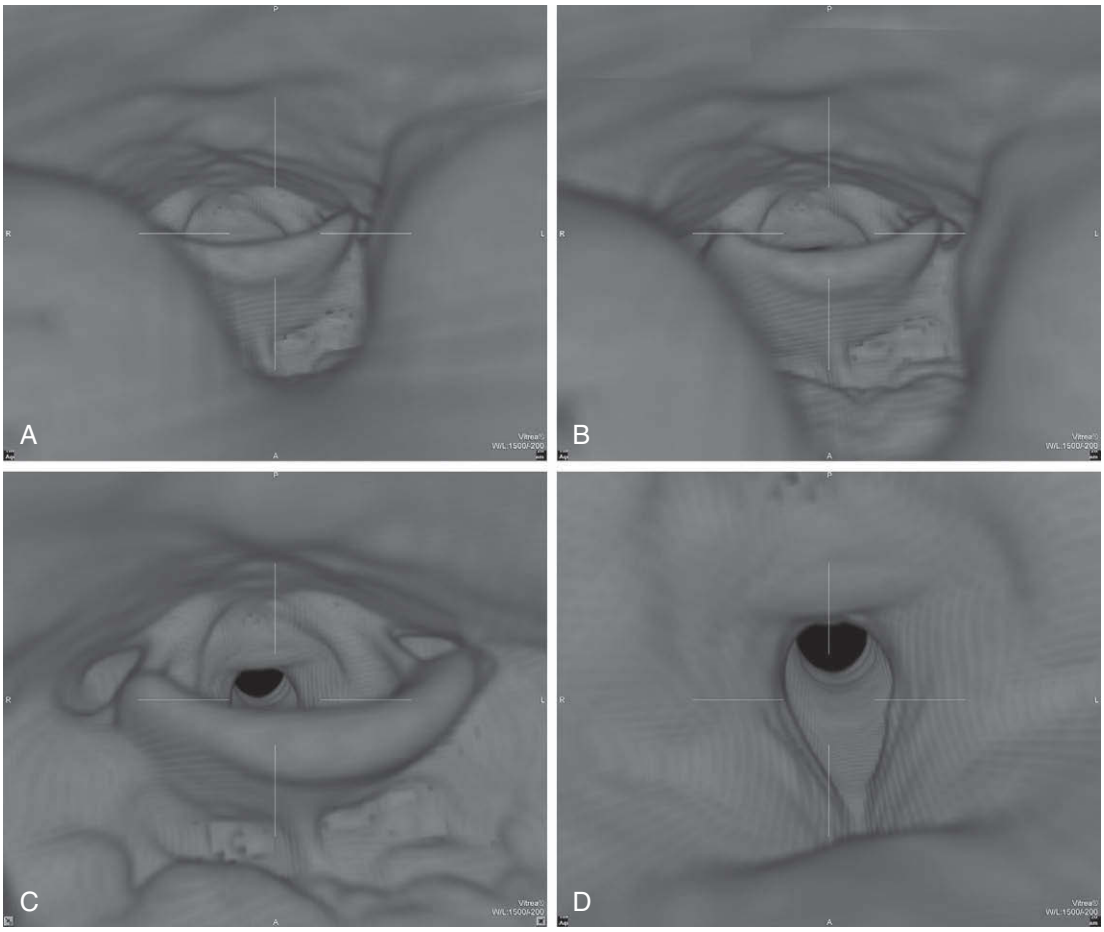

Figure 11-10. Normal virtual laryngoscopy. A real-time navigation in the larynx can be performed with ease using a workstation and special software.

inflammatory, and autoimmune salivary gland diseases. Supplemental CT-sialography may be performed in evaluation of a dense gland that is suspected to harbor a mass in patients who cannot have MRI. CT-sialography may be obtained at the time of intraductal injection of fat-soluble or water-soluble contrast or after a routine sialogram (the gland may be reinjected during the CT with the catheter left in place). The plane of study is the same as that used for NCCT and should be similarly angled to avoid dental filling artifacts. The use of concentrated sialographic contrast material may cause significant streak artifacts if too much contrast collects in dilated ducts, acini, or large pools, all of which can obscure smaller masses in the gland. For optimal CTS, the injection is extended into the acinar phase to maximize parenchymal opacification and thereby silhouette mass lesions within the parenchyma.[14]

Larynx and Infrahyoid Neck

Laryngeal and infrahyoid neck CT is most commonly requested to evaluate squamous cell carcinoma of the larynx or hypopharynx, associated cervical lymph node metastasis, trauma, and inflammation. The fine detail of the larynx and vocal cords requires thinner reconstructions than the routine 3-mm sections. Sections through the vocal cords are optimally reconstructed parallel to the plane of the true vocal cords. Because assessment of vocal cord mobility is important in staging glottic carcinoma, various provocative techniques may facilitate laryngeal imaging in those cases where the vocal cords are obscured on physical examination. Quiet breathing places the cords in a partially abducted position. By having the patient blow through a straw or do a modified Valsalva maneuver (puffing out the cheeks) the hypopharynx and supraglottic larynx can be distended, allowing better separation of the aryepiglottic folds from the hypopharynx, while simultaneously abducting the cords (see Fig. 11-3). The vocal cords can be assessed during phonation ("eeee"), which causes the cords to adduct and move to a paramedian position (see Fig. 11-3). Breath holding will also adduct the vocal cords, close the glottis, and significantly reduce motion artifacts. By scanning the larynx twice, once to adduct and a second time (sections limited to the glottis) to abduct the vocal cords, the radiologist can assess vocal cord motion and identify fixation. Evaluation of laryngeal trauma may not require intravenous contrast. Bone windows are helpful for assessing cartilage fractures or tumor erosion.

Thyroid and Parathyroid Glands

The scanning should extend to the aortic arch to cover potential sites of ectopic thyroid and parathyroid tissue. Although the normal thyroid is hyperdense because of its natural iodine content on NCCT, a CECT is preferred for this study. The normal thyroid enhances intensely on CECT, with most mass lesions of the thyroid appearing less enhanced. The parathyroids are rarely imaged primarily by CT because nuclear medicine and ultrasound techniques are more feasible for localizing parathyroid adenomas.

Paranasal Sinuses

Paranasal sinus CT can be approached in several ways depending on the anticipated disease process. A screening axial sinus NCCT (Fig. 11-12A) is clearly superior to conventional radiographs and provides information on specific sinus involvement by inflammatory processes as well as better delineation of bony sclerosis or destruction. One method is to use 5-mm-thick sections obtained at 10-mm intervals (5-mm gap), which can cover the entire paranasal sinuses with six to eight slices. The technical parameters can be optimized to achieve a low radiation exposure that is similar to radiographs.

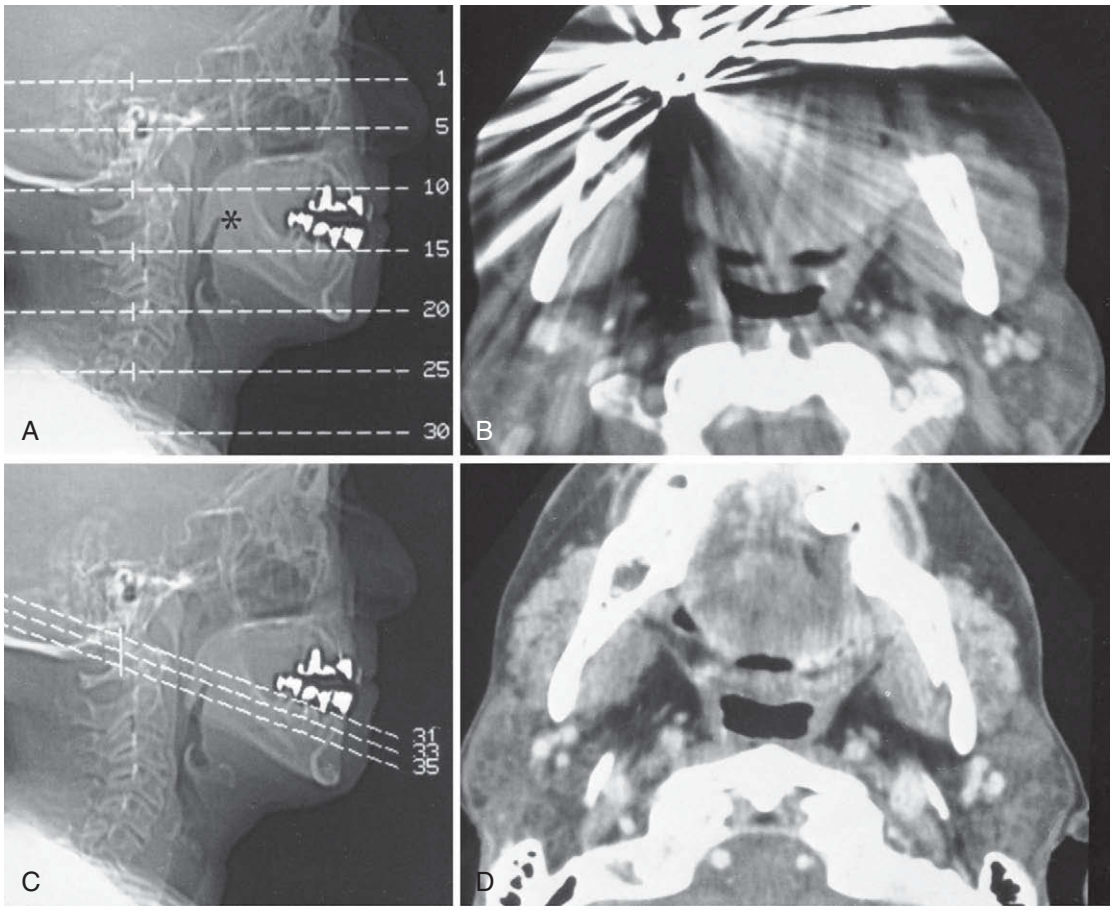

Figure 11-11. Avoiding dental artifacts on computed tomography (CT). **A,** Lateral scout image without angulation of the CT gantry (dashed lines represent selected axial images) in a patient with numerous metallic densities in teeth from dental work. Posterior tongue *(asterisk)* and soft palate lie directly posterior to metal. **B,** Axial contrast-enhanced computed tomography (CECT) at the level of the dental work is not interpretable because of the numerous streak artifacts caused by metallic fillings and crowns. **C,** Scout view depicting additional slices with the CT gantry angled to avoid dental work. **D,** Angled axial CECT at the same level as B shows a significant improvement in image quality of the posterior tongue and oropharynx.

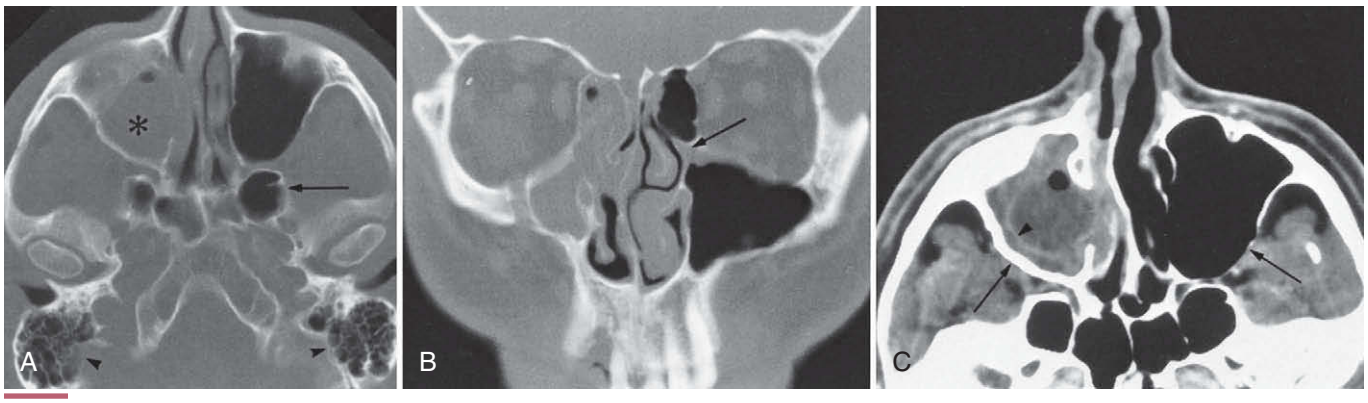

Figure 11-12. Computed tomography in evaluation of sinusitis. **A,** Axial 5-mm sinus screening noncontrast computed tomography (NCCT) using bone algorithm and bone windows in a patient with chronic right maxillary sinusitis. Excellent bony detail is obtained of both maxillary sinuses (posterior wall thickening and sclerosis are present on right) and mastoids. Clear discrimination of soft tissue opacification of the right maxillary sinus *(asterisk)* is achieved compared with the normal air-filled left maxillary sinus. Pneumatized pterygoid process *(arrow)* is an extension of sphenoid sinus pneumatization. **B,** Coronal 3-mm NCCT with bone algorithm and bone windows in the same patient clearly demonstrates mucosal thickening and opacification of the right maxillary and ethmoid sinuses, and left maxillary infundibulum *(arrow)*. Sharp anatomic detail of the bony architecture and the use of coronal plane are essential for preoperative planning before endoscopic sinus surgery. **C,** Axial 3-mm contrast-enhanced computed tomography with soft tissue algorithm and soft tissue windows exaggerates the right maxillary sinus posterior wall thickness *(arrows)*. Thickened mucosa has a thin rim of enhancement along its luminal margin *(arrowhead)*. Combination of bony sclerosis and mucosal thickening is often seen in chronic sinusitis.

When endoscopic sinus surgery is anticipated, NCCT imaging of the sinuses is mandatory for preoperative evaluation of the extent of sinus disease, to detect anatomic variants, and for planning the surgical approach (see Fig. 11-12B). This study is done in the axial plane while the patient is supine with thin sections reconstructed in sagittal and coronal planes. Frequently, only the bone algorithm with its edge enhancement properties is needed for evaluating the detailed anatomy of the ostiomeatal complex. Contrast administration is usually not necessary for routine sinusitis, although when severe nasal polyposis is suspected, contrast may be useful to demonstrate the characteristic "cascading" appearance of the enhancing polyps or to characterize an associated mucocele. A soft tissue algorithm with soft tissue windows may be useful when using CECT for intracranial complications from sinus inflammatory processes. A nasal decongestant may be used to help decrease normal but asymmetrical nasal mucosa congestion (normal nasal mucosal cycle) from a mucosal based mass.

The assessment of sinus tumors requires the most detailed imaging. The intracranial compartment, parapharyngeal, masticator, and buccal spaces should sufficiently be included in the field-of-view as to allow for assessment of tumor extension. At least the lymph node levels I and II should be visualized. For an optimal study, both soft tissue and bone algorithms are used. This differentiates the soft tissue component, as well as evaluating subtle bony destruction (see Figs. 11-12A and C). The coronal plane is best for evaluating the cribriform plate. CECT is used to maximize the enhancement characteristics of the tumor and differentiate it from adjacent soft tissue structures.

Facial Trauma

Facial trauma CT characterizes fractures and facial soft tissue injury very well. Contrast material is not needed. Bone algorithm is mandatory for demonstration of fine bone detail but soft tissue algorithm for assessing orbital and facial soft tissue injury is often very helpful. Three-dimensional surface reconstructions or volume-rendered images are helpful when planning facial restoration and assessing surgical results.

Temporal Bone and Skull Base

High-resolution CT images obtained with a multichannel scanner are now the standard of imaging for the temporal bone. The acquired data set is reconstructed at 0.5-mm slice thickness at any plane desired. Rotationally reformatted images are most helpful in displaying an entire semicircular canal in a single plane to aid in the diagnosis of dehiscent superior semicircular canal. In general, intravenous contrast is not necessary for temporal bone imaging, although vascular tumors or squamous cell carcinoma invading the temporal bone may require the use of intravenous contrast plus supplemental soft tissue algorithms to best image the extracranial and intracranial soft tissue component of the lesion. However, bone algorithm with bone windows is used in all temporal bone imaging.

Application of Magnetic Resonance Imaging in Head and Neck Region

Suprahyoid Neck

MRI is ideally suited for imaging the suprahyoid neck (including nasopharynx, oropharynx, oral cavity, and tongue). The standard head coil which has a high signal efficiency will permit visualization of the suprahyoid neck structures caudally down to approximately the level of the inferior margin of the mandible and floor of mouth. For imaging the oral cavity, floor of mouth, submandibular space, and cervical lymph node chains, a head coil will not suffice. Either an anterior or volume neck coil is needed to visualize the entire neck from the skull base to the thoracic inlet (from dura to pleura). Several pulse sequences and imaging planes using 5-mm thick sections are required to adequately assess the deep and superficial structures of the neck. (Implicit in this discussion of MRI technique for all areas of the head and neck is the fact that a sagittal T1WI is obtained as the initial sequence in all of the authors' studies and is used primarily as a scout view for the proper positioning in other imaging planes, as well as for anatomic information.) A precontrast axial T1WI, and often a coronal T1WI, are required to optimally assess fat planes in the neck. Fat provides an excellent white background from which muscle and fascial planes, bone, sinus, and vascular structures can easily be discriminated. The coronal plane is particularly useful for visualizing the relationships of the suprahyoid neck structures to the skull base and also for delineating the anatomy of the tongue and floor of mouth. A T2WI or STIR, usually obtained in the axial plane, is required to detect structures with a long T2 (e.g., tumors, cysts, lymphadenopathy, edema) that appear brighter than the background muscle and fat. Postgadolinium T1WIs with fat suppression in the axial and coronal plane are frequently helpful to discriminate the enhancing margins of a lesion or to detect perineural spread of tumor. The T2WI may also be combined with fat suppression to optimize the information obtained.

Lymphadenopathy

Before the widespread use of gadolinium and fat suppression techniques, MRI was often less specific than CT in characterizing cervical lymph node metastases because of the lower ability to show heterogeneously enhancing nodes which is a highly accurate sign of nodal metastasis in the setting of squamous cell cancer of the neck. However, improved MRI scanner technology, gadolinium enhancement, and fat suppression sequences have allowed a comparable accuracy. Also, the MRI detection of carotid artery invasion by extracapsular spread of tumor from nodes is often superior to CECT.

An anterior or volume neck coil using 5-mm thick sections with a small 1- to 2-mm interslice gap is necessary to encompass the entire lymph node chain throughout the neck from the skull base to the clavicles within the imaging field of view. The detection of cervical lymphadenopathy with MRI may be accomplished with (in decreasing order of sensitivity) a STIR sequence, a fat suppressed T2WI, a fat-suppressed post gadolinium T1WI, a conventional T2WI, or a precontrast T1WI. Although STIR is the most sensitive sequence, it may be limited by prominent pulsation artifacts from vessels. The significance of a heterogeneously enhancing node on MRI should be analogous to the same finding on CECT and is best demonstrated on post-contrast, fat-suppressed T1WIs.

Salivary Glands

MRI of the parotid gland can be accomplished with a standard head coil using 3- to 5-mm slices, but at the risk of excluding a portion of the submandibular gland that lies at the edge of the usable field of view. A volume neck coil is the better coil for imaging both parotid and submandibular glands within the same field of view, especially if a malignancy is suspected and cervical lymph node metastases are sought lower in the neck. A smaller surface coil may be necessary for evaluation of perineural tumor spread along with facial nerve into the mastoid segment of the facial nerve canal. Depending on the fat content of the parotid gland, a tumor may be better defined on T1W or T2WIs. Fat suppression on postcontrast T1WI allows better depiction of the margins of the tumor which is a critical imaging finding in differentiating malignant from benign masses. More recently, magnets with superior gradient performance allowed MR sialography images. Despite its limitation in spatial resolution compared with conventional sialography, MR sialography eliminated the need for conventional sialography in many clinical scenarios.

Larynx and Infrahyoid Neck

The larynx and infrahyoid neck require either an anterior or a volume neck coil, preferably using no thicker than 3-mm sections for the larynx. The field of view should include the area from the inferior margin of the mandible to the clavicles. Although the larynx can be examined well by both axial CECT and MRI, laryngeal MRI has a higher proportion of suboptimal studies. Laryngeal MRI is more susceptible to motion artifacts than MRI of other regions of the neck because of a combination of swallowing, breathing, and vascular pulsation from the adjacent common carotid arteries. Precontrast axial and coronal T1WIs are essential to assess the paraglottic fat planes. The coronal plane, angled parallel to the airway, is especially useful for determining transglottic tumor spread. Fat saturation postgadolinium

T1WIs in the axial and coronal planes are best for detecting lesion margins, invasion of adjacent cartilage, and associated malignant nodes. T2WI in the axial plane may help detect moderately increased tumor signal and improve detection of high signal cystic or necrotic neck lesions.

Thyroid and Parathyroid Glands

The same techniques and slice thickness as those of the larynx are used for the thyroid and parathyroid glands. The field of view may need lower centering to include the upper mediastinum and ensure complete evaluation of the inferior extent of a thyroid tumor or an ectopic parathyroid gland. Coronal and sagittal views aid understanding of the craniocaudal extent of the lesion relative to the aortic arch, great vessels, and mediastinum. This information is especially useful to the surgeon. Although MRI may detect an unsuspected thyroid or parathyroid lesion during routine neck or cervical spine imaging, MRI is less frequently used for primary evaluation of these lesions because of the cost of the study and susceptibility to motion artifacts. The normal thyroid gland will enhance mildly on both gadolinium-enhanced MRI and CECT. A solid mass in the thyroid or parathyroid is usually low intensity on T1WI and high signal on T2WI, and it may enhance with gadolinium. Cystic lesions are bright on T2WI.

Paranasal Sinuses

Sinus MRI is primarily indicated for evaluating sinus tumors (and occasionally inflammatory disease such as a mucocele) and may be accomplished with a standard head coil, using 3- to 5-mm slices. The principal value of MRI over CT for sinus tumors is the ability of MRI to distinguish between tumor and obstructed sinus secretions and to predict the true extent of the tumor. A precontrast sagittal, axial, or coronal T1WI will provide a good demonstration of the sinuses, nasal cavity, cribriform plate, masticator and parapharyngeal spaces, and orbits. Sinus secretions with low protein content show low T1 and high T2 signal. With increasing protein content the T1 signal increases and T2 signal decreases. Very high concentrations of protein result in low signal on both pulse sequences and may occasionally mimic normally pneumatized sinus. No enhancement of the sinus secretion is seen on postcontrast images except for the mucosa of the sinus whereas tumors often enhance and show intermediate T2 signal allowing differentiation of postobstructive secretions from tumor. Fat saturation T1WI is recommended to better define the sinus tumor margins when the tumor extends directly or by perineural spread beyond the sinus into the anterior cranial fossa, orbit, parapharyngeal space, or pterygopalatine fossa. The sagittal and coronal planes are very helpful for evaluating cribriform plate extension. The coronal and axial planes are best for orbital, cavernous sinus, pterygopalatine fossa, and parapharyngeal space spread.

Temporal Bone

MRI is the imaging standard for the detection of internal auditory canal (IAC), facial nerve canal, and jugular foramen lesions. MRI is useful, in combination with CT, for assessing expansile or destructive lesions of the temporal bone and external auditory canal. A standard head coil is adequate for most temporal bone lesions, but a smaller 5- to 10-cm surface coil may provide improved resolution for certain regions in the expense of coverage. The small size of the temporal bone structures and their respective lesions requires high spatial resolution images, which may be accomplished by using thinner slices of 0.5 to 3.0 mm (preferably without an interslice gap), smaller surface coils (higher signal-to-noise ratio), volume acquisition, or T1WI (higher signal-to-noise ratio). Precontrast T1WI in the sagittal and axial planes is useful for defining anatomy and for detection of high-signal lesions such as fat, methemoglobin, and viscous or proteinaceous cysts. Postgadolinium T1WIs (without or with fat saturation) in the axial and coronal planes are essential for detecting small enhancing lesions and determining the extent of larger lesions. In fact, for routine evaluation of a suspected acoustic schwannoma, only a postgadolinium axial and coronal T1WI study may be required. T2WIs are frequently unnecessary for IAC tumors but may be helpful when brainstem ischemic or demyelinating disease, meningioma, blood products, proteinaceous secretions, or a large destructive tumor is suspected or is being further evaluated after a preliminary temporal bone CT. A facial nerve lesion in the mastoid segment of the facial nerve canal is best evaluated for proximal and distal extension using a surface coil with sagittal and coronal pregadolinium and postgadolinium T1WIs.

Skull Base

MRI may be indicated for primary lesions of the skull base or for intracranial and extracranial lesions that secondarily involve the skull base. A standard head coil using 3- to 5-mm slices images this region well. Pregadolinium sagittal, axial, or coronal T1WI allows for assessment of the fat planes of the suprahyoid neck and detection of high signal intensity blood breakdown products, proteinaceous fluids, or fat within the lesion. Postgadolinium axial and coronal (occasionally sagittal) fat saturation T1WIs are excellent for determining the extent of an enhancing lesion above, below, and within the skull base. T2WI in the axial or coronal plane may be helpful for detecting a high signal lesion. STIR images usually give similar information to T2WIs in the skull base and may not be necessary.

Ultrasound Applications in the Head and Neck

High-resolution ultrasound evaluation of the suprahyoid neck, salivary glands, and infrahyoid neck is limited to the more superficial neck structures because of the impediment to sound transmission caused by the highly reflective facial bones, mandible, mastoid tip, and air within the oral cavity and pharynx. The ultrasound technique, using a high-frequency (e.g., 10 MHz) transducer and multiple imaging planes, is similar for all these regions. A small superficial lesion is best seen with a high-frequency transducer, which has a higher spatial resolution, whereas a deeper lesion requires a lower frequency transducer. Color flow Doppler technique may help differentiate vascular structures from a cystic or solid lesion. Head and neck ultrasound is performed less frequently in North America than in Europe, perhaps because of the common availability of CT in North America and the perception of the greater accuracy of CT.

Metastatic Lymphadenopathy

Ultrasound, combined with fine needle aspiration, may be a very effective tool in evaluating metastatic lymph nodes in head and neck cancer. The upper one third of the internal jugular, retropharyngeal, and tracheoesophageal groove nodes are poorly evaluated, however, because of obscuration by bone or airway structures. Ultrasound may be the best method (possibly better than MRI or CT) for determining the presence of tumor invasion of the carotid by the extracapsular spread from metastatic nodes, but evaluation may not be reliable as the tumor approaches the skull base. Invasion of the carotid artery is characterized by loss of the echogenic fascial plane between the vessel wall and the tumor.

Salivary Glands

Ultrasound has indications for both inflammatory and neoplastic disease. It may detect salivary duct stones as small as 2 mm. An obstructed dilated duct may appear as a tubular cystic structure. An abscess may be detected and drained under ultrasound guidance during the acute stage of sialadenitis. A mass in the superficial parotid gland is easily assessed by ultrasound, but the deep lobe of the parotid gland is obscured by the mandible, styloid process, and mastoid tip. Ultrasound is also very sensitive for a mass in the submandibular gland. Although ultrasound can determine the sharpness of margins of the lesion, an aggressive neoplasm or inflammatory process extending beyond the margins of the gland is better evaluated by MRI or CECT because the deep landmarks are more easily demonstrated with these methods. Well-defined margins usually indicate a benign mass, and infiltrative margins suggest malignancy.

Infrahyoid Neck

Ultrasound using a high-frequency transducer is usually the first imaging modality for evaluating thyroid gland and parathyroid gland masses because it is relatively inexpensive, has no side affects, and is

easily performed. Solid and cystic masses and calcification are easily identified but, like with other imaging modalities, a reliable differentiation of malignant thyroid nodules from benign ones is not possible. Ultrasound is the imaging modality of choice for image-guided biopsies. A parathyroid adenoma is readily evaluated if its location is cranial to the sternum.

FDG-PET Applications in Head And Neck Cancer

PET technology is still evolving as is its exact role in imaging head and neck malignancies. PET-CT is becoming more widely available as the preferred method.

Staging

T-Staging

The detection rate of a primary tumor in the setting of squamous cell carcinoma of the head and neck (SCCHN) with FDG-PET is slightly superior to that with MRI and CT and comparable to that of panendoscopy. For the superficial mucosal lesions, however, the limitations of all imaging modalities including PET are well recognized and panendoscopy remains the best way to evaluate such lesions. PET, because of limited spatial resolution and lack of anatomic detail, is often insufficient for the assessment of submucosal extent of disease and involvement of adjacent structures. MRI and CT remain the modality of choice for this purpose. FDG-PET may identify a primary tumor that is not detected by other diagnostic modalities in the setting of cervical nodal metastasis with unknown primary, although false-positive results are also frequent in this setting.

N-Staging

The sensitivity of FDG-PET in detection of metastatic lymph nodes in the neck is higher than that of CT and MRI. The impact of this increased sensitivity on patient management remains to be seen. A modality that would reliably differentiate N0 from N1 necks is very much needed, but it is unrealistic to expect PET to diagnose microscopic metastasis—even in the future—because of inherent technical limitations of spatial resolution. Currently available data do not justify the routine use of FDG-PET for nodal staging despite its proven superiority.

M-Staging

FDG-PET imaging is suitable for detection of distant disease because of its great sensitivity and ability to examine virtually the entire body in a single study. Synchronous lesions in the upper aerodigestive tract and lungs are also detected with FDG-PET more accurately than other modalities, although false-positive results remain problematic.

Therapy Planning and Monitoring

Radiotherapy fields can be determined on the basis of PET-CT data. Tracer uptake can be quantified and changes in tumor metabolism can be monitored by PET imaging during treatment. Whether these changes can predict response to treatment is an active area of research. Early data suggest that very early FDG-PET study performed days after initiation of treatment may separate responders from nonresponders even before any structural changes have occurred. If this is proved to be true, it may permit modification of treatment very early in the process.

Detection of Residual and Recurrent Disease

Evaluation of the neck after surgery and radiotherapy is limited both clinically and radiologically. PET is definitely superior to anatomic imaging modalities and clinical examination in distinguishing recurrent disease from fibrosis or scar tissue (Fig. 11-13). It is, however, well recognized that false-positive results, because of surgery and radiotherapy-induced inflammation, are common in the first months after therapy. It is generally recommended to defer FDG-PET studies at least 2 months after treatment, which limits the use of this modality in the evaluation of planned neck dissection cases.

Principles of Image Interpretation

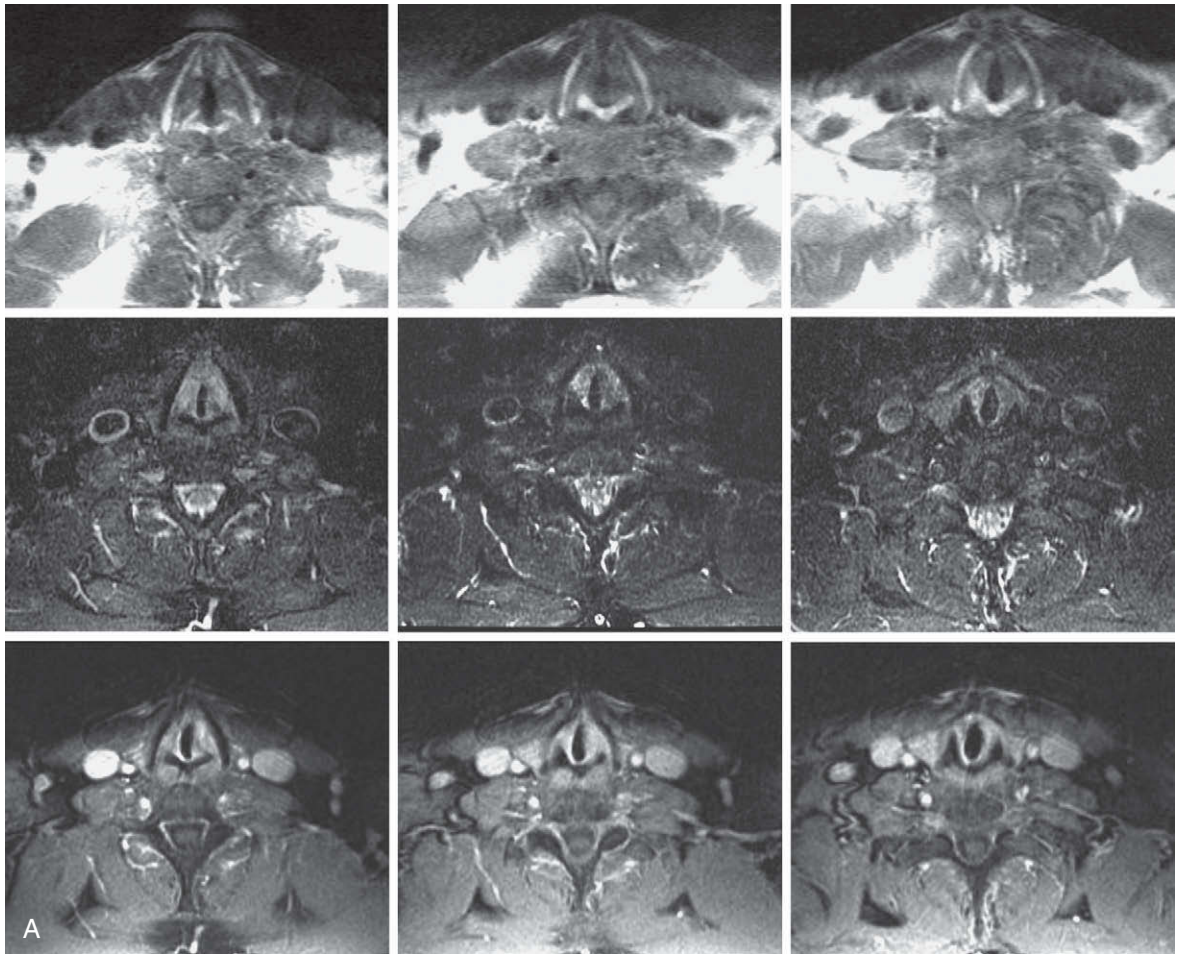
Strategy for Image Interpretation and Differential Diagnosis

This section is included to aid the beginning surgeon or oncologist in developing a basic strategy for image interpretation. Normally, the radiologist chooses and supervises the appropriate imaging study, evaluates and interprets the images, and communicates its significance to the referring physician. However, frequent dialogue between the referring physician and the radiologist will significantly improve interpretation of the imaging study. Accurately interpreting an imaging study of the head and neck requires a systematic method of observation, knowledge of the complex anatomy and pathophysiology, and an understanding of imaging principles. The differential diagnosis of lesions of the head and neck requires a systematic approach as well. One such diagnostic imaging process is summarized here:

1. Obtain clinical data: age, sex, history, physical findings.
2. Survey the films for all abnormalities and summarize these findings.
3. Compartmentalize the lesion.
4. Interpret the chronicity and aggressiveness of the observations: acute or chronic, nonaggressive or aggressive, benign or malignant.
5. Develop a differential diagnosis. Use pathologic categories: congenital, inflammatory, tumor, trauma, vascular. Use clinical and radiographic information to narrow the choices and arrive at the most appropriate diagnosis.

By using such a strategy, it is unlikely that important findings will be missed because all the images have been evaluated. This may be done by looking at all the anatomic spaces on each slice and proceeding sequentially through all the slices. Alternatively, each anatomic space can be evaluated on serial slices, followed by the next anatomic space, and so on. Characterizing a lesion requires specific observations: location, anatomic space of the epicenter, size, definition of margins, extent of spread in each direction, invasion of adjacent compartments, involvement of neurovascular structures, enhancement pattern, cysts, calcification, density, signal intensity, echogenicity, hemorrhage, and lymphadenopathy. Next, summarizing the findings helps to tie them together into a logical pattern. Compartmentalizing a lesion is the last step in the observational process and requires placing the epicenter or site of origin of the lesion in a specific anatomic space, although some lesions may be multicompartmental. The origin of a lesion is limited by the types of tissue that reside in each specific space. An example of such a summary would be, "A 35-year-old male has a cystic, nonenhancing mass in the sublingual space." A frequent cause of misdiagnosis is the failure to make all the observations first. Interpretation and differential diagnosis of the lesion are the final steps.

The interpretation of the significance of a lesion uses both its radiologic and clinical features. For example, the interpretation might use the following descriptions: inflammatory (edema, abscess cavity, fever), nonaggressive (remodeling of bone, slow progression of symptoms), aggressive (destruction of bone, rapid progression), benign neoplastic (well-defined margins, displacement of adjacent structures, nonpainful), malignant (poorly defined margins, invasion and destruction of adjacent structures, pain and neuropathies), or cystic (low-density center with a thin rim of enhancement, fluctuant). The differential diagnosis is narrowed by further refining the interpretation, "A 35-year-old male has an asymptomatic cystic, nonenhancing mass in the sublingual space that appears chronic and nonaggressive." With knowledge of the relevant clinical findings, the proper differential diagnosis, which is specific for each anatomic space, can then be constructed and limited to one (or at least a few) possible pathologic causes. In this example, a ranula would be the most likely consideration.



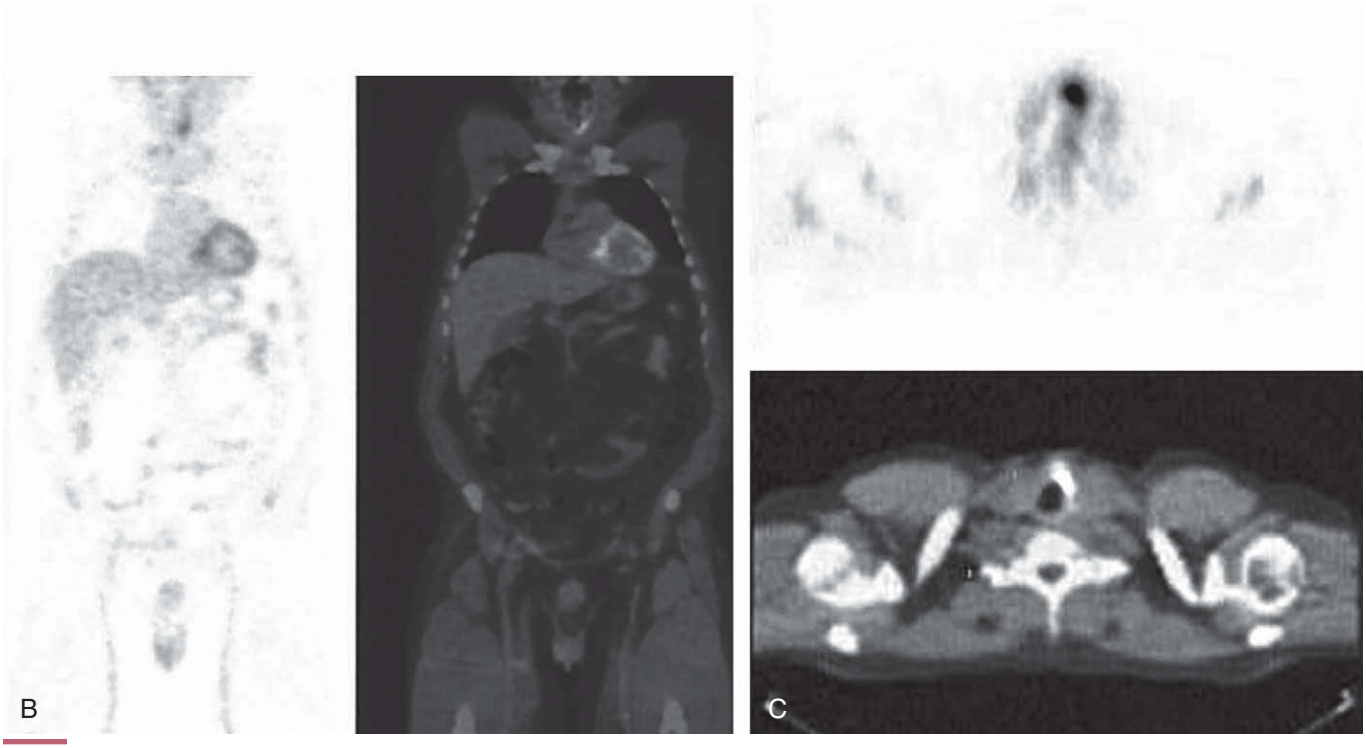


Figure 11-13. Recurrent glottic squamous-cell cancer previously treated with radiotherapy. **A,** T1-weighted, T2-weighted (STIR) and contrast enhanced, fat-saturated T1-weighted MRIs show mild fullness in the left true vocal cord without a discrete mass. It is impossible to differentiate post-therapy changes from the recurrent tumor. **B,** Coronal PET *(left)* and PET-CT *(right)* demonstrate increased metabolic activity in the left glottic and subglottic region. **C,** Axial PET *(above)* and PET-CT *(below)* show uptake anterior to the cricoid, compatible with extra-laryngeal involvement not visualized on the MRI (surgery-pathology proven).

Imaging Anatomy, Site-Specific Lesions, and Pseudotumors of Head and Neck

Spaces of Suprahyoid Neck

With the advent of cross-sectional imaging in radiology, first with CT and later with MRI, the radiologic interpretive approach changed from a pattern based on surgical compartmental anatomy to one dependent on fascial spaces. However, a combination of the two interpretive approaches, for example, parapharyngeal space at the nasopharyngeal level (with the compartmental designation serving as a modifier) may be more helpful in precisely defining a lesion location.

The head and neck region, the anatomic territory that extends from the skull base to the thoracic inlet, is best and most conveniently divided into the suprahyoid and infrahyoid neck with the hyoid bone serving as the divisional point.[15] Figures 11-14 through 11-16 demonstrate normal cross-sectional CT and MRI anatomy of the suprahyoid neck. The suprahyoid neck may be divided into a series of fascial spaces based on the division and layers of the superficial and deep cervical fascia. The superficial cervical fascia surrounds the face and neck, providing a fatty layer on which the skin is able to slide. The underlying deep cervical fascia is separated into three distinct layers: superficial (investing) layer, middle (visceral) layer, and deep (prevertebral) layer.

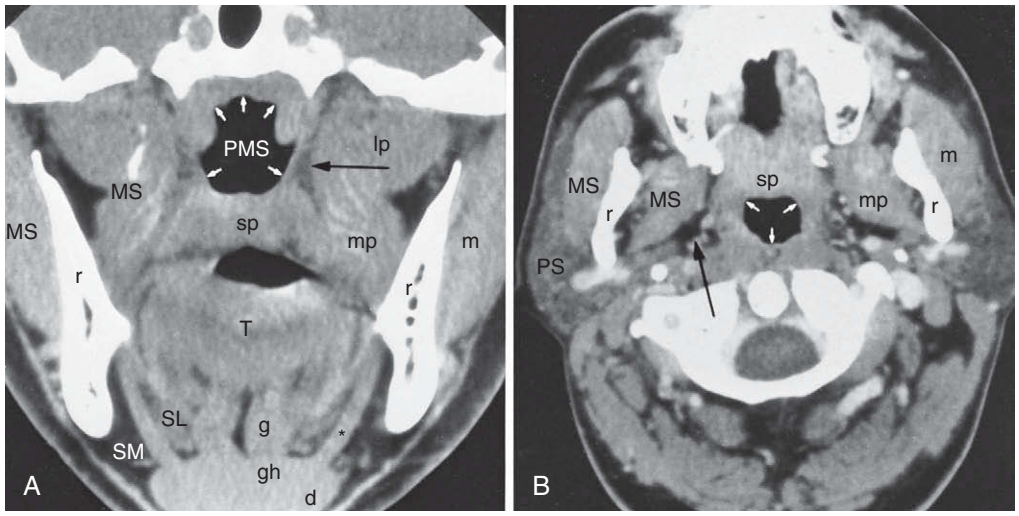

Figure 11-14. The normal computed tomography anatomy of suprahyoid neck. **A,** Coronal contrast-enhanced computed tomography (CECT) and, **B,** axial CECT demonstrate low-fat density of the parapharyngeal space *(arrow)*. Note its central position as a marker space. The following structures can be identified: anterior belly of digastric muscle (d), genioglossus muscle (g), geniohyoid muscle (gh), lateral pterygoid muscle (lp), masseter muscle (m), medial pterygoid muscle (mp), masticator space (MS), mylohyoid muscle *(asterisk)*, nasopharyngeal mucosal space (PMS, small arrows), parotid space (PS), ramus of mandible (r), sublingual space (SL), submandibular space (SM), soft palate (sp), and intrinsic tongue musculature (T).

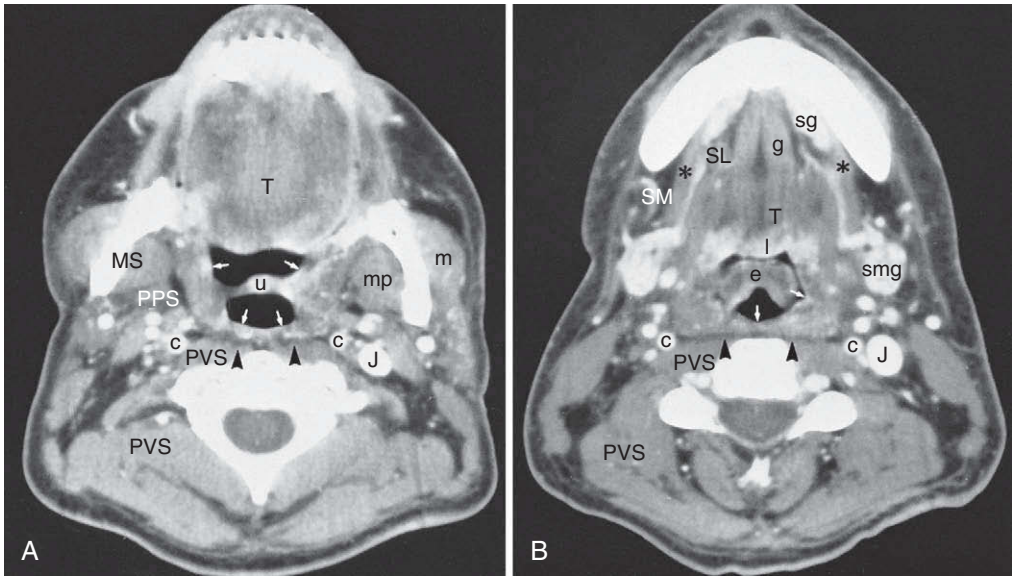

Figure 11-15. The normal computed tomography anatomy of sublingual space, submandibular space, and oral cavity. **A,** Axial contrast-enhanced computed tomography at superior and, **B,** inferior tongue levels, respectively. Note the following structures: internal carotid (c), epiglottis (e), genioglossus muscle (g), jugular vein (J), lingual tonsil (l), masseter muscle (m), medial pterygoid muscle (mp), masticator space (MS), mylohyoid muscle *(asterisk)*, pharyngeal mucosal space of oropharynx (*small arrows)*, prevertebral space (PVS), retropharyngeal space *(arrowheads)*, sublingual space (SL), submandibular space (SM), submandibular gland (smg), intrinsic musculature of tongue (T), and uvula of soft palate (u).

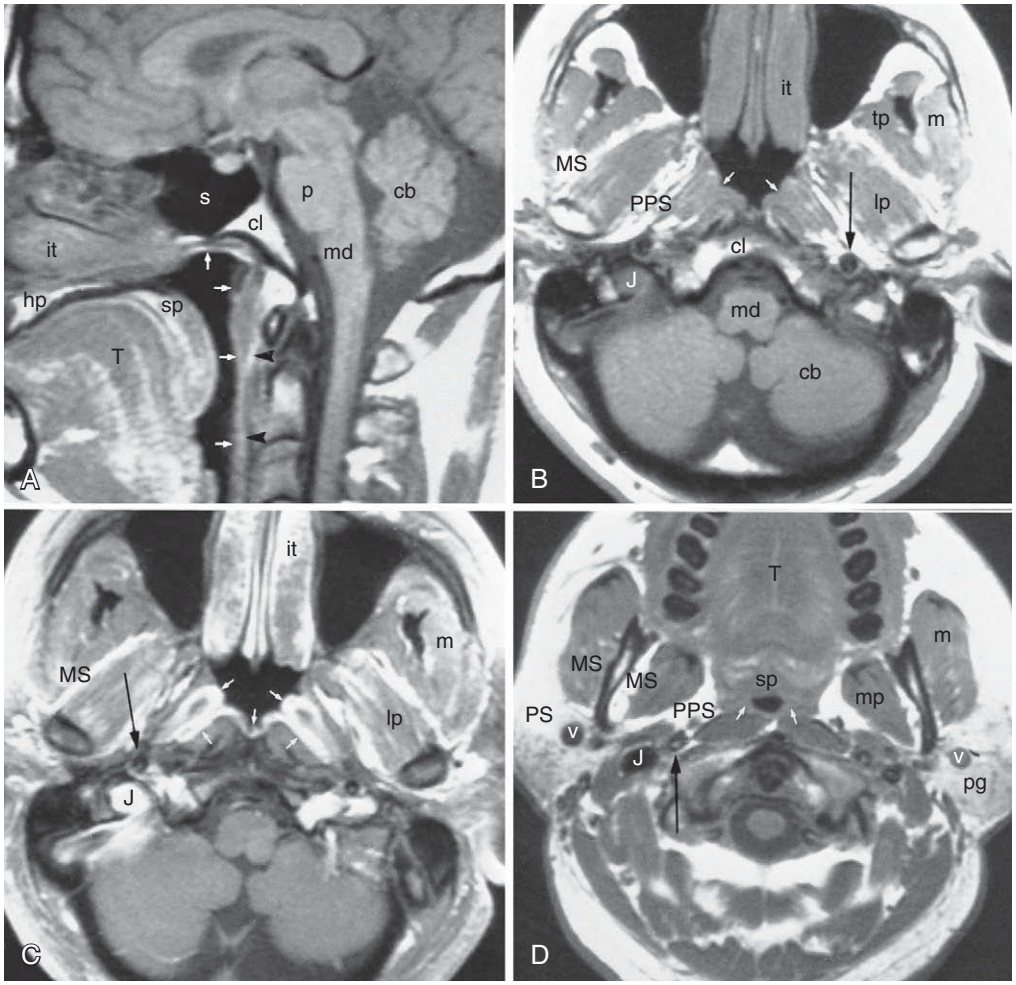

Figure 11-16. The normal magnetic resonance imaging anatomy of suprahyoid neck. **A,** Sagittal midline noncontrast T1-weighted image (T1WI). **B,** Axial noncontrast T1WI at the level of jugular foramen. **C,** Axial postgadolinium T1WI at the same level of **B** demonstrates enhancement of the nasopharyngeal mucosa and jugular veins. **D,** Axial noncontrast T1WI at the level of C2 vertebral body and mid tongue demonstrates high signal intensity of parapharyngeal space fat. The following structures are labeled: cerebellum (cb), clivus (cl), hard palate (hp), internal carotid artery *(arrow)*, inferior turbinates (it), jugular vein (J), lateral pterygoid muscle (lp), masseter muscle (m), medulla (md), masticator space (MS), nasopharyngeal mucosal space (*small arrows*), pons (p), parotid gland (pg), parapharyngeal space (PPS), parotid space (PS), retropharyngeal space *(arrowheads)*, sphenoid sinus (s), soft palate (sp), intrinsic musculature of tongue (T), temporalis muscle (tp), and retromandibular vein (v).

(Space limitations and the complexity of the fascial spaces do not allow for a detailed description or explanation of the deep cervical fascia.) Although not usually visualized on CT or MRI, these fascial layers divide the suprahyoid neck into distinct anatomic and surgically defined spaces:

1. Parapharyngeal space (PPS)
2. Pharyngeal mucosal space (PMS)
3. Parotid space (PS)
4. Carotid space (CS)
5. Masticator space (MS)
6. Retropharyngeal space (RPS)
7. Prevertebral space (PVS)
8. Oral cavity (OC)
9. Sublingual space (SLS)
10. Submandibular space (SMS)

Inflammatory and neoplastic disease, the major pathophysiologic processes of the head and neck territory, tend to grow and spread in the boundaries and confines of these fascial spaces.[16] Nevertheless, this approach based on the use of fascial anatomy allows delineation of specific anatomic spaces, with identification of disease-specific lesions for each of these spaces. As a consequence, a more accurate differential diagnosis and resulting final diagnosis are attained.

Parapharyngeal Space

The crucial anatomic center point to understanding suprahyoid anatomy is the parapharyngeal space (PPS). This fibrofatty fascial space extends from the skull base to the level of the hyoid bone and serves as a marker space around which the remaining fascial spaces are arranged. It contains fat, portions of the third division of cranial nerve V, the internal maxillary artery, the ascending pharyngeal artery, and the venous plexus. In the axial plane, this space has a triangular configuration and demonstrates bilateral symmetry. In the coronal plane, the

PPS has an hourglass shape, thicker at the skull base and hyoid level and thinner in the mid suprahyoid neck.

The PPS is clearly defined and located on both the axial and coronal planes with both CT and MRI.[17] With the former technique, the predominant fat content serves as a low-density marker between the medial muscles of deglutition found in the pharyngeal mucosal space and the muscles of mastication, located more laterally. With MRI, the PPS has bright signal intensity on T1WI (the scanning sequence that best highlights fat and muscle tissue differences). With longer TR times and more T2 weighting, this fatty space becomes less intense in signal.

Because this space is the epicenter around which the other fascial spaces are arranged, it serves as a potential marker or pivotal space. By noting the position and direction of displacement of the PPS, one can determine the epicenter and fascial space origin of a suprahyoid lesion. Because the PPS contains few structures from which lesions arise, most lesions found in this space have spread here secondarily from an adjacent fascial space.[18]

The fascial spaces that are centered about the parapharyngeal space include the pharyngeal mucosal space (PMS), the carotid space (CS), the parotid space (PS), the masticator space (MS), the retropharyngeal space (RPS), and the prevertebral space (PVS). Each space has well-defined anatomic boundaries, contains major structures of importance, and gives rise to pathologic processes that are site selective for that space. For consideration of pathologic processes in each fascial space, it is convenient to use the following outline: congenital, inflammatory, neoplastic (benign and malignant), pseudolesions, and miscellaneous. This approach, using these few disease categories, elicits most of the major lesions to be found in the head and neck and is used in the following discussion of suprahyoid and infrahyoid lesions.

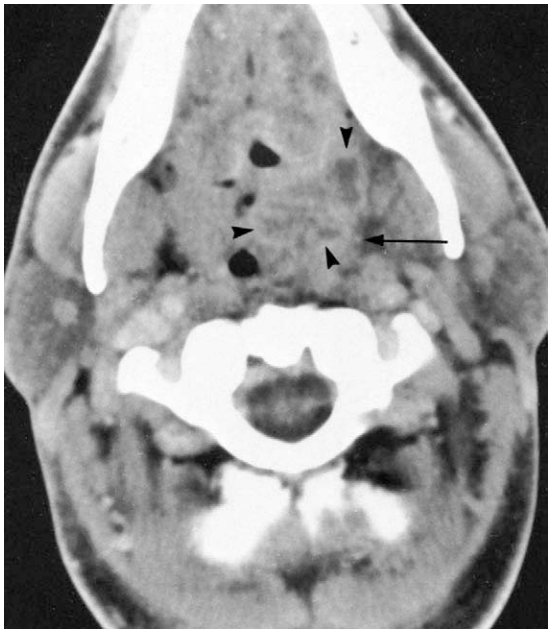

Figure 11-17. Tonsillar abscess. Axial contrast-enhanced computed tomography demonstrates a low-density left tonsillar lesion *(arrowheads)* with thin peripheral rim enhancement. The left tonsil is increased in size. Partially effaced left parapharyngeal space *(arrow)* is lateral in position.

Pharyngeal Mucosal Space

The PMS lies medial to the PPS and anterior to the PVS. It encompasses the mucosal surfaces of the inner boundaries of the nasopharynx and oropharynx and includes lymphoid (adenoidal) tissue, minor salivary glands, portions of the constrictor muscles, and muscles of deglutition. The medial portion of the eustachian tube passes through it. These structures lie medial to or on the airway side of the buccopharyngeal fascia. This fascial structure may be seen on MRI as a band of low signal intensity. On CECT or gadolinium-enhanced MRI studies, the overlying pharyngeal mucosa enhances.

The PMS extends from the skull base to the lower margin of the cricoid cartilage, extending into the upper portion of the infrahyoid neck. It encompasses the nasopharynx, oropharynx, and portions of the hypopharynx. Lesions in this space displace the PPS laterally.

In general, caution is used when interpreting the mucosal surfaces of the pharynx, oral cavity, and larynx. The normal mucosa is high signal on T2WI and STIR and enhances on postgadolinium T1WI (and with CECT). It may be confused with a superficial mucosal based malignancy. Likewise, a small superficial mucosal based tumor may be indistinguishable from the adjacent normal mucosa. The direct clinical examination of the mucosal surfaces is still superior to cross-sectional CT or MR imaging in detecting superficial tumor; however, both CT and MRI excel in detecting submucosal tumor and deep invasion. Mucosal irregularity and slight asymmetry are common, especially near the fossa of Rosenmüller (the lateral pharyngeal recesses of the nasopharynx), and care is taken in ascribing abnormality. Repeat studies with a modified Valsalva maneuver to distend the airway may be helpful. Involvement of the submucosal muscles and adjacent deep structures, such as the PPS, will confirm the presence of a suspected neoplastic mucosal lesion. Lymphoid (adenoidal) tissue is often hypertrophic and prominent, especially in children and young adolescents, and may encroach on the airway. On CT, lymphoid tissue is isodense to muscle. With MRI, it has a similar intensity to muscle on T1WI but has a bright signal on T2WI. It lies superficial to the buccopharyngeal fascia and is relatively homogeneous.

Inflammatory lesions of the PMS include pharyngitis, abscess (especially tonsillar abscess), and postinflammatory retention cysts (Fig. 11-17). Benign mixed salivary tumor is the most common benign neoplasm.

A Thornwaldt cyst is a common congenital lesion of the midline posterior nasopharyngeal mucosa and only rarely becomes secondarily infected. It is very bright on long TR sequences on MRI.

Squamous cell carcinoma (SCC), the most common tumor of the upper aerodigestive tract, originates from the PMS. The majority of lesions arise from squamous epithelium in the region of the lateral pharyngeal recess (Figs. 11-18 and 11-19). Small submucosal lesions may be missed on the clinical examination but may be detected with cross-sectional imaging. Involvement of the adjacent musculofascial spaces confirms the presence of a mucosal lesion. It may become large and lead to extensive invasion and destruction of the neighboring fascial spaces or extend medially to involve the PPS. With CT, SCC demonstrates inhomogeneous lesion enhancement, commonly with extension into adjacent spaces. With MRI, it is of intermediate intensity on T1WI and high intensity on T2WI and enhances after gadolinium infusion.[19] It may cause serous otitis media and mastoid cell opacification because of dysfunction of the eustachian tube from invasion or mass effect. Extension superior to the skull base is common. The foramen lacerum, foramen ovale, carotid canal, jugular foramen, and clivus may be affected. Perineural tumor spread along cranial motor nerve V is common and its presence should be diligently sought, especially if there is unilateral atrophy of the muscles of mastication innervated by the mandibular division of the fifth cranial nerve. Inferiorly, nasopharyngeal SCC may extend to involve the soft palate, tonsillar pillars, and nasal cavity. Asymptomatic cervical adenopathy with involvement of the superior internal jugular and spinal accessory lymph node chains is the presenting mode in more than 50% of patients. Lymph nodes are usually considered positive when larger than 1.5 cm in diameter. An enhancing lymph node rim with necrotic low-density center on CECT indicates neoplastic involvement. On MRI, lymph nodes have bright signal intensity on T2WI. On T1WI, after gadolinium administration, lymph node enhancement may be seen.

The extensive lymphoid tissue in this space is a source for development of non-Hodgkin's lymphoma (Fig. 11-20). Both SCC and lymphoma may have extensive lymph node involvement. The nodes associated with SCC commonly have necrotic centers, whereas those of lymphoma are usually noncavitary and homogeneous. Malignant

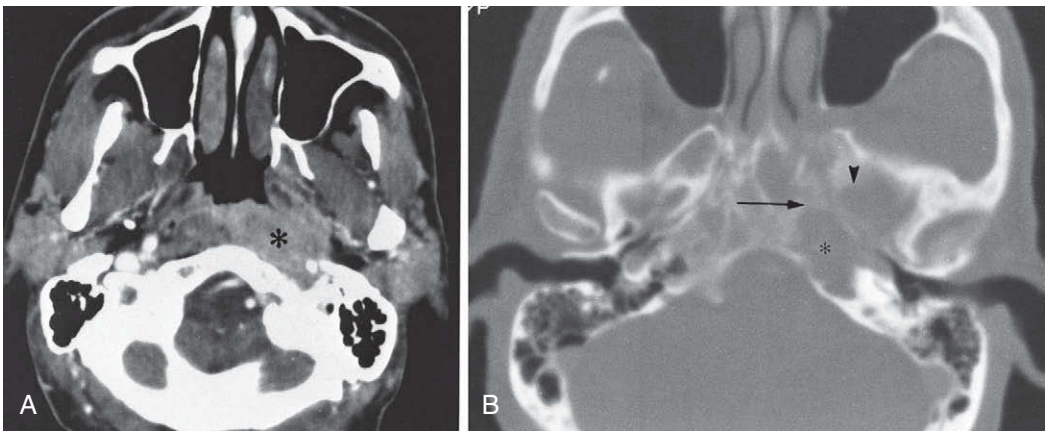

Figure 11-18. Nasopharyngeal carcinoma. **A,** Axial contrast-enhanced computed tomography (CECT) demonstrates enhancing lesion *(asterisk)* involving the pharyngeal mucosa space, retropharyngeal spaces, and prevertebral space. A tumor abuts the skull base. **B,** Axial CECT image with bone settings at the level of the skull base demonstrates a lytic destructive lesion involving the anteromedial left petrous bone *(asterisk)*, medial portion of greater sphenoid wing *(arrowhead)*, and adjacent clivus *(arrow)*.

Figure 11-19. Squamous cell carcinoma of oropharynx. Axial contrast-enhanced computed tomography demonstrates a mixed-density enhancing lesion *(asterisk)* in the right oropharynx. The tumor has extended posterolaterally to surround the carotid vessels *(arrow)*. Enhancing lymph node *(arrowhead)* with low-density necrotic center is noted posterior to the carotid space, lying just beneath the sternocleidomastoid muscle. Enhancement of the adjacent sternocleidomastoid muscle indicates muscle invasion.

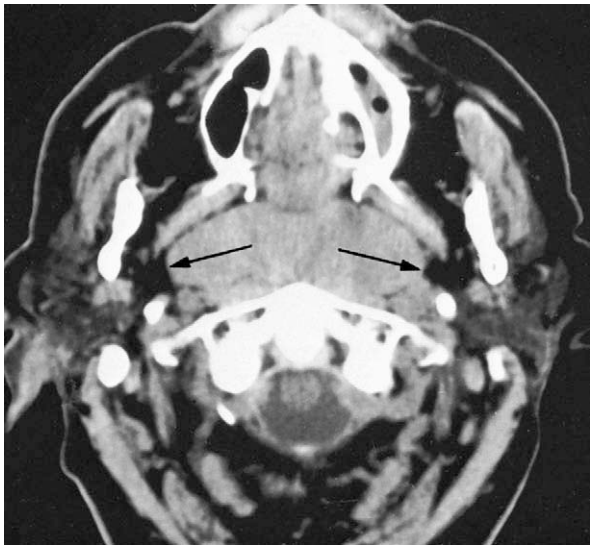

Figure 11-20. Nasopharyngeal lymphoma. Axial non-contrast computed tomography demonstrates a large homogeneous pharyngeal mucosal space with a nasopharyngeal mass lesion, displacing prevertebral and retropharyngeal spaces posteriorly. The lesion bulges into parapharyngeal space bilaterally *(arrows)*.

minor salivary gland tumors also occur in this space. These three malignant lesions are difficult to separate radiologically.

Parotid Space

The PS, the home of the parotid gland and the extracranial portion of the facial nerve, lies lateral to both the PPS and the CS and posterior to the masticator space. It extends superiorly from the level of the mid squamous temporal bone to the angle of the mandible inferiorly. It contains the parotid gland, multiple lymph nodes (within and outside the parotid gland parenchyma), the facial nerve, the retromandibular vein, and branches of the external carotid artery. The parotid gland overlies the posterior portion of the masseter muscle. Its deep retromandibular portion lies posterior to the mandible and lateral to the PPS and the CS. The posterior belly of the digastric muscle separates the PS from the CS.

Because of its high fat content, especially in the adult, the parotid gland parenchyma is frequently low density on CT but may vary and approach muscle density. It is high intensity on T1WI (slightly less than subcutaneous fat) and has decreased intensity on T2WI but often retains its bright T2 signal intensity relative to muscle. The retromandibular vein lies just posterior to the lateral margin of the mandibular ramus. The diagonal course of the facial nerve, paralleling a line drawn from the stylomastoid foramen to a point just lateral to the retromandibular vein, divides the parotid gland into superficial and deep portions. Although this is not a true anatomic division, it is useful for surgical planning. The facial nerve may be seen on some MRI studies. Its course must be considered and determined when removal of deep parotid lobe lesions is planned.

Lesions in the parotid space are usually surrounded by parotid gland tissue and are better defined with MRI than CT.[20] With NCCT, lesions are usually isodense to the normal gland or of increased density. With MRI, lesions are of muscle intensity on T1WI and usually hyperintense to normal parotid gland on T2WI.[17] When small, parotid

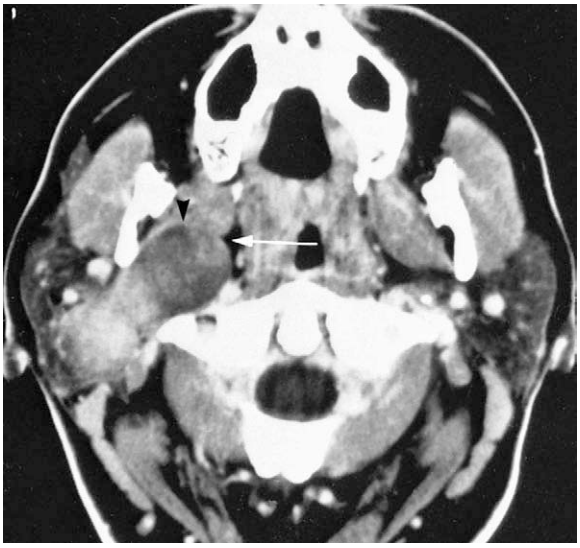

Figure 11-21. Benign pleomorphic adenoma of the right parotid gland. Axial contrast-enhanced computed tomography demonstrates a dumbbell-shaped tumor with enhancement of its superficial portion. Its deep portion is predominantly low density. Parapharyngeal space is displaced medially *(arrow)*. The lateral pterygoid muscle is indented and lies anteriorly *(arrowhead)*. The lesion has displaced the ramus of mandible anteriorly.

lesions tend to be homogeneous. With increase in lesion size, areas of hemorrhage, necrosis, and calcification may develop. If the lesion extends or originates from the deep portion of the gland, it displaces the PPS medially and occasionally anteriorly. Large lesions in the parotid gland proper will cause widening of the stylomandibular notch, the space between the posterior border of the mandible and the styloid process. Comparison with the contralateral side will make subtle widening of this space evident.[21] Deep lobe lesions, if large, may displace the carotid artery posteriorly. Benign lesions as a general rule are well defined. Malignant lesions have indistinct margins and may invade adjacent structures. Lesions in the PPS or CS may extend laterally into the parotid space, mimicking a parotid lesion clinically.

Congenital lesions of the PS include hemangioma, lymphangioma, and first and second branchial cleft cyst, the latter presenting as a cystic-appearing lesion with smooth walls.[22] Enhancing margins of the cyst indicate it is secondarily infected. Inflammatory disease may present as diffuse swelling or as a localized abscess. Infection of the adjacent skull base is best demonstrated with CT. Infection may occur secondary to calculus disease.

Calculi are also best demonstrated by sialography as intraluminal filling defects or by CT because of its tenfold higher sensitivity over plain films for detecting calcified calculi. Sialadenitis, autoimmune disease, and strictures are still best evaluated by conventional sialography, which best demonstrates ductal anatomy. Chronic sialadenitis will cause the affected parotid gland CT density to approach that of muscle. This appears as lower parotid gland signal on T1WI and brighter signal on T2WI than that of the contralateral parotid gland. Autoimmune diseases, such as Sjögren's syndrome, demonstrate bilateral parotid enlargement. Bilateral gland enlargement by benign lymphoepithelial cysts is seen in acquired immunodeficiency syndrome.

Benign pleomorphic adenoma (benign mixed tumor), the most common benign neoplasm of the parotid gland, is well defined and demonstrates variable degrees of contrast enhancement (Fig. 11-21). It is usually ovoid in configuration and may involve either the superficial or deep lobe of the parotid gland or, less commonly, both. Rarely, benign mixed tumors may arise from salivary rest tissue medial to the deep lobe and have a fat border on both their medial and lateral margins. Calcification is occasionally seen within the tumor. The tumor is hypointense on T1WI and hyperintense on T2WI. Both the superficial and deep lobes of the parotid gland may be involved, leading to a dumbbell configuration of the mass and associated widening of the stylomandibular notch.

Malignant lesions include mucoepidermoid carcinoma, adenoid cystic carcinoma, acinic cell carcinoma, and malignant mixed tumor (Fig. 11-22). High-grade malignant lesions have infiltrative borders. MRI is superior to CT for showing lesion margins and extent. Because of the abundant lymph node tissue within the parotid gland, lymph node involvement may be seen with non-Hodgkin's lymphoma, and metastatic involvement may be seen with SCC and malignant melanoma. Basal cell carcinoma of the adjacent ear and cheek may metastasize to the parotid lymph nodes.

Carotid Space

The CS—the space of vessels, nerves, and lymph nodes—lies posterior to the PPS, lateral to the retropharyngeal space, anterolateral to the prevertebral spaces, and medial to the PS and styloid process. The posterior belly of the digastric muscle separates the CS from the parotid space. The CS is formed from portions of all three layers of the deep cervical fascia. The CS extends from the temporal bone and base of the skull superiorly to the mediastinum inferiorly.[23] It contains the common carotid artery, its major divisions, the internal and external carotid artery, the jugular vein, cranial nerves IX to XII, sympathetic plexus, and lymph nodes. The jugular vein lies lateral and posterior to the carotid artery. The vagus nerve lies in the posterior groove between the two vessels. Cranial nerves IX, XI, and XII migrate to the anteromedial portion of the CS lower in the neck. Lesions of the CS displace the PPS anteriorly and, if large, may remodel the styloid process, displacing it anterolaterally.

Infection of the CS occurs most commonly secondary to spread of infection from adjacent fascial spaces. Reactive inflammatory lymph nodes, which are characteristically homogeneous and less than 1 cm in size, may be seen in any portion along the carotid space and be seen with such varied infectious processes as sinusitis, infectious mononucleosis, and tuberculosis. Suppurative lymph nodes may have low-density centers and may not be distinguished from malignant lymph nodes. Clusters or groups of lymph nodes lumped into large masses are not uncommon. Cellulitis causes a loss of normal soft tissue planes. Abscesses are characterized by focal fluid collections with enhancing margins.

On CECT, normal blood vessels demonstrate contrast enhancement. With dynamic CECT, a wash-in phase (early visualization of contrast) may be demonstrated within normal vessels and within the feeding or draining vessels of a mass, which further indicates the vascular etiology of a lesion. On MRI, blood vessels appear as circular or linear areas of flow void, because of flow of fast-moving blood. Turbulent or slow flow may lead to areas of mixed signal intensity. Vessel ectasia, dissection, aneurysm, pseudoaneurysm, and thrombosis may be diagnosed readily with either cross-sectional imaging technique. Assessment of adjacent sectional images will demonstrate a tubular configuration to the lesion. An ectatic carotid artery or an asymmetrically enlarged jugular vein may present clinically as a lateral neck mass, but is readily discernible radiologically. The right jugular vein is usually larger than the left and at times may be several times larger than the left, reflecting its greater venous drainage from the brain. Thrombosis, either arterial or venous in nature, appears as a linear or tubular intraluminal filling defect with or without associated mass effect on CECT because the vasa vasorum of the vessel wall enhances in a ringlike fashion.[24] Subacute thrombosis or vessel wall hemorrhage secondary to dissection or trauma will yield a bright signal on T1WI because of the T1 shortening effects of paramagnetic methemoglobin, a blood breakdown product.

Most mass lesions originating in the CS are of neoplastic origin. Most neurogenic tumors are schwannomas (Fig. 11-23). A schwannoma arises from Schwann cells that form the covering of nerves and most commonly originate from the vagus nerve (less commonly from the sympathetic plexus). A neurofibroma contains mixed neural and Schwann-cell elements and arises from the peripheral nerves. Neurofibromas are rare; when present, they usually are multiple and part of neurofibromatosis. Both tumors are well defined with CT, with either tumor having a low-density component because of fat infiltration. On

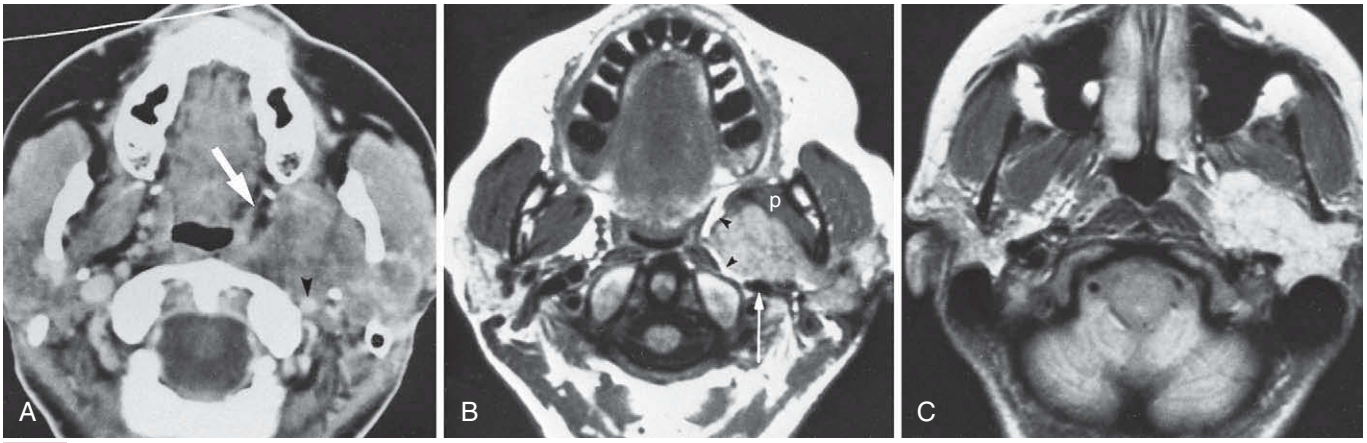

Figure 11-22. Acinic cell tumor of left parotid gland. **A,** Axial contrast-enhanced computed tomography at the level of C1 and C2 demonstrates an inhomogeneous irregular mass lesion involving both the superficial and deep portions of the left parotid gland. Lesion displaces the parapharyngeal space anteriorly and medially *(arrow)*. Stylomandibular distance is increased. Areas of patchy enhancement are noted around the periphery and throughout the lesion. Lesion has displaced the carotid artery posteriorly *(arrowhead)*. **B,** Axial T1-weighted image demonstrates superior contrast resolution of magnetic resonance imaging. Both superficial and deep portions of the lesion are well outlined. The margin of the lesion can be separated from the lateral pterygoid muscle (p), which is displaced anteriorly and laterally. PPS *(arrowheads)*, indicated by its high-intensity fat, is displaced medially. The flow void marks the site of the left carotid artery *(arrow)*. **C,** Axial spin density magnetic resonance imaging image at the level of the skull base demonstrates a well-defined lesion of increased signal intensity. Involvement of both superficial and deep lobes is well delineated.

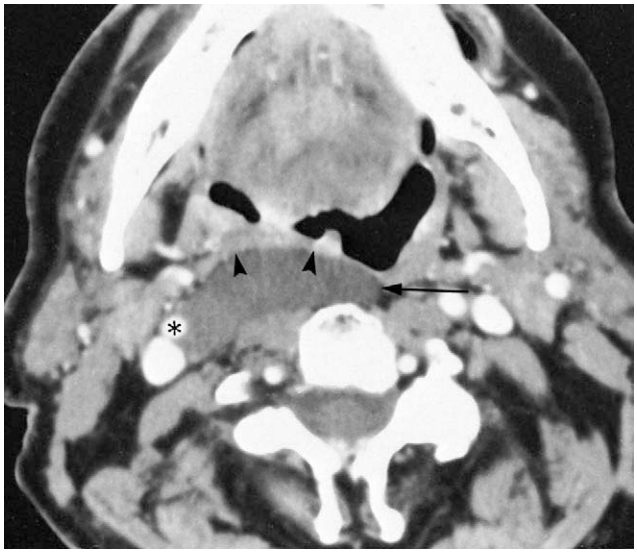

Figure 11-23. Left carotid space and retropharyngeal space ganglioneuroma. Axial contrast-enhanced computed tomography at the level of mid tongue demonstrates a C- or sausage-shaped, well-defined, low-density lesion in the anteromedial portion of the left carotid space. The lesion partially encases the left carotid artery *(asterisk)* and displaces it posterolaterally. It extends medially into the left retropharyngeal space *(arrow)*. Parapharyngeal space has been displaced laterally. Pharyngeal mucosal space *(arrowheads)* lies anterior to the lesion.

CECT, neurofibromas demonstrate variable degrees of enhancement. On MRI, they have a similar appearance. On both CT and MRI, most neural tumors have similar density and intensity characteristics to salivary gland tumors and often may not be differentiated. Neural tumors may have dense enhancement and simulate paragangliomas. On angiography, neuromas characteristically are hypovascular in contrast to paragangliomas, which are hypervascular. Neurogenic lesions arise posterior to the internal carotid artery and thus cause anterior displacement of the latter.

Paragangliomas—lesions developing from neural crest cell derivatives—may arise in the jugular foramen (glomus jugulare), along the course of the vagus nerve (glomus vagale), or at the carotid bifurcation (carotid body tumor) (Figs. 11-24 and 11-25). Paragangliomas are multiple in up to 5% of patients. The lesion is ovoid with smooth margins. Because of its marked hypervascularity, it is densely enhancing on CT. Angiography reveals a very vascular tumor with dense capillary staining. At the skull base, it erodes the jugular spine and causes permeative bone erosion of the jugular foramen in contradistinction to a schwannoma, which causes a smooth expansion with intact cortical margins. A jugular foramen paraganglioma may extend into the temporal bone or infiltrate through the skull base, presenting as a posterior fossa mass. In the midneck, a paraganglioma causes characteristic displacement of the carotid artery anteriorly and the jugular vein posterolaterally. At the carotid bifurcation, a lesion causes splaying of the internal and external carotid arteries. On MRI, it is recognized by its hypervascularity, characterized by multiple areas of signal void and flow-related enhancement from enlarged feeding and draining vessels.[25]

Lymph node involvement in the CS may be seen most commonly with metastases from SCC or as part of a general involvement by non-Hodgkin's lymphoma. Lymph node involvement may be the initial manifestation of squamous cell carcinoma. Extracapsular spread of disease may occur. Complete encasement of the carotid artery (carotid fixation) may indicate inoperability. However, the carotid artery may be sacrificed at operation if the patient successfully tolerates a carotid balloon occlusion test. Metastatic lymph nodes are characteristically inhomogeneous, especially after contrast enhancement.

Masticator Space

The MS, the space of the muscles of mastication and the posterior portion of the mandibular ramus, lies anterior to the PS and is separated from the muscles of deglutition in the pharyngeal mucosal space by the parapharyngeal space. It contains the masseter, temporalis, and medial and lateral pterygoid muscles, motor branch of the third division of cranial nerve V, inferior alveolar nerve, internal maxillary artery and its branches, pterygoid venous plexus, and the ramus and posterior body of the mandible. It includes the temporal fossa (suprazygomatic MS) superiorly, encompasses the zygomatic arch, and extends inferiorly to include the infratemporal fossa and structures on both sides of the mandible. A mass in the MS displaces the PPS posteriorly and medially.

Infection (cellulitis, abscess, osteomyelitis) may involve the mandible or the muscles of mastication. Extension through the skull base or involvement of the suprazygomatic masticator space may occur and

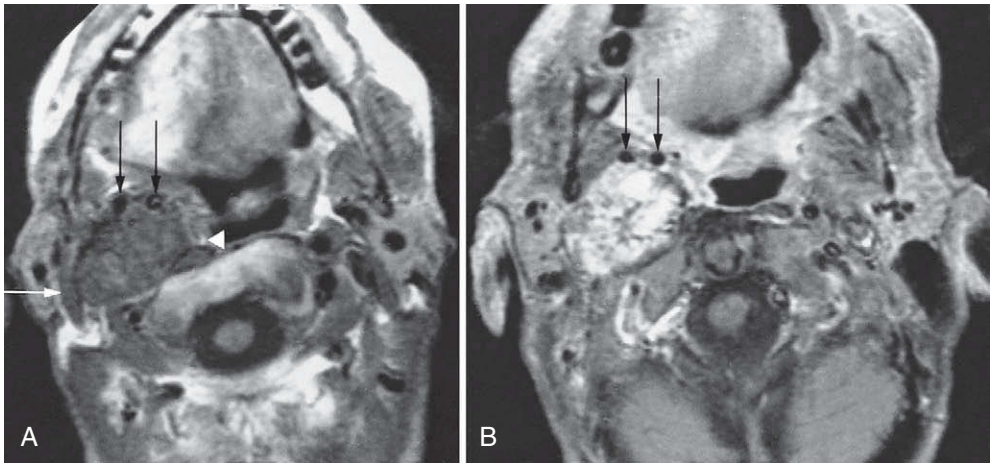

Figure 11-24. Glomus vagale (paraganglioma) of right carotid space. **A,** Axial T1-weighted image (T1WI) at the level of C2 demonstrates a mixed-density, predominantly low-density lesion involving the posterior aspect of the left carotid space. The lesion displaces the posterior belly of the digastric muscle laterally *(white arrow)* and the internal and external carotid arteries anteriorly *(black arrows)*. Parapharyngeal fat is displaced medially *(arrowhead)*. The lesion bulges into the medial aspect of the airway. The small areas of punctate low intensity noted along the margin and in the anterior portion of the lesion represent the tumor vessel flow voids. **B,** Axial T1WI at the same level postgadolinium injection demonstrates dense patchy enhancement of the lesion. Again noted are multiple punctate vascular flow voids within the lesion and around the periphery. Carotid vessels *(arrows)* are noted overlying the anterior lesion margin.

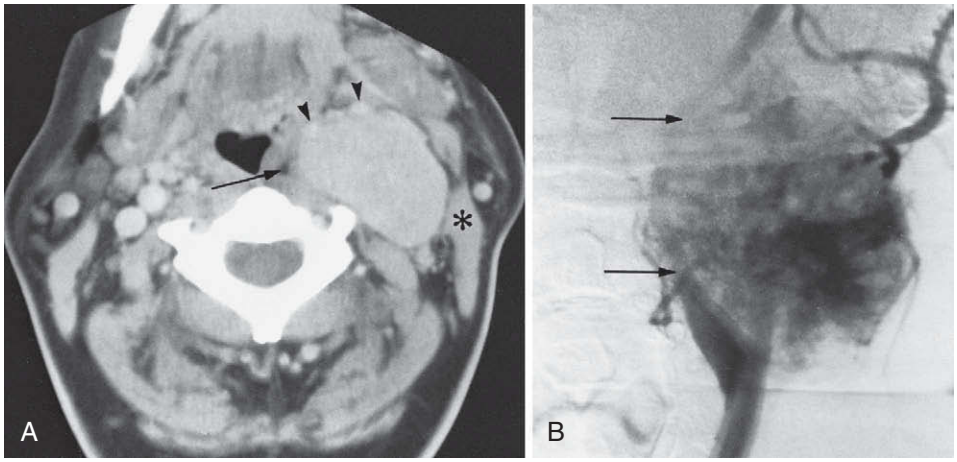

Figure 11-25. Glomus vagale of left carotid space. **A,** Axial contrast-enhanced computed tomography at the level of mid tongue demonstrates a relatively homogeneous, well-defined enhancing lesion in the left carotid space. Carotid vessels lie on the anteromedial margin of the lesion *(arrowhead)*. Parapharyngeal space is displaced medially *(arrow)*. The lesion lies deep to the sternocleidomastoid muscle *(asterisk)*. **B,** Anteroposterior digital subtraction angiogram demonstrates a densely vascular staining tumor displacing the internal carotid artery medially *(arrows)*. Vascularity and dense tumor stain indicate the lesion is paraganglioma.

should be ruled out (Fig. 11-26). Abscesses commonly arise from an odontogenic focus or from poor dentition. The bone changes of osteomyelitis are best demonstrated with CT.

Benign lesions include hemangioma and lymphangioma (Fig. 11-27). Nasopharyngeal angiofibroma, a tumor of young adolescent males, arises in the pterygopalatine fossa and commonly extends into the masticator space (Fig. 11-28). Primary bone neoplasms may arise from the mandible. Chondrosarcoma and osteosarcoma present with chondroid calcification and new bone formation, respectively. The bone lesion is characteristically muscle intense on T1WI and hyperintense with T2WI. Postgadolinium T1WI demonstrates extensive enhancement. An infiltrating mass with mandibular destruction may be indistinguishable from metastatic disease. Non-Hodgkin's lymphoma may present with bone involvement, with a soft tissue mass, or as a lymph node mass. SCC presents as an infiltrating mass and occurs secondary to extension from a neighboring fascial space (Fig. 11-29). Perineural spread of tumor is common in the MS. The fifth nerve should be assessed for thickening and enhancement along its course as it passes from the brainstem to the cavernous sinus, through the foramen ovale, and eventually below the skull base as it passes inferiorly to innervate the individual muscles of mastication (Fig. 11-30). The foramen ovale may be increased in size, and a tumor may be found within the cavernous sinus. Tumor involvement of the inferior alveolar nerve may cause erosion, irregular enlargement, or destruction of the inferior alveolar canal of the mandible.[26]

Pseudotumors may mislead the unwary. An accessory parotid gland overlying the anterior border of the masseter muscle or asymmetric enlargement of the parotid gland may simulate tumor. In both situations the parotid gland variant retains MRI signal characteristics identical to the normal parotid gland. Hypertrophy of the masseter muscle may occur secondary to teeth grinding, mimic a mass lesion, or be bilateral. If the fifth cranial nerve is injured or invaded by a tumor resulting in denervation of the muscles, ipsilateral atrophy of the muscles of mastication and fat infiltration ensue. The normal contralateral muscle group may be incorrectly considered enlarged and misinterpreted as tumor involvement.

Retropharyngeal Space

The RPS, a potential space between the middle and deep layers of the deep cervical fascia, lies posterior to the pharyngeal mucosal space, anterior to the PVS, and medial to the carotid space. It extends from the skull base superiorly to the T3 level of the upper mediastinum inferiorly.[27] The importance of the RPS derives from its potential to serve as a passageway for infection to spread among the head, neck, and mediastinum. Its contents are fat and lymph nodes, the principal nodes being the nodes of Rouvière (the classic lateral retropharyngeal nodes) and the medial retropharyngeal nodes. This nodal group is commonly involved in children, and up to 1 cm in size is considered normal. But a node larger than 5 mm is viewed with suspicion in an adult. A mass lesion in the RPS will displace the PPS anterolaterally. Infection, either pharyngitis or tonsillitis, may give RPS lymph node involvement. Diffuse cellulitis or abscess may occur, the latter usually secondary to infection of the pharyngeal mucosal space or prevertebral space. Infection or mass in the lateral alar portion of the infrahyoid RPS may have a "bow-tie" appearance on axial imaging (Fig. 11-31). SCC may invade the RPS directly or may present solely with lymph node involvement. The pattern is one of inhomogeneous enhancement, commonly with necrotic low-density centers. With non-Hodgkin's lymphoma, lymph nodes are homogeneous and multiple, commonly involving more than one of the fascial spaces.

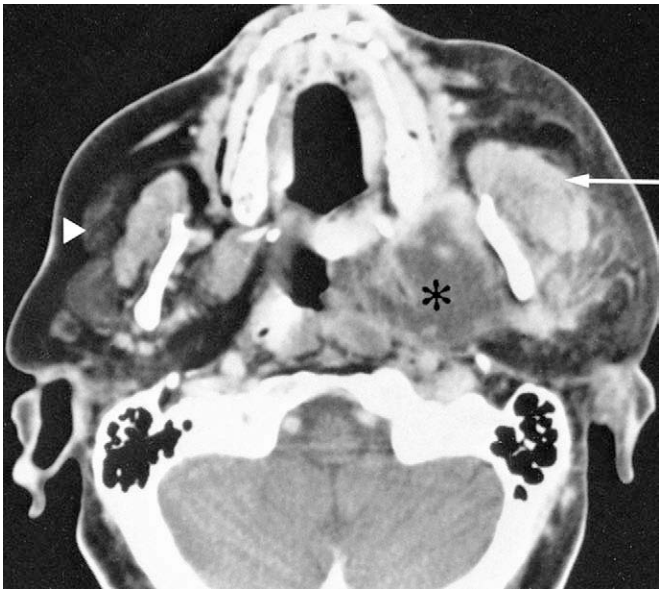

Figure 11-26. Left masticator space abscess. Axial contrast-enhanced computed tomography at the level of the superior alveolar ridge demonstrates a low-density lesion *(asterisk)* in the medial aspect of the left masticator space, involving the left lateral pterygoid muscle. The abscess is surrounded by a rim of irregular enhancement. Edema has infiltrated and obscured the parapharyngeal space. Left masseter muscle *(arrow)* is thickened and edema is present in the soft tissue planes, lateral to the masseter muscle and in the buccal space anteriorly. Note the accessory parotid gland overlying the right masseter muscle *(arrowhead)*.

Prevertebral Space

The PVS, also defined by the deep layers of the deep cervical fascia, is divided into anterior and posterior compartments. The former encompasses the anterior cervical vertebral bodies, extending from one transverse process to another. The posterior compartment surrounds the posterior spinal elements. The PVS contains the prevertebral, scalene, and paraspinal muscles, the brachial plexus, the phrenic nerve, the vertebral body, and the vertebral artery and vein. Similar to the anatomy of the RPS, the PVS extends from the skull base superiorly to the mediastinum inferiorly.

The PVS lies directly posterior to the RPS and posteromedial to the carotid space. An anterior compartment PVS mass causes thickening of the prevertebral muscles and displaces the prevertebral muscles and the PPS anteriorly. A mass in the posterior compartment of the PVS displaces the paraspinous musculature and the posterior cervical space fat laterally, away from the posterior elements of the spine. Infection and malignant disease, the common disease processes of the PVS, usually involve the vertebral body.

Infection, including tuberculosis and bacterial pathogens, characteristically involves the vertebral body, as well as the adjacent intervertebral disc space. Benign processes, although much less common, include chordoma, osteochondroma, aneurysmal bone cyst, giant cell tumor, and plexiform neurofibroma. Malignant disease processes include metastatic disease, leukemia, lymphoma, and direct invasion by SCC. Vertebral body destruction with associated soft tissue mass may be seen. The spinal canal and dural sac may be compromised.

Oral Cavity

The oral cavity, the space of the anterior two thirds of the tongue and the floor of the mouth, lies below the hard palate, medial to the supe-

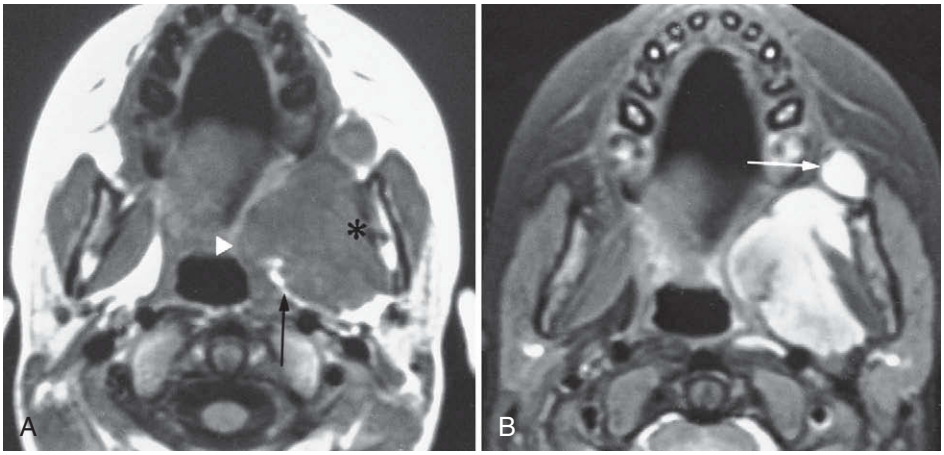

Figure 11-27. Lymphangioma of left masticator space. **A,** Axial T1-weighted image at the level of the base of the tongue and tonsillar region of the oropharynx demonstrates an inhomogeneous low-density soft tissue mass involving the left lateral pterygoid muscle *(asterisk)*. It displaces parapharyngeal space medially and anteriorly *(arrow)*. The mass extends to the anterior medial wall of the left oropharynx *(arrowhead)*. **B,** Axial spin density image with fat suppression demonstrates a lesion with bright signal intensity. The lesion margins are now better defined. The lesion can now be separated from the lateral pterygoid muscle. The lesion abuts the anteromedial wall of oropharynx. Anteriorly, the lesion extends into the buccal space *(arrow)*, anterior to the cortical margin of mandible.

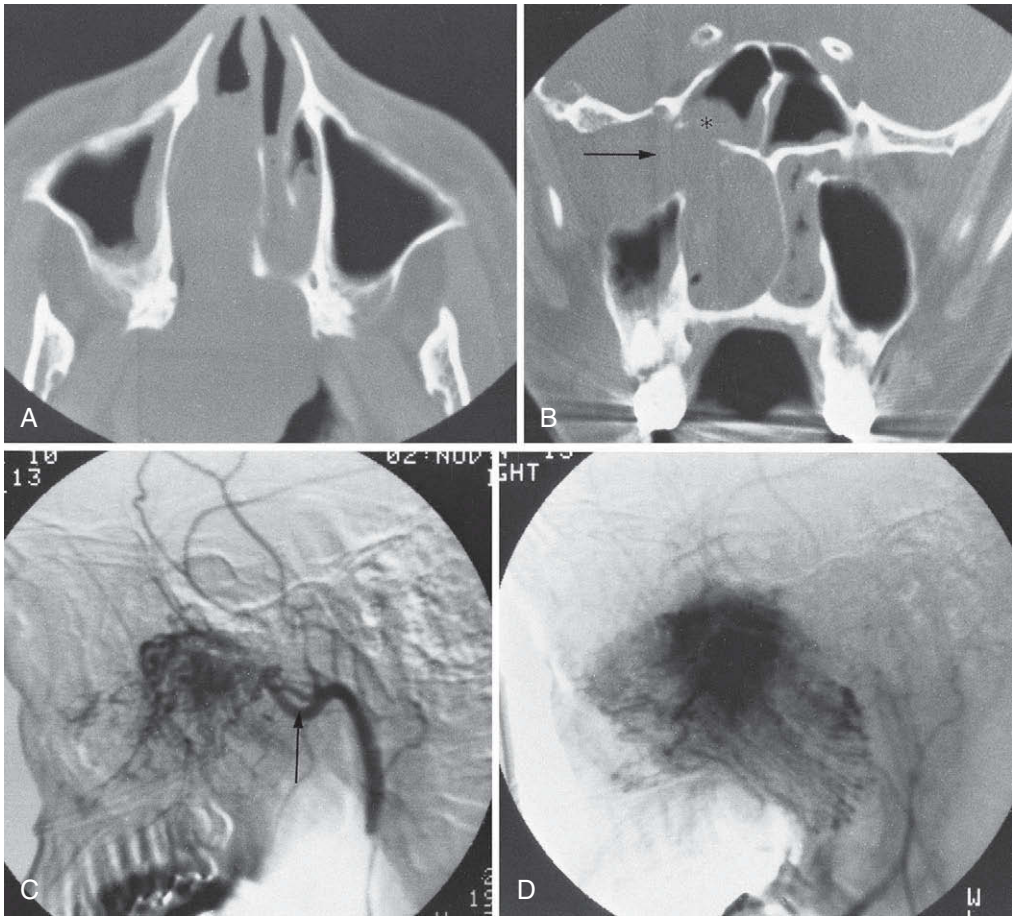

Figure 11-28. Nasopharyngeal angiofibroma. **A,** Axial noncontrast computed tomography (NCCT) demonstrates a homogeneous soft tissue mass enlarging the right nasal aperture. A large component of the tumor projects posteriorly into the nasopharynx and oropharynx. **B,** Coronal NCCT also demonstrates the complete opacification and expansion of the right nasal aperture by a soft tissue mass. The tumor extends into and widens the right infraorbital fissure *(arrow)*. The tumor *(asterisk)*, having destroyed right floor, is present in the sphenoid sinus. **C** and **D,** Lateral subtraction angiograms (early arterial and capillary phase) demonstrate a vascular mass in the nasopharynx and nasal aperture. Internal maxillary artery *(arrow)* gives rise to leash of tumor vessels. Dense tumor stain is noted in the capillary phase.

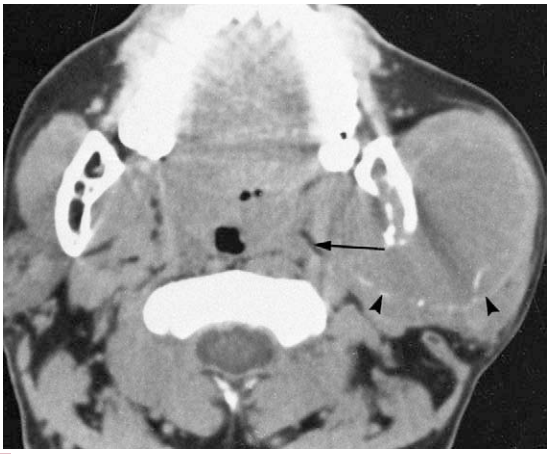

Figure 11-29. Squamous cell carcinoma of mandibular ramus. Axial contrast-enhanced computed tomography at the level of C2 demonstrates a large soft tissue tumor destroying the central portion and medial margin of the left mandibular ramus with an extension of the soft tissue tumor into the masseter and lateral pterygoid muscles. Parapharyngeal space has been displaced medially *(arrow)*. Thin rim of circular enhancement is noted posteriorly and laterally *(arrowheads)*.

rior and inferior alveolar ridge and teeth, anterior to the oropharynx, and superior to the mylohyoid muscle, the muscle stretching between the inferomedial margins of the mandible. The oral cavity is separated from the oropharynx posteriorly by the circumvallate papillae, tonsillar pillars, and soft palate. The oral cavity includes the oral tongue (the anterior two thirds of the tongue), whereas the oropharynx contains the base of the tongue (the posterior one third of the tongue), the soft palate, the tonsils, and the posterior pharyngeal wall.

The oral cavity can be divided into two major spaces, the sublingual space (SLS) and the submandibular space (SMS). The mylohyoid muscle, which constitutes the floor of the mouth, is the boundary marker between these two spaces. Other areas of the oral cavity include the floor of the mouth, oral tongue, hard palate, buccal mucosa, upper alveolar ridge, lower alveolar ridge, retromolar trigone, and lip.

Most masses in the oral cavity and oropharynx are amenable to direct clinical assessment. Mucosal lesions are readily visualized. The purpose of sectional imaging is to evaluate the degree of submucosal involvement. The majority of neoplasms of the oral cavity are readily detected on clinical examination. SCC accounts for approximately 90% of oral cavity and oropharyngeal neoplasms (Figs. 11-32 through 11-34). Cross-sectional imaging has an important role to play in estimation of tumor size, identification of tumor invasion, and assessment of nodal metastasis.

Congenital lesions include lingual thyroid and cystic lesions (epidermoid, dermoid, and teratoid cysts). Most infections of the oral cavity are dental in origin. Dental infections anterior to the second

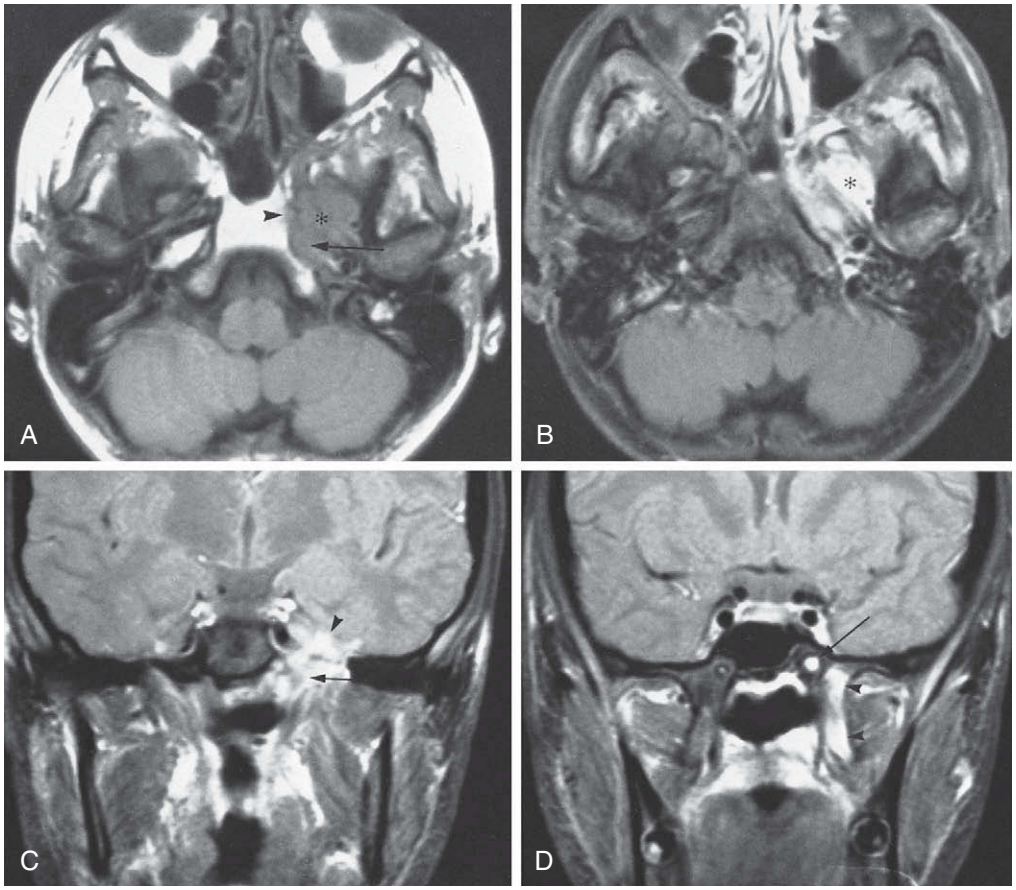

Figure 11-30. Adenoid cystic carcinoma of masticator space invading left skull base. **A,** T1-weighted (T1WI) magnetic resonance image demonstrates a low-density, well-defined lesion *(asterisk)* abutting the lateral border of the clivus and destroying the medial apex of the left petrous temporal bone *(arrow)*. Lateral cortical margin of the clivus has been eroded *(arrowhead)*. **B,** Axial postgadolinium fat-suppressed T1WI demonstrates diffuse patchy enhancement of the left middle fossa lesion *(asterisk)*. On this sequence, the normal high signal intensity of fat has been suppressed. **C,** Coronal postgadolinium fat-suppressed spin density image demonstrates an enhancing tumor *(arrowhead)* below the skull base with the extension through the foramen ovale into the left middle fossa *(arrow)*. **D,** Coronal spin density with fat suppression postgadolinium infusion demonstrates an enhancing tumor in the expanded vidian canal *(arrow)* and pterygoid fossa *(arrowheads)*.

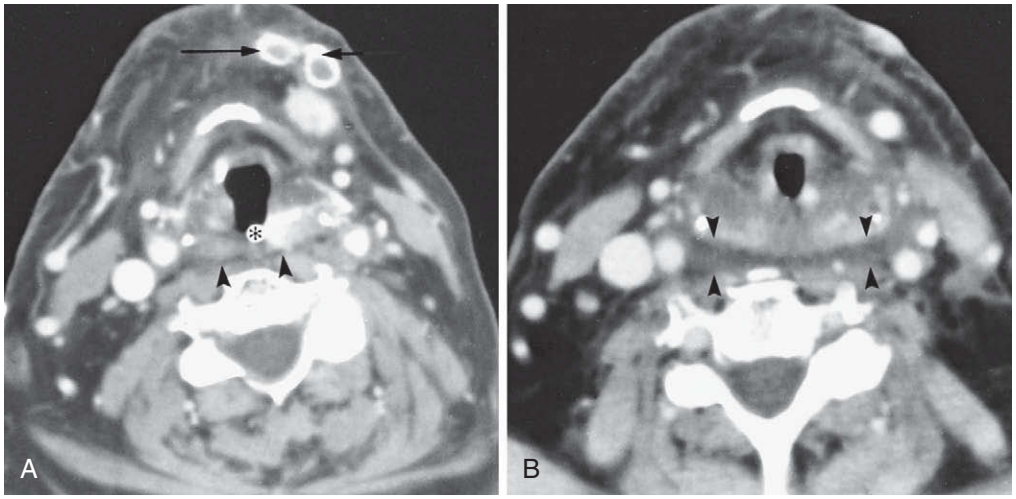

Figure 11-31. Retropharyngeal space (RPS) edema and abscess. **A,** Axial contrast-enhanced computed tomography (CECT) at the level of the superior margin of the hyoid bone demonstrates a nasogastric tube *(asterisk)* in the posterior wall of the oropharyngeal airway and mild thickening of the lateral wall of the larynx. RPS is normal *(arrowhead)*. Two lymph nodes *(arrows)* with rim enhancement lie anterior to the left submandibular gland. **B,** Repeat axial CECT at the same level 6 months later demonstrates a well-defined "bow-tie" appearance of edema in the RPS *(arrowheads)*.

molar tend to involve the sublingual space and lie superior to the mylohyoid muscle. Infections of the posterior molars usually involve the SMS and lie inferior to the mylohyoid muscle. Knowledge of which space is involved is crucial to plan adequate surgical drainage.

Sublingual Space

The SLS is located in the anterior tongue, lateral to the intrinsic muscles of the tongue (genioglossus and geniohyoid) and superior and medial to the mylohyoid muscle. Anteriorly, it extends to the genu of the mandible and, posteriorly, it connects freely with the SMS at the posterior margin of the mylohyoid muscle. It contains the anterior portion of the hyoglossus muscle, the lingual nerve (sensory division of cranial nerve V), the chorda tympani branch of cranial nerve VII, the lingual artery and vein, the deep portion of the submandibular glands and ducts, and the sublingual glands and ducts.

Congenital lesions of the sublingual space include epidermoid, dermoid, lymphangioma, and hemangioma. Lingual thyroid tissue will result if there is failure of normal descent of developing thyroid tissue from the base of the tongue into the lower neck. On CT, the lingual thyroid is midline in the posterior portion of the tongue and demonstrates dense contrast enhancement. Nuclear medicine thyroid scans demonstrate functioning thyroid tissue.

Cellulitis and abscess may occur secondary to dental or mandibular infections or arise as a consequence of calculus disease of either the submandibular or sublingual glands. Abscess is characterized by central areas of low density with or without boundary enhancement (Fig. 11-35). As with parotid gland calculi, CT readily identifies calcified stones and demonstrates bone destruction and sequestra of mandibular osteomyelitis. Ranula, a postinflammatory retention cyst of the sublingual gland, presents as a cystic low-density lesion. As it enlarges, it extends posteriorly and inferiorly into the submandibular space, where it is referred to as a "diving ranula" (Fig. 11-36).

SCC, the most common malignancy of the SLS, may spread from the oropharynx, oral cavity, alveolar ridge, or anterior portion of the tongue. A mass with irregular areas of enhancement, ulceration, central necrosis, and lymph node involvement is characteristic. Normal fat planes may be obscured. Tumor spread across the midline of the tongue, along the lingual or mandibular nerve, or invasion of the cortex or medulla of the mandible is an important finding that alters treatment planning.

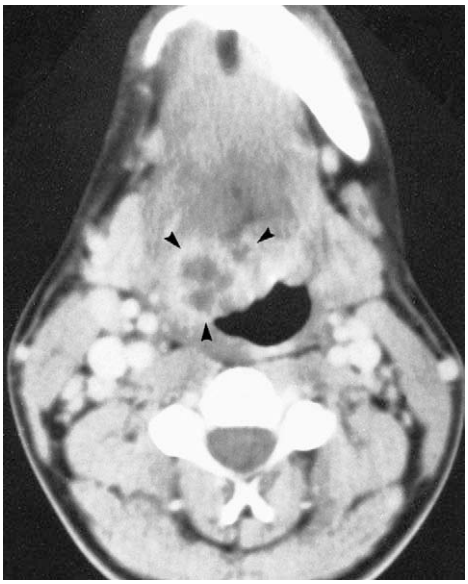

Figure 11-32. Right base of tongue and tonsillar abscess. Axial contrast-enhanced computed tomography of the suprahyoid neck demonstrates an inhomogeneous mixed low-density enhancing mass *(arrowheads)* in the base of the tongue and in the right tonsillar region. Low-density area of the lesion indicates pus within the abscess.

Submandibular Space

The SMS lies inferior and lateral to the SLS. It is located inferior to the mylohyoid bone and superior to the hyoid bone. It contains the anterior belly of the digastric muscle, fat, submandibular and submental lymph nodes, the superficial portion of the submandibular gland, the inferior portion of the hypoglossal nerve, and the facial artery and vein.

Congenital lesions are not uncommon and include second branchial cleft cyst, thyroglossal duct cyst, and cystic hygroma (lymphangioma). Branchial cleft cyst occurs most commonly at the angle of the mandible, posterior to the submandibular gland, anterior to the sternocleidomastoid muscle, and anterolateral to the carotid space (Fig. 11-37). It may have an associated fistula or sinus tract. Thyroglossal duct cysts are midline in location and are found anywhere

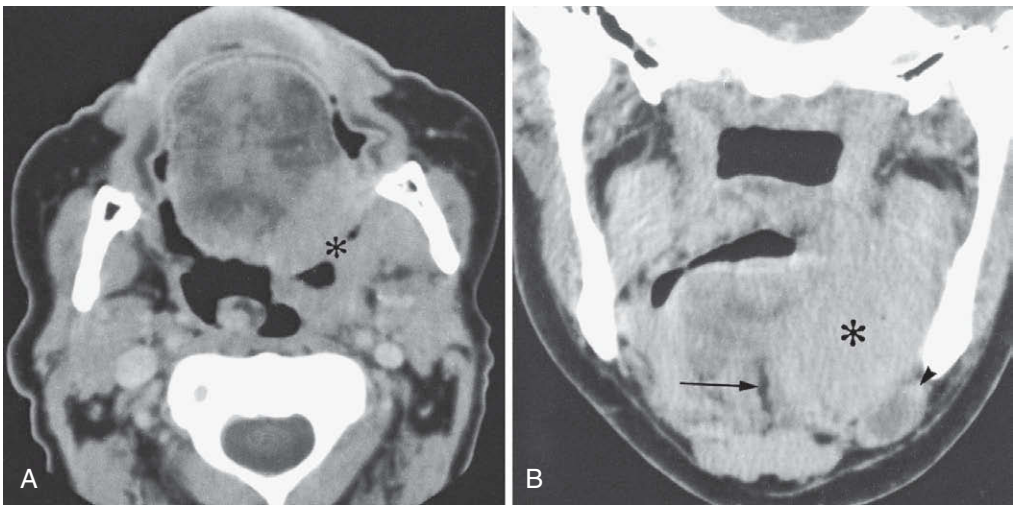

Figure 11-33. Squamous cell carcinoma of the base of tongue and the floor of the mouth. **A,** Axial contrast-enhanced computed tomography (CECT) at the level of the mid tongue demonstrates a homogeneous lesion *(asterisk)*, isodense relative to the muscles of mastication, involving lateral and posterior margins of the left side of tongue, left lateral pterygoid muscle, and tonsillar region of oropharynx. **B,** Coronal CECT demonstrates a homogeneous mass involving the lateral portion of the tongue, extending from the floor of mouth inferiorly to the tonsillar region superiorly *(asterisk)*. Midline septum *(arrow)* of the tongue is displaced laterally. Necrotic lymph node *(arrowhead)* lies inferior to the tongue.

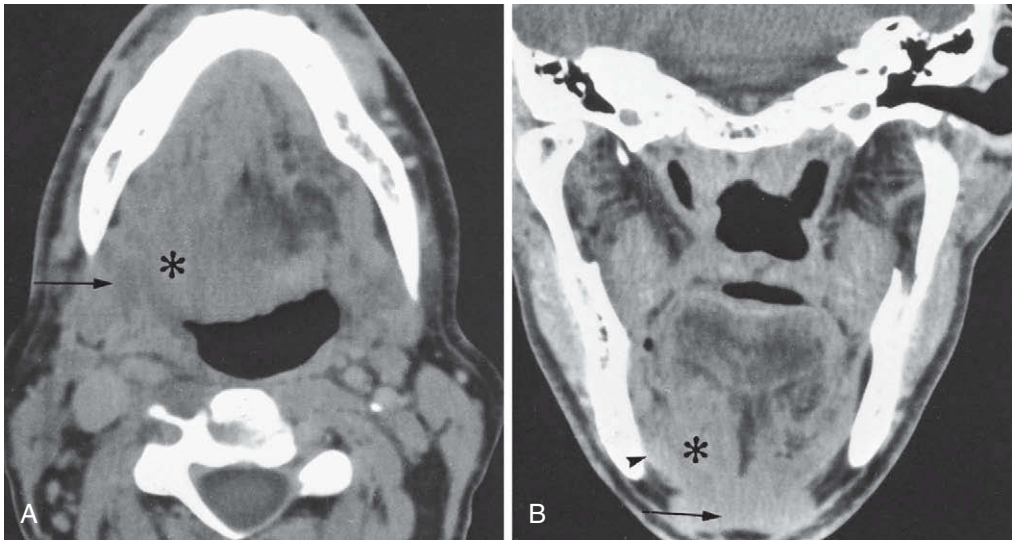

Figure 11-34. Non-Hodgkin's lymphoma of the base of tongue and the floor of the mouth. **A,** Axial contrast-enhanced computed tomography (CECT) at the midlevel of the tongue demonstrates an enlargement of the right side of the tongue by a homogeneous mass lesion *(asterisk)*, isodense to the normal tongue musculature. Submandibular space *(arrow)*, located more laterally, is also involved. **B,** Coronal CECT demonstrates homogeneous involvement of the right inferior lateral base of the tongue *(asterisk)*, mylohyoid muscle *(arrowhead)*, and floor of the mouth. Lesion lies above the anterior belly of digastric muscle *(arrow)*. Homogeneous nature of the lesion favors lymphoma.

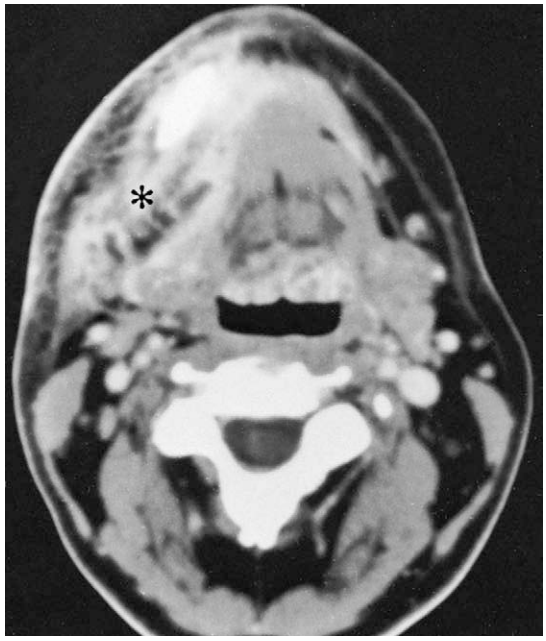

Figure 11-35. Submandibular abscess and cellulitis. Axial contrast-enhanced computed tomography demonstrates a mixed low-density and enhancing lesion *(asterisk)* involving the right submandibular space (SMS). Abscess displaces the midline structures of the tongue to the left. Edema extends laterally from the SMS into overlying soft tissues. Fat is of increased density because of infiltration by edema.

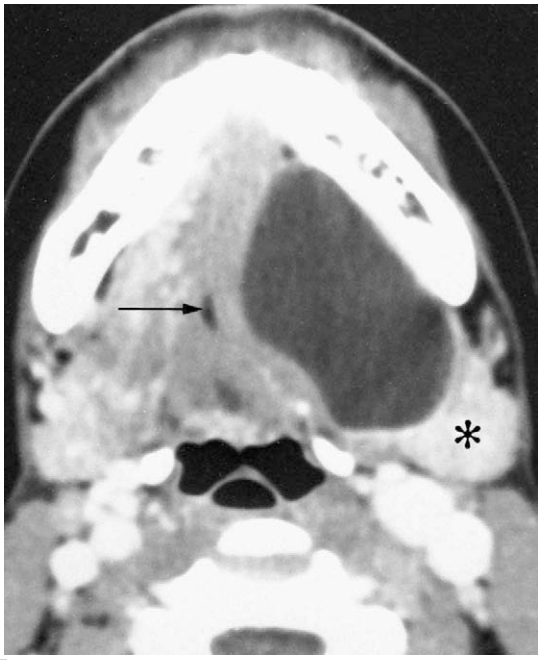

Figure 11-36. Ranula of left lingual and submandibular space. Axial contrast-enhanced computed tomography at the level of the body of the mandible demonstrates a large, low-density lesion with well-defined margins involving both sublingual and submandibular space. Lesion displaces the midline tongue structures *(arrow)* to the right. Submandibular gland is displaced posteriorly and laterally *(asterisk)*.

from the tongue base to the midportion of the thyroid gland. Cystic hygroma, a malformation of lymphatic channels, is a multilocular fluid density lesion that may involve both the SLS and SMS in the adult.

Ranula, a retention cyst of the sublingual gland, commonly extends into and may predominantly involve the SMS. It is unilocular in configuration. Its tail of origin should be carefully searched for in the SLS because this will aid in establishing its origin and diagnosis.

Benign tumors include benign mixed cell tumor, lipoma, dermoid, and epidermoid. Most malignant disease represents secondary submandibular and submental nodal involvement, commonly from SCC of the oral cavity and face. Multiple enlarged lymph node involvement may be seen with non-Hodgkin's lymphoma.

Spaces of Infrahyoid Neck

The infrahyoid neck extends superiorly to the hyoid bone and inferiorly to the clavicles and contains the following spaces:

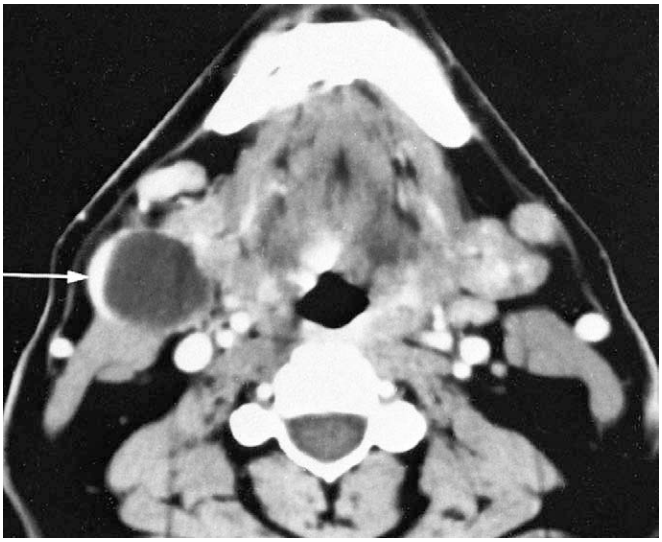

Figure 11-37. Infected branchial cleft cyst. Axial contrast-enhanced computed tomography at the midlevel of the tongue and base of the mandible demonstrates a well-defined, low-density lesion in the lateral portion of the submandibular space lying anterior to the right sternocleidomastoid. A thin rim of peripheral enhancement is noted anteriorly and medially. The lateral wall demonstrates thick enhancement *(arrow)*. Location favors the second branchial cleft cyst. Enhancement of the cyst wall indicates that it is infected.

1. Infrahyoid RPS
2. Infrahyoid PVS
3. Anterior and posterior (lateral) cervical spaces
4. Hypopharyngeal mucosal space (PMS)
5. Visceral space and larynx
6. CS

Normal cross-sectional anatomy of the infrahyoid neck is presented in Figures 11-38 through 11-40. The PPS ends at the hyoid bone and does not continue into the infrahyoid neck. The mucosal, carotid, retropharyngeal, prevertebral, and posterior cervical spaces are all continuous superiorly with the suprahyoid neck and extend inferiorly to the thoracic inlet.[28] These spaces are discussed in more detail in the suprahyoid neck section of this chapter. The posterior cervical space is described in the next section. Lesions may secondarily invade the structures of the infrahyoid neck from the cranial margin (submandibular, parapharyngeal, carotid, retropharyngeal, and oropharyngeal mucosal spaces), posterior margin (prevertebral space and vertebrae), and inferior margin (mediastinum and chest wall).

Infrahyoid Retropharyngeal Space

The infrahyoid RPS, a potential space containing a thin layer of fat and no lymph nodes, is bounded by the middle layer of deep cervical fascia anteriorly, the alar fascia of the carotid sheath laterally, and the deep layer of deep cervical fascia posteriorly.[29] Unlike the suprahyoid RPS, which contains both fat and lymph nodes, the infrahyoid RPS only contains fat. On CT and MRI, the normal infrahyoid RPS is an inconsistently demonstrated fat stripe overlying the anterior margin of the longus colli muscles, nestled between the two carotid sheaths.

The infrahyoid RPS may be involved by processes arising from tissues within this space, but more commonly it is affected by external invasion from the adjacent spaces. Lesions within this space have a characteristic "bow-tie" configuration and lie anterior to the longus colli muscles (Fig. 11-41). Lipomas and lymphangiomas are two low-density congenital lesions arising primarily in, or secondarily extending into, the infrahyoid RPS. Inflammation of this space may arise from pharyngeal mucosal laceration, discitis, or osteomyelitis from the PVS, or from infections tracking in through the posterior cervical space. Gas in this space suggests laceration of the pharynx, larynx, or trachea, pneumomediastinum, or the presence of gas-forming organisms (Fig. 11-42). Edema from inflammation in an adjacent space may track into the RPS and occasionally mimic a true fluid collection or abscess. Neoplasms arising in the hypopharyngeal MS, CS, posterior thyroid gland, and larynx may involve the RPS. Extracapsular spread of internal jugular and spinal accessory metastatic nodes, as well as recurrent visceral space neoplasms, occasionally may invade the RPS. One common pseudomass that indents into this space is a tortuous common or internal carotid artery, usually seen in the middle-aged and elderly populations.

Infrahyoid Prevertebral Space

The infrahyoid PVS continues superiorly into the suprahyoid PVS and inferiorly to the mediastinum. This space is susceptible to the same pathologic processes as the suprahyoid component, which include inflammatory and infectious processes (arthritis, discitis, osteomyelitis), as well as neoplasms arising in the spinal canal, brachial plexus, paraspinous musculature, or vertebral bodies (Fig. 11-43).

Anterior and Posterior Cervical (Lateral Cervical) Spaces

The posterior cervical (lateral cervical) space corresponds to the posterior triangle and is a fibrofatty layer containing the internal jugular, spinal accessory, and transverse cervical lymph node chains, as well as the spinal accessory and phrenic nerves. The posterior cervical space is limited by the sternocleidomastoid muscle and investing layer of deep cervical fascia anterolaterally, the carotid sheath anteriorly, and the prevertebral fascia posteromedially. It extends superiorly from the mastoid process and skull base down to the first rib and clavicles inferiorly.[34] Thus a small portion of the posterior cervical space extends into the suprahyoid neck, with the majority occupying the infrahyoid neck.

A trans-spatial lesion (lymphangioma, plexiform neurofibroma, lipoma, hemangioma) may invade two or more anatomic compartments, without respect for fascial boundaries.[30] Congenital lesions of the posterior cervical space include a second branchial cleft cyst, which tends to lie along the anterior margin of the sternocleidomastoid muscle, and a lymphangioma or cystic hygroma (Fig. 11-44). Both lesions are CSF density on CT, low intensity on T1WI, high intensity on T2WI, and may ring-enhance if secondarily infected. Inflammation may enter this space from cutaneous lesions or from abscessed lymph nodes. Benign neoplasms include neurogenic tumors (plexiform neurofibroma, schwannoma), a lipoma, or a hemangioma. Malignant neoplasms in the posterior cervical space are most commonly metastatic to the spinal accessory or internal jugular lymph nodes, with SCC representing the largest group of both primary and secondary tumors involving this space. Less commonly, sarcomas such as liposarcoma, leiomyosarcoma, or malignant fibrous histiocytoma arise here. Normal structures such as the scalene muscles, poorly opacified vessels on CT, and high-signal, flow-related enhancement in vessels on MRI may be misinterpreted as a pseudomass. Denervation atrophy of the sternocleidomastoid muscle or other neck muscles may occasionally cause an incorrect interpretation of the contralateral (normal-sized) muscles as representing masses.

Hypopharyngeal Mucosal Space

The hypopharyngeal mucosal space forms the walls of the hypopharynx and includes the continuation of the pharyngeal mucosal space below the hyoid bone posteriorly, the piriform sinuses laterally, the aryepiglottic folds and epiglottis anteriorly, and the cricopharyngeus muscle inferiorly. The hypopharyngeal mucosal space, piriform sinuses, and aryepiglottic folds are frequently challenging to evaluate on CECT and MRI because they are relatively thin membranous spaces that are normally collapsed together when the pharynx is relaxed. A modified Valsalva maneuver is usually required to distend the hypopharynx enough to obtain adequate imaging (see Fig. 11-2).

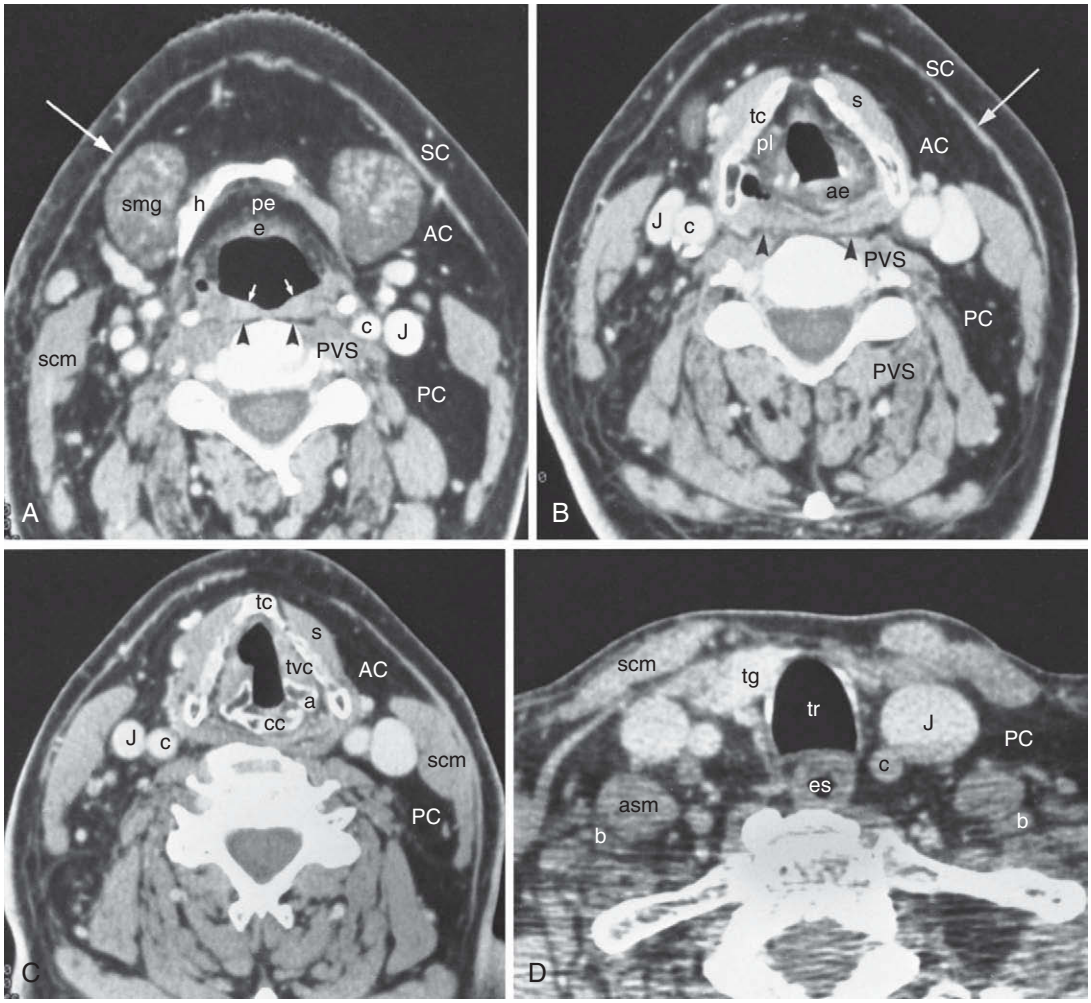

Figure 11-38. Normal axial contrast-enhanced computed tomography (CECT) anatomy of infrahyoid neck. CECT obtained at hyoid bone **(A),** false vocal cord **(B),** true vocal cord **(C),** and thyroid gland levels **(D).** (Streaky densities in the superficial fat of the right neck area in **A** and **B** are from earlier radiation of the right parotid mass.) Note the following structures: arytenoid cartilage (a), anterior cervical space (AC), aryepiglottic fold (ae), anterior scalene muscle (asm), brachial plexus (b), carotid artery (c), cricoid cartilage (cc), epiglottis (e), esophagus (es), hyoid bone (h), jugular vein (J), posterior cervical space (PC), preepiglottic fat (pe), paralaryngeal fat (pl), prevertebral space (PVS), pharyngeal mucosal space *(small arrows),* platysma muscle *(large arrow),* retropharyngeal space *(arrowheads),* strap muscle (s), superficial cervical space (SC), sternocleidomastoid muscle (scm), submandibular gland (smg), thyroid cartilage (tc), thyroid gland (tg), trachea (tr), and true vocal cord (tvc).

As with the suprahyoid pharyngeal mucosal space, caution must be exercised in assigning abnormality to this space, since redundancy of the mucosa and incomplete distention may mimic a tumor. Foreign bodies, inflammation, and SCC are the most common lesions in this space. Inflammation may cause ulceration or swelling of the mucosa, with gas or a ring-enhancing fluid collection suggesting the diagnosis. Reactive lymph nodes are common. The best indicator of hypopharyngeal malignancy is a bulky mass with invasion and destruction of submucosal and deep structures including the retropharyngeal space, aryepiglottic folds, cricoid cartilage and larynx, as well as associated necrotic lymph nodes (Fig. 11-45).

Visceral Space and Larynx

The visceral space, corresponding to the muscular triangle, is confined by the middle layer of deep cervical fascia with the anterior fascial layer splitting around the thyroid gland. The visceral space contains the larynx, trachea, hypopharynx, esophagus, parathyroid glands, thyroid gland, recurrent laryngeal nerve, and tracheoesophageal lymph nodes.[31] The superior margin is the hyoid bone, and the inferior border is the mediastinum. The skeleton of the larynx includes the thyroid, cricoid, arytenoid, cuneiform, and corniculate cartilages. These cartilages may reveal a variable degree of calcification or ossification. These findings progress with the patient's age. Ligaments from the styloglossus and stylohyoid muscles frequently calcify. Knowledge of the normal patterns of calcification is helpful for distinguishing opaque foreign bodies, such as chicken bones, from normal structures on plain films or CT.

Larynx

The hyoid bone supports the laryngeal skeleton and is occasionally fractured in blunt trauma or destroyed by neoplasms. Fractures of the laryngeal skeleton appear on CT as linear lucencies, often with displacement or distortion of the cartilage. A fracture is best appreciated (on bone windows) in well-ossified cartilage, but its identification is more challenging in noncalcified cartilage requiring the use of a narrower window width and careful scrutiny of cartilage configuration. Laryngeal trauma may result in hematomas of the aryepiglottic folds, false cords, true cords, or subglottis, and may potentially compromise the airway (Fig. 11-46). Adjacent subcutaneous emphysema may result from trauma to the laryngopharyngeal mucosa, from a penetrating injury to the neck, or from upward dissection from the chest wall or mediastinum.

Laryngoceles are formed by increased intraglottic pressure (e.g., in horn players and glass blowers) or from obstruction of the laryngeal ventricle and its distal appendix by inflammatory or neoplastic lesions

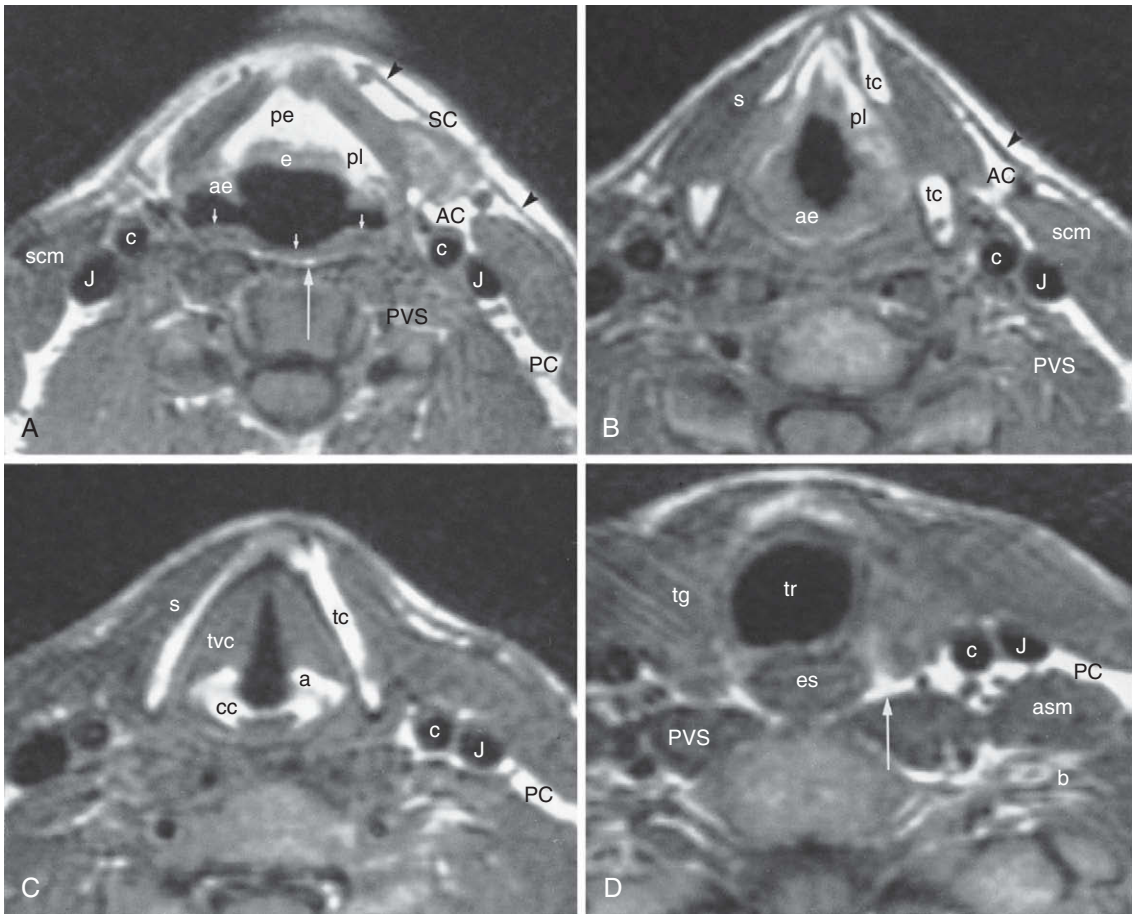

Figure 11-39. Normal axial magnetic resonance anatomy of infrahyoid neck. Noncontrast T1-weighted images obtained at hyoid bone **(A),** false vocal cord **(B),** true vocal cord **(C),** and thyroid gland levels **(D).** The following structures are labeled: arytenoid cartilage (a), anterior cervical space (AC), aryepiglottic fold (ae), anterior scalene muscle (asm), branchial plexus (b), carotid artery (c), cricoid cartilage (cc), epiglottis (e), esophagus (es), jugular vein (J), posterior cervical space (PC), preepiglottic fat (pe), paralaryngeal fat (pl), prevertebral space (PVS), pharyngeal mucosal space *(small arrows),* platysma muscle *(arrowheads)*, retropharyngeal space *(large arrow),* strap muscle (s), superficial cervical space (SC), sternocleidomastoid muscle (scm), thyroid cartilage (tc), thyroid gland (tg), trachea (tr), and true vocal cord (tvc).

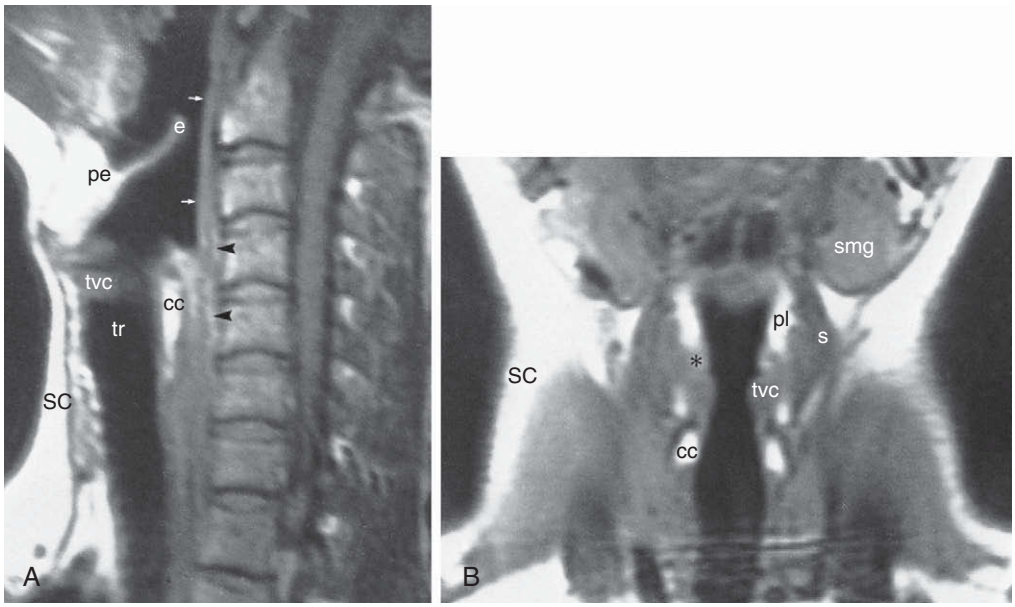

Figure 11-40. Normal sagittal and coronal magnetic resonance of infrahyoid neck. **A,** Sagittal T1-weighted image (T1WI) and, **B,** coronal T1WI obtained through the larynx. Note the following structures: cricoid cartilage (cc), epiglottis (e), false vocal cord *(asterisk)*, pharyngeal mucosal space (*small arrows*), preepiglottic fat (pe), paralaryngeal fat (pl), retropharyngeal space *(arrowheads)*, strap muscle (s), superficial cervical space (SC), submandibular gland (smg), trachea (tr), and true vocal cord (tvc).

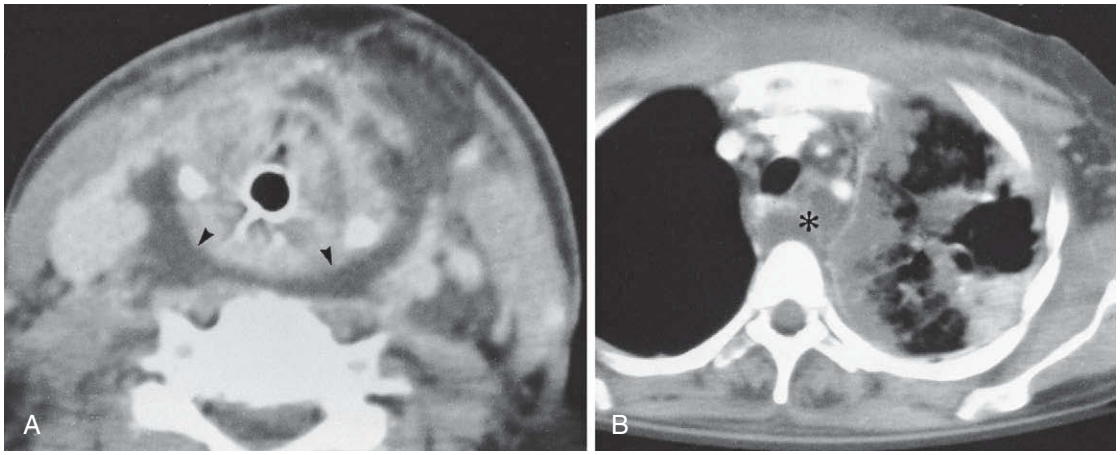

Figure 11-41. Infrahyoid retropharyngeal space and visceral space abscess. **A,** Axial contrast-enhanced computed tomography at the level of the false vocal cords demonstrates a low-density abscess in the retropharyngeal space *(arrowheads)* creating a "bow-tie" configuration. The abscess extends laterally to the left posterior cervical space and anteriorly into the visceral and anterior cervical spaces. **B,** Communication between the retropharyngeal space and mediastinum is well demonstrated by cephalad extension of this mediastinal abscess *(asterisk)* posterior to the trachea.

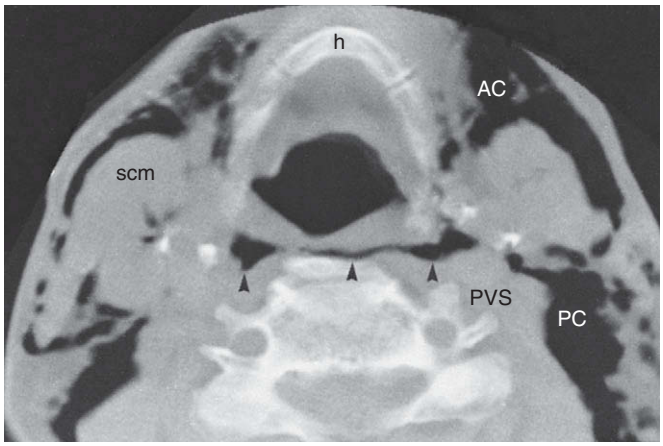

Figure 11-42. Axial non-contrast computed tomography of subcutaneous emphysema highlighting cervical spaces. Gas from a pneumomediastinum has dissected into the anterior cervical space (AC), posterior cervical space (PC), and retropharyngeal space *(arrowheads)*. Note the "bow-tie" pattern of the retropharyngeal space. Other labeled structures include the hyoid bone (h), sternocleidomastoid muscle (scm), and prevertebral space (PVS).

(Fig. 11-47). An internal laryngocele tracks superiorly within the paralaryngeal (paraglottic) fat, is air- or fluid-filled (obstructed laryngocele), and causes variable compromise of the supraglottic larynx. A mixed (external) laryngocele extends further superolaterally, piercing the thyrohyoid membrane, and may present as a neck mass. A mucocele (mucous retention cyst) of the supraglottic laryngeal mucosa may be indistinguishable from an obstructed internal laryngocele. Inflammation of the supraglottic larynx may lead to epiglottitis, thickening the epiglottis and aryepiglottic folds, and compromising the airway (Fig. 11-48).

Apart from routine evaluation of adenopathy from suprahyoid neck and sinus tumors, laryngeal and hypopharyngeal SCC is the most common indication for imaging the infrahyoid neck. Because both CECT and MRI are relatively insensitive to superficial mucosal based lesions, knowledge of the physical examination findings and specific locations of concern is mandatory to facilitate lesion localization and characterization. Findings that help identify SCC of the superficial mucosa of the larynx or pharynx are a mass, mucosal irregularity or asymmetry, and ulceration. Fat planes in the laryngopharynx are critical for determining the extent of deep invasion or inflammation. The fat in the preepiglottic space, epiglottis, and aryepiglottic folds and paralaryngeal fat of the supraglottic larynx are major landmarks that are easily identified on axial CT and MRI. Coronal T1WIs are particularly useful for evaluating the configuration of the airway and for determining the craniocaudal margins of a supraglottic, glottic, infraglottic, or transglottic lesion because the vertically oriented paralaryngeal fat plane terminates inferiorly at the true vocal cords (thyroarytenoid muscle). A lesion becomes transglottic when the fat interface between the thyroarytenoid muscle (true vocal cord) and the paralaryngeal fat (false vocal cord) is eliminated, indicating the tumor has crossed the laryngeal ventricle (Fig. 11-49A). The anterior commissure should be less than 1-mm thick. Greater thickness in this area represents tumor spread from the anterior margin of one cord to another. A diagnosis of vocal cord fixation may be made when the involved cord remains paramedian during quiet breathing or with a modified Valsalva maneuver (see Fig. 11-49B).

Cartilage invasion or destruction by aggressive infections or tumors is an important part of staging, and is often difficult to predict on CECT or MRI when the cartilage is incompletely calcified. If the cartilage has ossified, CECT and MRI are relatively sensitive for detecting cartilage erosion. MRI, using a combination of T1WI, T2WI, and postgadolinium fat saturation T1WI, may be more sensitive than CECT to invasion of the central layer of the thyroid cartilage, especially if the cartilage has ossified and the central fatty marrow has been locally replaced by an invading tumor. The best indicator of cartilage invasion is the presence of a tumor on the external margin of the cartilage in the strap muscles (Fig. 11-50).

Thyroid Gland

The thyroid gland lies within the anterior leaves of the middle layer of deep cervical fascia (within the visceral space), anterior and lateral to the thyroid, cricoid, and upper tracheal cartilages. It consists of the lateral thyroid lobes, isthmus, and pyramidal lobe. Normal iodine content of the thyroid gland makes it higher density than muscle on NCCT. The gland is normally homogeneous with enhancement on both CECT and MRI, but internal inhomogeneity from calcification, goiter, colloid cyst, or a solid mass is occasionally encountered on routine neck imaging. When physical examination, ultrasound, or thyroid scintigraphy raises the suspicion of a thyroid carcinoma or thyroid lymphoma, CECT or MRI may be used for further characterization, especially if it is a low thoracic inlet thyroid or parathyroid mass.

Absence of the thyroid gland at the level of the thyroid cartilage should redirect attention to the tongue for an ectopic lingual thyroid gland (Fig. 11-51). A thyroglossal duct cyst is a remnant of the

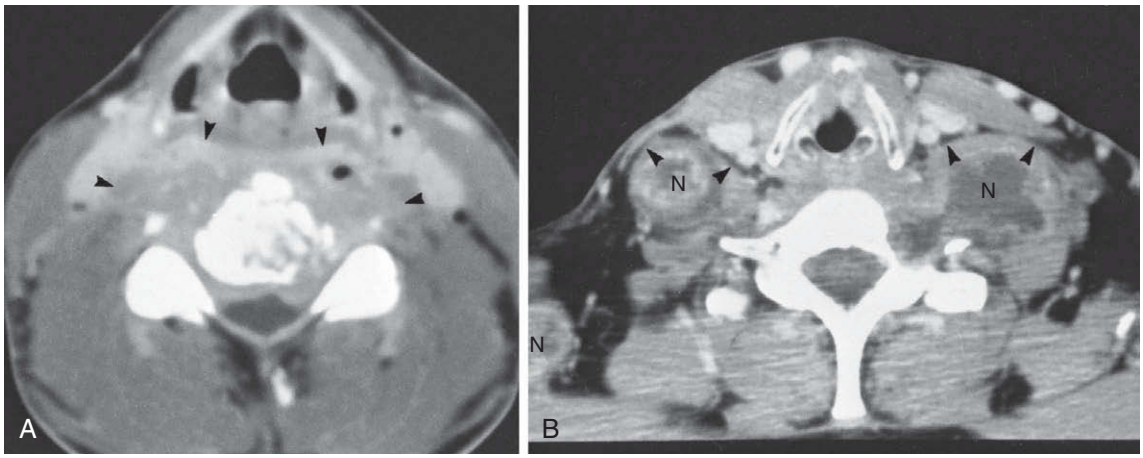

Figure 11-43. Prevertebral space (PVS) lesions. **A,** Axial contrast-enhanced computed tomography (CECT) of the prevertebral abscess extends anteriorly from C5-6 discitis. Anterolateral margins of the abscess *(arrowheads)* displace pharyngeal mucosa and posterior cervical spaces anteriorly. A small amount of gas is present in the abscess on the left. **B,** Axial CECT of bilateral plexiform neurofibromas (N) arising from the brachial plexus in the PVS shows anterior displacement of fat in the posterior cervical spaces *(arrowheads)*.

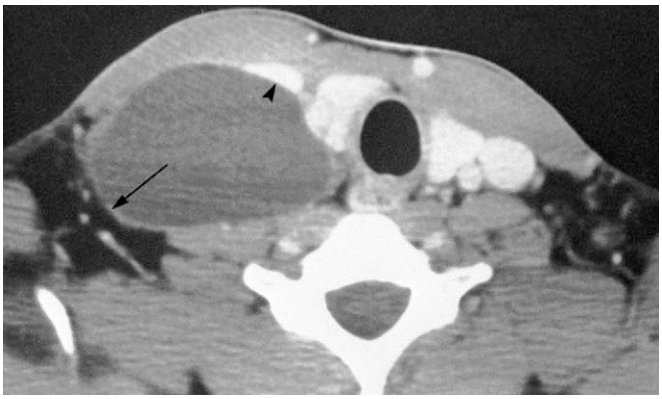

Figure 11-44. Posterior cervical space lymphangioma. Contrast-enhanced computed tomography reveals a homogeneous, bright, low-density mass with sharp margins displacing the posterior cervical space fat *(arrow)* posterolaterally and internal jugular vein *(arrowhead)* anteriorly.

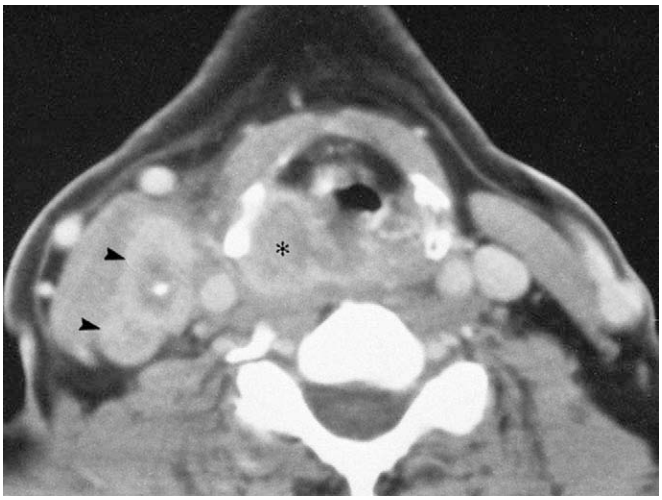

Figure 11-45. Piriform sinus squamous cell carcinomas. Axial contrast-enhanced computed tomography shows a mildly enhancing mass in the right piriform sinus *(asterisk)* displacing the aryepiglottic fold anteromedially. Focal defects in the internal jugular and spinal accessory nodes *(arrowheads)* indicate metastatic tumor spread. Calcification is noted in the internal jugular node.

embryonic thyroglossal duct and may occur anywhere along its migratory path from the foramen cecum in the tongue to the pyramidal lobe, although most occur just inferior to the hyoid bone (Fig. 11-52). Inflammatory thyroiditis may enlarge the thyroid gland. Benign enlargement may also result from colloid cysts and goiters. Thyroid calcification is nonspecific and occurs in goiters, as well as in benign thyroid adenomas. Primary malignancies of the thyroid include papillary, follicular, mixed, and anaplastic carcinomas, as well as non-Hodgkin's lymphoma, all of which may have a similar imaging appearance (Fig. 11-53). Indistinct margins of a thyroid mass, infiltration of adjacent tissues, and necrotic lymph nodes are all indications of thyroid malignancy. Metastasis to the thyroid gland more commonly arises from extracapsular spread of SCC in adjacent nodes than from hematogenous deposits.

Parathyroid Glands

The parathyroid glands are usually four to six in number and underlie the posterior surface of the thyroid gland. Because they are quite small, normal parathyroid glands are frequently not visualized on routine neck imaging. An ectopic parathyroid gland may occur in the mediastinum (Fig. 11-54). A parathyroid adenoma is usually a discrete mass lying deep to the thyroid lobes. Occasionally, an adenoma may be detected on routine CT or MRI as a nodular, enhancing mass that may be dif-

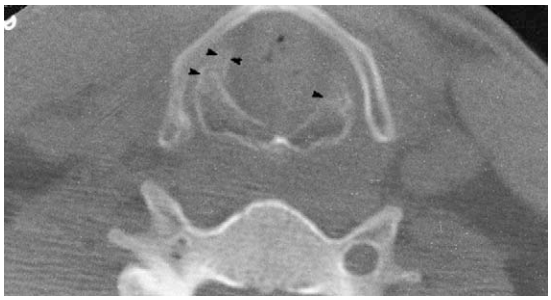

Figure 11-46. Laryngeal trauma. Axial noncontrast computed tomography at the level of cricothyroid articulation shows a laterally displaced cricoid ring *(arrowheads)* fracture and subglottic hematoma obstructing the airway.

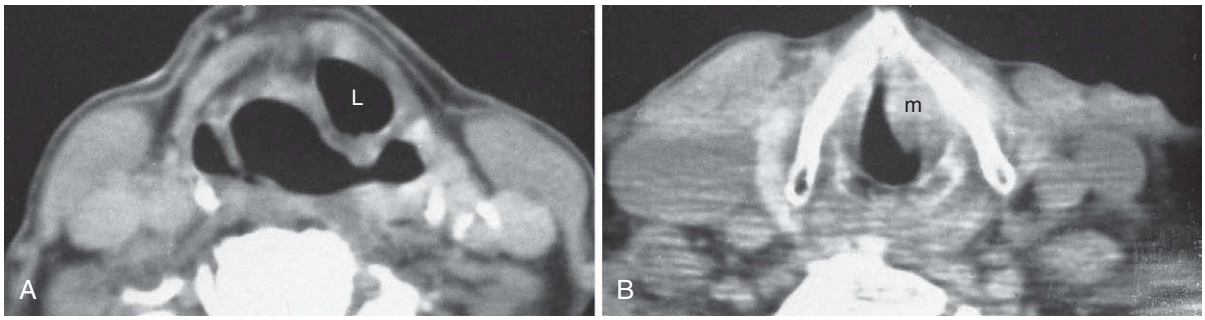

Figure 11-47. Laryngocele. **A,** Axial contrast-enhanced computed tomography (CECT) at the level of the thyrohyoid membrane demonstrates an air-filled internal laryngocele (L) displacing the preepiglottic fat and aryepiglottic fold. Note that the thyrohyoid membrane is separated from the piriform sinus by the aryepiglottic fold. **B,** Axial CECT at the true cord level reveals the cause of the laryngocele—an obstructing transglottic carcinoma (m).

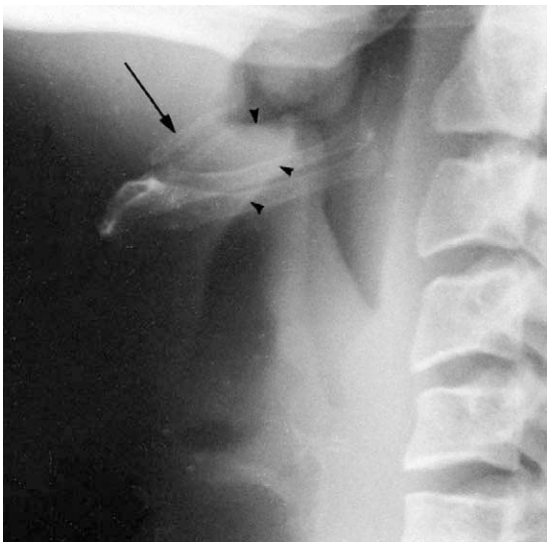

Figure 11-48. Epiglottitis. Lateral plain film of the neck demonstrates the swollen epiglottis *(arrowheads)* and aryepiglottic folds. The lower portion of the stylohyoid ligament *(arrow)* has ossified bilaterally.

ferentiated from lymph nodes by its location posterior to the thyroid gland.

Lymphadenopathy

Lymph Node Anatomy and Classification

The nodes of the superficial triangles of the neck are organized by major lymphatic chains. The traditional classification of lymph nodes of the head and neck includes 10 groups: lateral cervical, anterior cervical, submandibular, submental, sublingual, parotid, facial, mastoid, occipital, and retropharyngeal. The lateral cervical chains are further subdivided into the deep and superficial chains. The deep lateral cervical chain includes the internal jugular, spinal accessory, and transverse cervical (supraclavicular) nodes. The superficial lateral cervical chain consists of the external jugular nodes. The anterior cervical (juxtavisceral) group contains the prelaryngeal (Delphian), pretracheal, prethyroid, and lateral tracheal (tracheoesophageal or paratracheal) nodes.[32] The cervical lymph node chains are found throughout several of the spaces of the neck:

1. Posterior cervical space: spinal accessory, transverse cervical, and internal jugular (posterior to the internal jugular vein) nodes

2. Carotid space: internal jugular nodes (anterior to the internal jugular vein posterior margin)

3. Submandibular space: submandibular and submental nodes

4. Parotid space: parotid nodes

5. Suprahyoid retropharyngeal space: medial and lateral retropharyngeal nodes

6. Visceral space: prelaryngeal, prethyroid, pretracheal, and tracheoesophageal nodes

7. Subcutaneous tissues of the scalp and face: occipital, mastoid, and facial nodes

A condensation of this nomenclature into seven groups with Roman numerals (levels I to VII) has been proposed and is a useful shorthand for node documentation and statistical analysis. Som and others[20] have proposed an imaging-based nodal classification to find a common ground between anatomic imaging criteria and the two most commonly used clinical nodal classifications: the American Joint Committee on Cancer and the American Academy of Otolaryngology-Head and Neck Surgery.

In this classification, level I combines the submandibular and submental lymph nodes. Levels II to IV divide the internal jugular chain roughly into thirds, using landmarks that are easily recognizable on cross-sectional imaging. Level II is the jugulodigastric nodes (upper internal jugular), including the nodes from the skull base down to the bottom of the body of the hyoid bone. Level III is the supraomohyoid internal jugular chain (middle internal jugular), from the bottom of the body of the hyoid bone to the level of the bottom of the cricoid cartilage. Level IV includes the infraomohyoid (low internal jugular), nodes from the level of the bottom of the cricoid to the level of the clavicles. Level V includes the spinal accessory and transverse cervical nodes from the skull base to the clavicles, which lie posterior to the sternocleidomastoid muscle. Level VI includes the upper visceral nodes, which lie between the carotid arteries from the level of the bottom of the hyoid bone to the level of the top of the manubrium. Level VII nodes are located in the superior mediastinum between the carotid arteries, below the level of the manubrium and above the level of the innominate vein.

Subdivisions of the levels I, II, and V are also defined. Level Ia nodes are the submental nodes; they lie medial to the lateral margin of the anterior belly of the digastric muscle. Level Ib nodes lie lateral to the digastric muscle about the submandibular gland. Level IIa nodes are located at the level of, or anterior to, the internal jugular vein. Level II nodes that are posterior to and separate from the internal jugular vein are in Level IIb. Level Va nodes lie above the level of the bottom of the cricoid arch. Level Vb nodes are below the level of the cricoid and above the level of the clavicle. The levels Ib and IIa are divided by an arbitrarily selected imaginary coronal plane that follows the posterior border of the submandibular gland. The posterior margin of the sternocleidomastoid muscle separates the levels II, III, and IV from the level V.

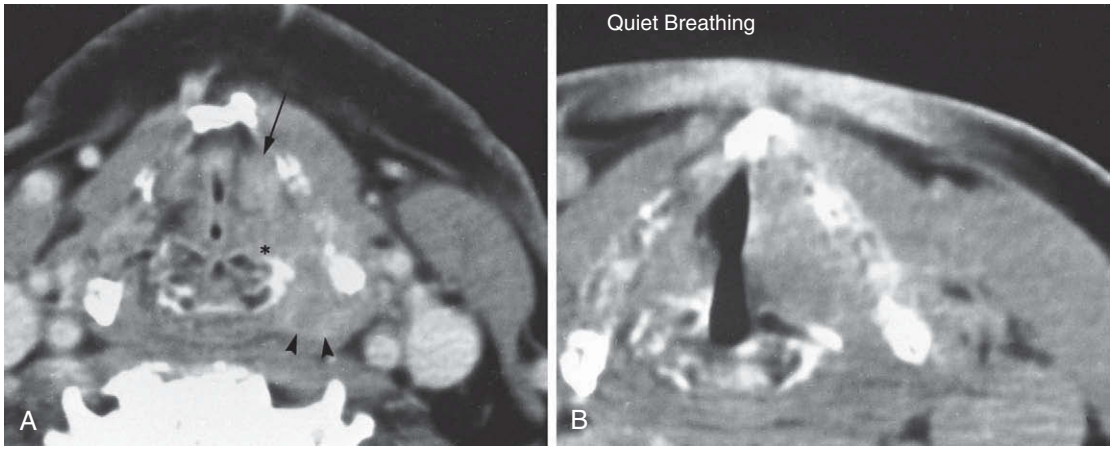

Figure 11-49. Transglottic laryngeal squamous cell carcinoma with vocal cord fixation. **A,** True vocal cords are adducted on an axial contrast-enhanced computed tomography (CECT) obtained during breath holding, with the tumor extending anteriorly and superiorly from the left true cord into adjacent paralaryngeal fat *(arrow)* and posteriorly into the cricoarytenoid joint *(arrowheads)*. Anterior corner of the calcified left arytenoid cartilage *(asterisk)* has been eroded by the tumor. **B,** Repeat axial CECT performed during quiet breathing reveals fixation of the left true cord in midline. Right cord is partially abducted.

Figure 11-50. Transglottic squamous cell carcinoma with cartilage invasion. Axial CECT at the true vocal cord level shows an enhancing mass (m) originating in the left vocal cord, crossing the anterior commissure, and invading the anterior third of the right cord. The tumor has invaded through the anterior thyroid cartilage and displaces the thyroid strap muscles anteriorly *(arrowheads)*.

The retropharyngeal, supraclavicular, and parotid nodes are not included in the level classification. The retropharyngeal nodes lie medial to the internal carotid arteries within 2 cm from the skull base. Supraclavicular nodes lie at the level of, or caudal to, the clavicle and lateral to the carotid arteries. Separation of the supraclavicular nodes from low level IV and level V nodes may be difficult on the transverse images because of the oblique course of the clavicle.

Lymph Nodes: Normal and Pathologic

CECT remains the gold standard for detecting and classifying cervical lymphadenopathy as benign or malignant. The important considerations in radiographic lymph node detection and characterization are location, size, number, clustering, enhancement pattern, calcification, sharpness of margins, and invasion or displacement of adjacent structures. First, the nodes must be detected and localized to a specific nodal chain or level using one of the conventions for labeling node regions discussed previously. Node involvement is described as unilateral or bilateral and in terms of the specific level or chain affected.

Inflammatory (reactive) lymph nodes on CECT tend to be less than 10 mm (rarely larger than 20 mm), have central hilar or mild homogeneous enhancement, and have well-defined margins (Fig. 11-55). Node margins should remain sharp in reactive adenopathy, except in cases with large abscessed nodes that elicit an inflammatory reaction in the adjacent fat, obscuring the node margins (Fig. 11-56). Calcification is a common finding in previously infected or healed nodes and frequently occurs in tuberculosis or bacterial infections. Multiple nodes may be present, but they tend not to cluster. On MRI, these reactive nodes are enlarged and have well-defined margins on all sequences. They are of muscle intensity on T1WI, enhance moderately and homogeneously on postgadolinium fat-suppressed T1WI, and are bright on T2WI and STIR.

The correlation of lymph node size with sensitivity and specificity in predicting malignant metastasis has been performed for different neck regions in patients with head and neck carcinoma, allowing more appropriate size criteria for distinguishing normal from abnormal lymph nodes.[32] Although CT can readily detect lymph node enlargement, it has also proven capable of accurately diagnosing metastases in "normal size" nodes from head and neck primary SCC. The upper range of normal for cervical lymph node size is between 5 and 10 mm, with the jugular digastric node ranging up to 15 mm. The exceptions are the retropharyngeal nodes, which are considered pathologic when larger than 10 mm in children or larger than 5 mm in adults. Generally, cervical nodes larger than 10 to 15 mm are potentially malignant and nodes smaller than this are considered reactive or inflammatory. Nodes larger than 20 mm are frequently malignant. Clinically occult neck disease occurs in 15% to 40% of patients with head and neck SCC. Clinically occult nodes average 12 mm (Fig. 11-57). Studies comparing clinical and CT staging of nodal metastases have shown that physical examination of the neck has an accuracy of 70% to 82% compared with 87% to 93% for CT. In patients with no nodal disease on examination, CT is likely to upstage an N0 neck to N1 in 20% to 46% of cases and upstage clinical staging of the neck between 5% and 67% of cases overall. CT may downstage the clinical neck examination in 3% to 36% of cases.[33,34]

The enhancement pattern on CT is very helpful, but not infallible, in distinguishing inflammatory nodes from metastatic nodes. The presence of a focal defect (central low density) or peripheral enhancement is characteristic of malignancy even in normal-sized nodes. A focal defect in an enlarged node is a strong indication of a necrotic node metastasis, although tuberculosis or an abscessed node may mimic this appearance. Central dense or linear enhancement of the hilum of an enlarged node without ring enhancement is usually a distinguishing

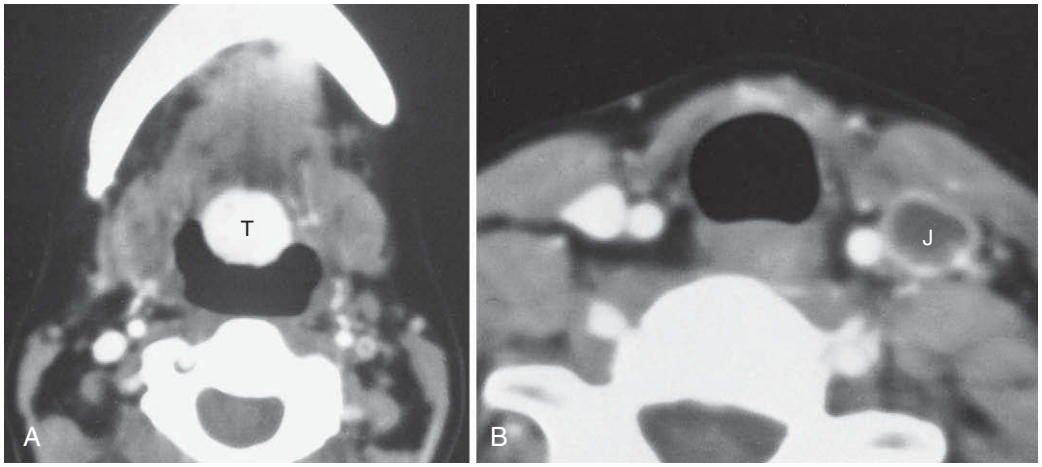

Figure 11-51. Lingual thyroid gland. **A,** Densely enhancing mass of ectopic thyroid tissue (T) bulges posteriorly from the tongue at the level of the foramen cecum on the axial contrast-enhanced computed tomography. **B,** CECT at the upper tracheal level reveals that the thyroid gland is absent from its normal location. Note the pseudotumor of the thrombosed internal jugular vein (J) mimicking ring-enhancing node metastasis.

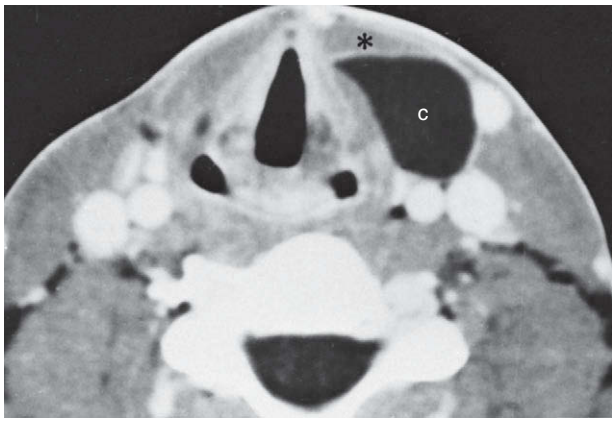

Figure 11-52. Thyroglossal duct cyst. Low-density thyroglossal duct cyst (c) elevates the thyroid strap muscles *(asterisk)* and laterally displaces the sternocleidomastoid muscle in this axial contrast-enhanced computed tomography.

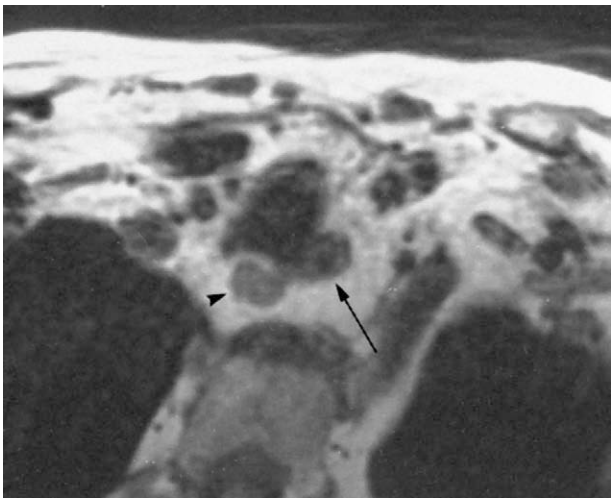

Figure 11-54. Parathyroid adenoma. Retrotracheal ectopic parathyroid adenoma *(arrowhead)* looks similar to the adjacent normal esophagus *(arrow)* on an axial T1-weighted image.

Figure 11-53. Thyroid follicular carcinoma. Axial contrast-enhanced computed tomography just below the cricoid shows a large mass with nodular calcification *(asterisk)* displacing the trachea to the right and distorting the airway. Posteriorly it has invaded the retropharyngeal space *(arrow)*.

sign of a reactive node. Nodes larger than 20 to 40 mm without central necrosis often indicate lymphoma or sarcoidosis (Fig. 11-58). Treated lymphomatous nodes may have dystrophic calcification and, rarely, calcium matrix-forming tumors (osteosarcoma, chondrosarcoma) may have radiodense metastases. When margins of an enlarged node with central necrosis are indistinct, extracapsular penetration of the tumor through the node capsule has likely occurred (Fig. 11-59). This sign may decrease the 5-year survival by 50%. The number of nodes involved is important. Multiple nodes suggest a more widespread inflammatory or neoplastic process. Clustering of multiple nodes—sometimes into a seemingly single, complex mass—suggests malignancy and may be palpable as a single large mass. Round, rather than bean-shaped nodes, clusters of nodes, and indistinct margins suggest malignancy but are less specific than having a size larger than 15 mm, ring enhancement, or focal defect.

MRI of malignant adenopathy has both advantages and limitations compared with CECT. Malignant nodes appear as muscle intensity on T1WI, may show ring enhancement on postgadolinium fat-suppressed T1WI, are very bright on STIR, and are usually bright on T2WI (although necrosis may give both a high and low signal on long TR sequences) (Fig. 11-60). Fat-suppressed long TR sequences

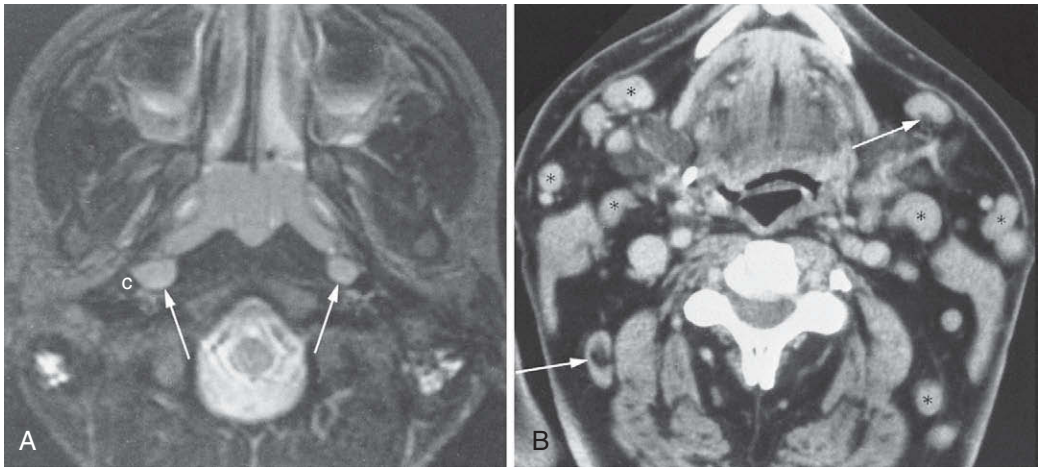

Figure 11-55. Normal lymph node anatomy. **A,** In this 8-year-old child, normal lateral retropharyngeal nodes *(arrows)* lie medial to the internal carotid arteries (c) and demonstrate a moderately high signal on the T2-weighted images. High-signal adenoidal tissue is commonly prominent at this age. **B,** Multiple mildly enlarged nodes *(asterisks)* are present in the submandibular, anterior jugular, internal jugular, and spinal accessory lymphatic chains on this contrast-enhanced computed tomography. Note the eccentric fatty hilum *(arrows)* in two nodes, a potential pitfall in the diagnosis of focal defect in the metastatic node.

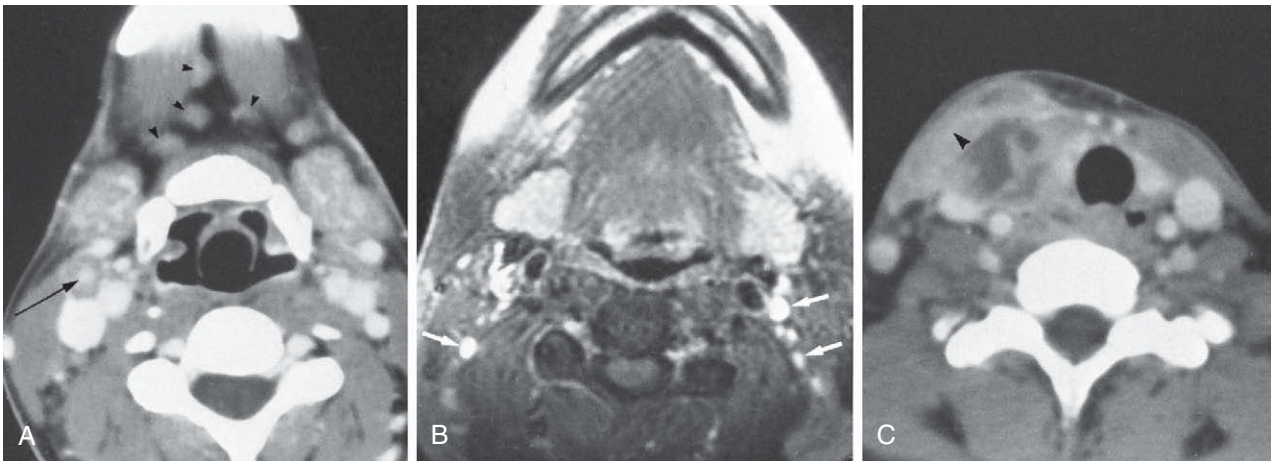

Figure 11-56. Reactive and inflammatory lymph nodes on contrast-enhanced computed tomography (CECT) and magnetic resonance imaging. **A,** Axial CECT of the hyperplastic nodes in a patient with acquired immunodeficiency syndrome-related complex displays multiple submental nodes *(arrowheads)* and an enlarged internal jugular node with central hilar enhancement *(arrow)*. **B,** Small, normal, or reactive lymph nodes *(arrows)* enhance on this fat saturation postgadolinium T1-weighted image. **C,** Axial CECT of a tuberculous nodal mass (scrofula) with peripheral enhancement and invasion of the sternocleidomastoid muscle *(arrowhead)* is difficult to distinguish from the cluster of metastatic nodes.

will diminish background fat signal, further improving detection. The STIR image is superior to CECT in sensitivity for any enlarged lymph node, but is nonspecific for metastases. MRI and CECT rely on the same criteria of size, clustering, margin sharpness, and shape for characterization of abnormal nodes. The specificity of ring enhancement on CECT is the main advantage of CT for diagnosis of metastases. The same finding of ring enhancement on postgadolinium fat-suppressed T1WI likely represents a focal tumor or central necrosis as well. Otherwise, the other MRI sequences described are nonspecific. MRI may better demonstrate invasion of adjacent structures, especially muscles, than does CECT.

Adjacent fat, bone, cartilage, and muscle are commonly compressed or invaded with extracapsular spread. Secondary invasion of adjacent structures and anatomic spaces by aggressive lymph node lesions may develop in the carotid sheath structures, skull base, PVS and vertebrae, and mandible. The superficial nodes may invade adjacent muscle and skin. Internal jugular and spinal accessory nodes may invade the carotid, parapharyngeal fat, prevertebral, and infrahyoid visceral spaces. Parotid nodes may violate the surrounding parotid parenchyma, skin, masticator space, and parapharyngeal space. Suprahyoid retropharyngeal nodes may extend laterally into the CS, posteriorly into the PVS, anteriorly into the mucosal space, and superiorly into the skull base. The tracheoesophageal nodes may involve the common carotid artery and the internal jugular vein in the CS, the recurrent laryngeal nerve, the visceral space structures of the larynx and thyroid, and the mediastinum.

Invasion of the carotid artery carries a poor prognosis, with a local recurrence rate of 46% and a distant metastatic rate of 56% to 68%. For patients with a tumor involving the carotid artery, the 5-year survival rate decreases to 7%, and the mean survival decreases to less than 1 year. Prolonged survival is possible if the involved carotid artery is resected. The best imaging modality among CECT, MRI, or ultrasound for evaluating carotid fixation remains controversial.[35] Surprisingly, criteria for carotid invasion are not well established in the literature. A very high likelihood of carotid invasion exists if the tumor involves 75% or more of the circumference of the carotid whereas invasion is unlikely if the contact of the tumor to the carotid is less than 25% of the circumference of the carotid (see Fig. 3-59). Ultra-

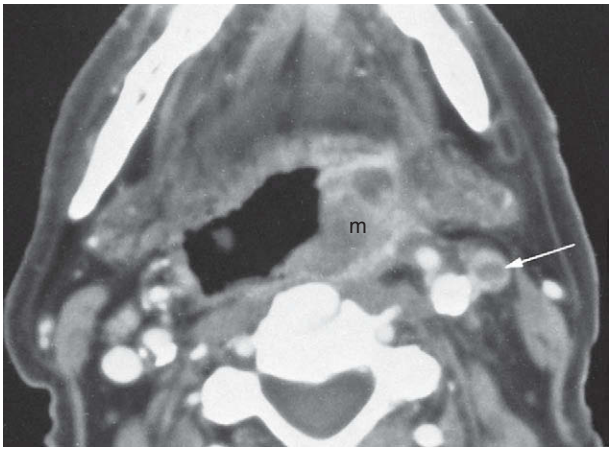

Figure 11-57. Metastatic node on contrast-enhanced computed tomography (CECT). Axial CECT in a patient with a left piriform sinus squamous cell carcinoma (m) and a "normal-sized" 9-mm node *(arrow)* with a focal defect (ring enhancement with "necrotic" center) is diagnostic of metastasis.

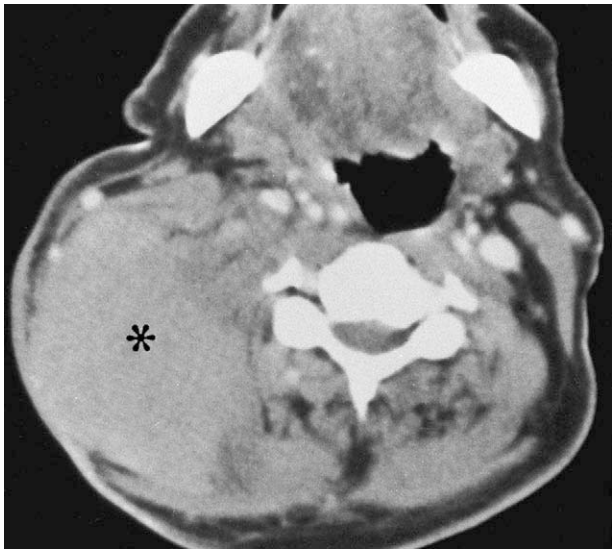

Figure 11-58. Node involvement by non-Hodgkin's lymphoma. Axial contrast-enhanced computed tomography shows a very large, homogeneous spinal accessory node *(asterisk)* invading both the skin and prevertebral space paraspinous musculature. The absence of central necrosis or focal defects in a mass this large is suggestive but not diagnostic of lymphoma.

sonography is a potentially valuable adjunctive technique capable of demonstrating invasion of the carotid artery.

Sinuses and Skull Base

Nose and Paranasal Sinuses

The sinonasal region can be divided into three major regions: the sinuses, the ostiomeatal complex, and the nasal cavity. The paranasal sinuses are mucosal-lined, air-filled cavities that are named after the bones of the face in which they develop. This mucosa is prone to both inflammatory and neoplastic disease. The frontal, maxillary, ethmoid, and sphenoid sinuses all drain through ostia into the nasal cavity. The frontal, maxillary, anterior ethmoid, and middle ethmoid sinuses drain into the semilunar hiatus under the middle turbinate. This area represents the ostiomeatal complex or unit. A small lesion here can cause

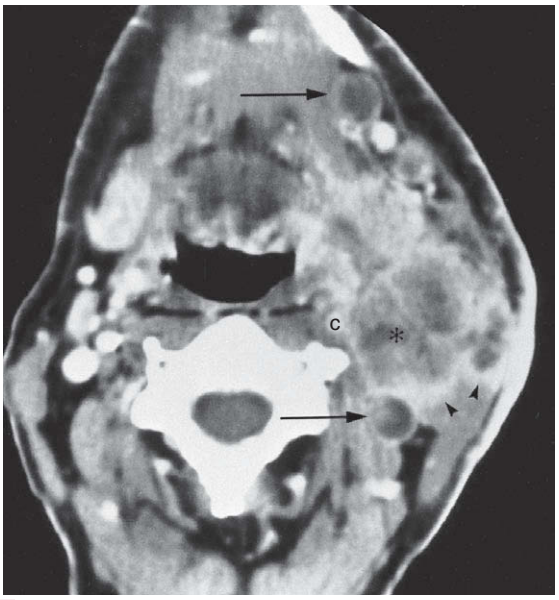

Figure 11-59. Extracapsular spread in multiple nodes in a patient with tonsillar squamous cell carcinoma. Left submandibular and spinal accessory node metastases *(arrows)* have typical ring enhancement and central low density on this axial contrast-enhanced computed tomography. The large cluster of metastatic nodes *(asterisk)* in the left internal jugular chain shows central low-density focal defects. Note the poorly defined infiltrative margins of this mass of nodes characteristic of extracapsular tumor spread. Tumor is invading the sternocleidomastoid muscle *(arrowheads)* posterolaterally and prevertebral space medially. About 40% of the left internal carotid artery (c) circumference is surrounded by tumor, which may still allow surgical preservation of the carotid artery.

obstruction to multiple sinus ostia. The posterior ethmoids and sphenoid sinus drain under the superior turbinate or sphenoethmoidal recess. The nasal cavity extends from the nares anteriorly to the choana posteriorly, and from the hard palate inferiorly to the cribriform plate superiorly. The midline nasal septum, lateral turbinates, and maxillary and ethmoid sinuses form the walls.

The compartments adjacent to the sinuses that are at risk for invasion by aggressive inflammatory or neoplastic processes include the anterior cranial fossa, orbits, cavernous sinus (from the sphenoid sinus), MS, pterygopalatine (pterygomaxillary) fossa, oral cavity, and anterior soft tissues of the face. These compartments are carefully viewed for dural or brain invasion, optic nerve and extraocular muscle compromise, perineural spread into the skull base, or direct extension into the deep compartments of the suprahyoid neck and oral structures. Involvement of any one of these secondary compartments can significantly alter treatment planning and surgical approach.

Paranasal Sinuses

Congenital and developmental anomalies of the sinonasal cavities are sought on all CT examinations. Common anatomic variants include pneumatization or paradoxic curvature of the turbinates, deviated septum, sinus hypoplasia, and Haller air cells (Fig. 11-61). Sinus underdevelopment may range from aplasia to hypoplasia. Pneumatization implies sinus development has occurred. Aeration indicates that the pneumatized portion of the sinus is air-filled. Mucosal thickening or opacification signifies the pneumatized section is filled with soft tissue inflammation or fluid. Either hypoplasia or the reactive new bone formation (chronic inflammation) may cause thickening and sclerosis of the sinus walls.

In general, evaluation of the paranasal sinuses involves assessment of two components: (1) the sinus contents (including the mucosa) and (2) the bony walls. Normal sinus mucosa is very thin and not seen on

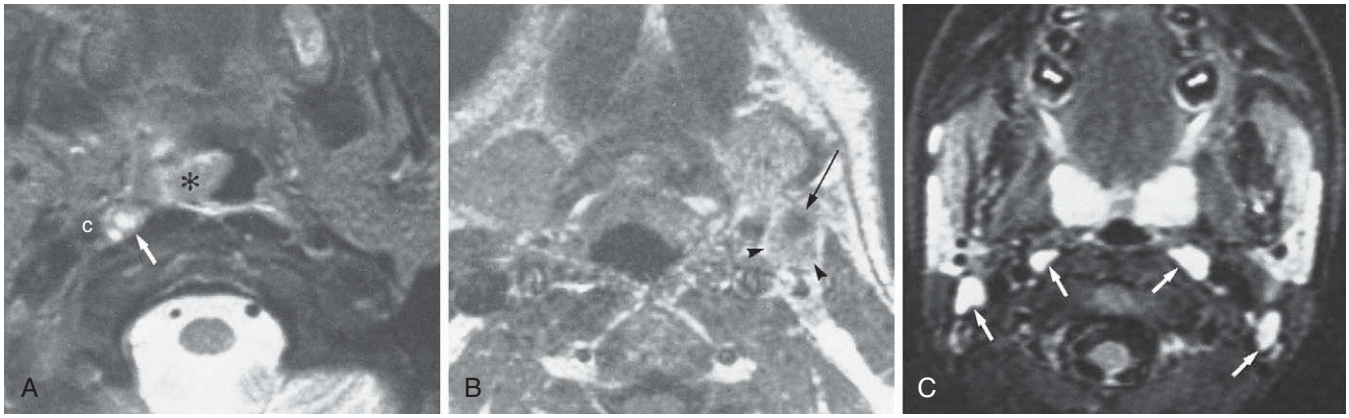

Figure 11-60. Metastatic nodes and focal defects on magnetic resonance imaging. **A,** Axial T2-weighted image at the soft-palate level depicts high-signal intensity at the right tonsillar squamous cell carcinoma *(asterisk)*. A 10-mm metastatic lateral retropharyngeal node of Rouvière with a high-signal intensity central defect *(arrow)* lies medial to the internal carotid artery (c). **B,** Left jugular digastric node *(arrowheads)* with low-signal intensity focal defect *(arrow)* on gadolinium-enhanced T1-weighted image is analogous to focal defect seen with metastases on a contrast-enhanced computed tomography. **C,** Axial short T1 inversion recovery (STIR) image achieves excellent fat suppression of subcutaneous fat. Metastatic neuroblastoma is demonstrated in the bright internal jugular and spinal accessory nodes *(arrows)*. Note the bright appearance of the normal tonsillar and parotid gland tissues on STIR.

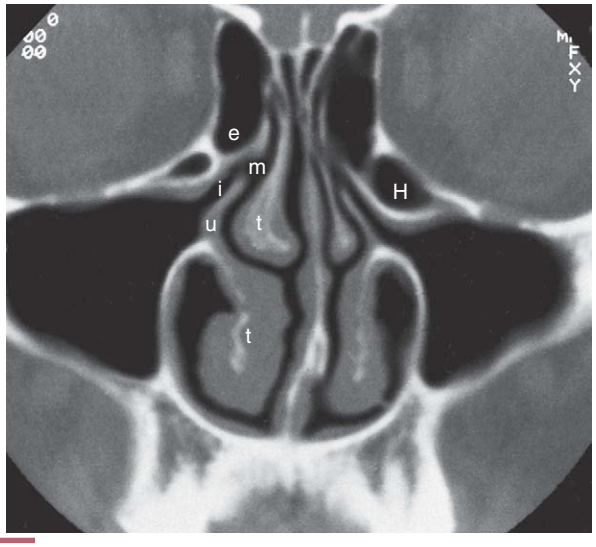

Figure 11-61. Normal ostiomeatal complex. Coronal noncontrast computed tomography demonstrates the ostiomeatal complex to the best advantage. Normal mucociliary drainage is from the maxillary sinus up through the infundibulum (i) and maxillary sinus ostium into the middle meatus (m). Ethmoid bulla (e) and uncinate process (u) form the lateral and medial walls of the infundibulum, respectively. Normal anatomic variant of a Haller air cell (H) underlying the orbit causes a mild narrowing of the left infundibulum. Smaller Haller cell is present on the right. Note the mildly asymmetric mucosa of the turbinates (t), which is part of the normal nasal cycle.

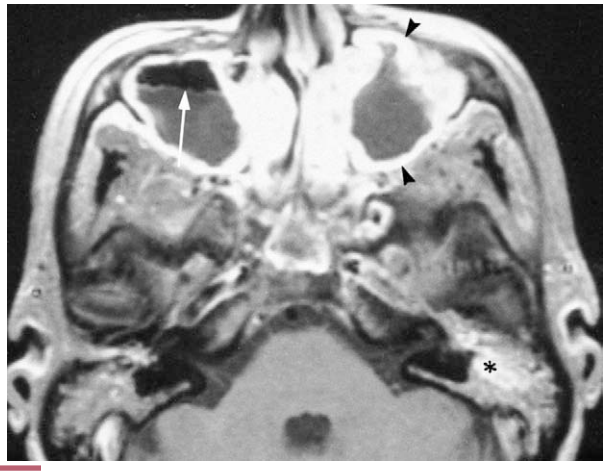

Figure 11-62. Acute and chronic sinusitis. Postgadolinium fat saturation T1-weighted image demonstrates an air-fluid level *(arrow)* in the right maxillary sinus and is diagnostic of acute sinusitis (superimposed on chronic sinusitis). Left maxillary sinus is filled with low-intensity secretions and has a peripheral ring of enhancing inflamed mucosa *(arrowheads)* typical of chronic sinusitis. Mastoid air cells and the left middle ear cavity *(asterisk)*, which normally appear black, are filled with enhancing inflammatory tissue.

CT or MRI, and the bone is normally thin and delicate in the posterior maxillary, ethmoid, and sphenoid sinuses. CT or MRI readily reveals the presence of a normally aerated sinus, mucosal thickening (chronic sinusitis, retention cysts, or polyps), an air-fluid level (acute sinusitis, intubation, and trauma), or complete opacification (mucocele, trauma, and acute or chronic sinusitis) (Fig. 11-62). The normally delicate posterolateral maxillary sinus wall is a much better indicator of bony sclerosis than the anterior wall. The normally thick anterior wall of the maxillary (and frontal) sinus may range from 1 to 3 mm (see Fig. 11-12A and C). Beginning observers frequently forget to assess the bone for important clues such as thickening and sclerosis (chronic sinusitis or hypoplasia), fractures, remodeling (slowly expanding mucocele or neoplasm), or destruction (malignancy or aggressive infection such as mucormycosis).

Deciding which portion of the opacified sinus, sinuses, or nasal cavity contains tumor and which contains obstructed mucous secretions is clinically important with a sinus or nasal tumor. The question is more problematic with NCCT or CECT because tumor and sinus secretions are frequently similar in density, and both the tumor and the mucosa may enhance; however, MRI is usually much more informative (Fig. 11-63). Evaluation of this problem requires a knowledge of signal intensity patterns of tumor versus mucus. Sinonasal tumors tend to be low-to-intermediate signal intensity on T1WI and intermediate signal intensity on T2WI, although minor salivary tumors and adenoid cystic carcinoma may be of high signal intensity.[36] The highly cellular aggres-

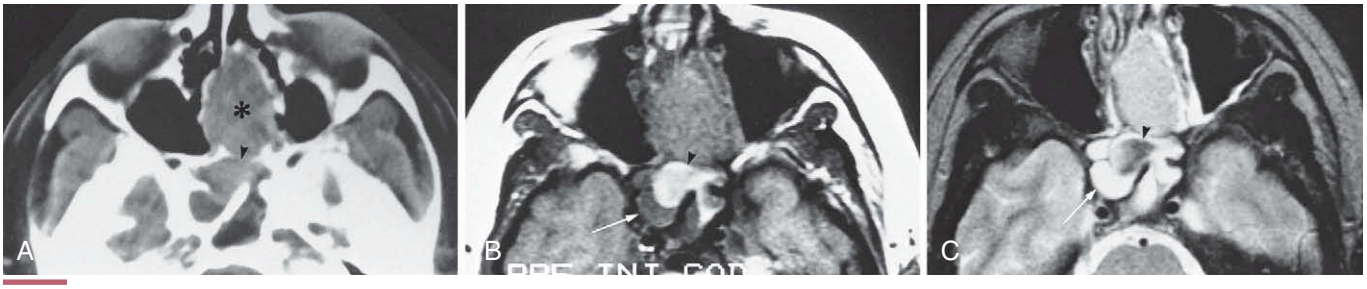

Figure 11-63. Comparison of computed tomography and magnetic resonance imaging for separating sinonasal small cell tumor from sphenoid pyomucocele. **A,** Axial contrast-enhanced computed tomography shows a mildly enhancing mass *(asterisk)* in the left posterior nasal cavity and ethmoids, which appears to extend into the sphenoid sinus. Sphenoid sinus contents actually represent two different viscosities of mucus, with higher density mucus anteriorly *(arrowhead)* correlating with most desiccated or viscous mucus. **B,** Axial noncontrast T1-weighted image demonstrates an intermediate-signal nasal tumor. Anterior, high-signal, viscous mucus *(arrowhead)* in the sphenoid sinus is clearly discriminated from the nasal tumor anteriorly and from the low-signal hydrated mucus *(arrow)* posteriorly. **C,** On axial noncontrast T2-weighted image, the nasal tumor signal is intermediate, similar to the brain. Anterior viscous mucus *(arrowhead)* in the sphenoid sinus has reversed signal to become low intensity, whereas hydrated mucus *(arrow)* posteriorly has now become very bright.

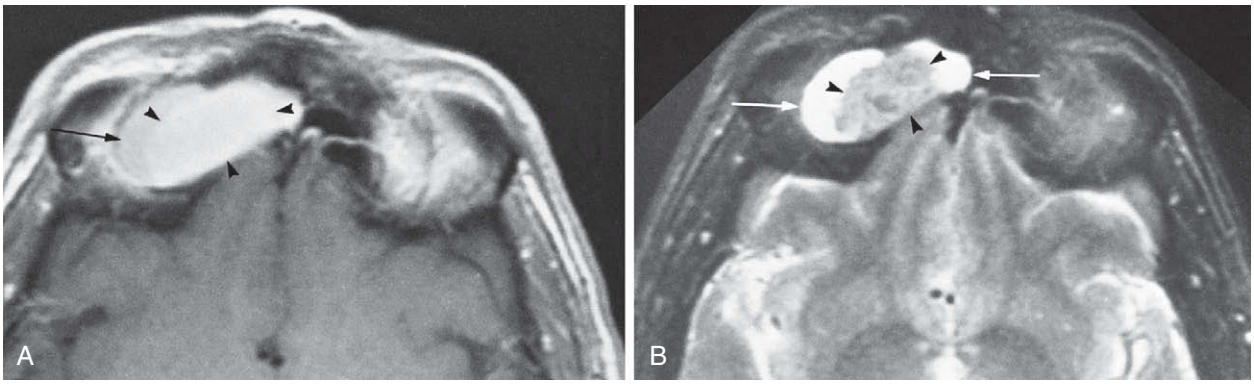

Figure 11-64. Simple mucocele on magnetic resonance imaging. **A,** Frontal mucocele on axial T1-weighted image expands the right frontal sinus and has a very high-signal central viscous or desiccated component *(arrowheads)* and a lower-intensity peripheral concentric ring of less viscous mucus *(arrow)*. **B,** Axial T2-weighted image reversal of signal intensities in concentric rings, with peripheral hydrated mucus *(arrow)* becomes bright and the central viscous mucus *(arrowheads)* loses signal.

sive neoplasms tend to have a lower water content and are less bright on T2WI. Tumors enhance moderately and, more or less, uniformly with gadolinium. Sinus secretions are complex in their patterns. Hydrated, nonviscous mucus is low intensity on T1WI and high intensity on T2WI. Desiccated, viscous mucus tends to be high intensity on T1WI and low-to-intermediate intensity on T2WI. Extremely desiccated mucus may lack signal intensity on T1WI or T2WI, simulating bone or air. Both an obstructed sinus and an expansile mucocele frequently have two or more layers of mucus in a concentric ring pattern with the most desiccated, viscous secretions located centrally. The peripheral mucosa of an obstructed sinus enhances in chronic sinusitis or with a pyomucocele, but does not enhance with a simple mucopyocele. The presence of tumor versus obstructed secretion is best solved by comparing the respective change in signal intensity of each component on the T1WI, T2WI, and post gadolinium T1WI, and is rarely answered by a single sequence. A minimum of a T1WI and a T2WI is required.

Ostiomeatal Complex

The ostiomeatal complex has become an area of active radiologic and pathophysiologic investigation with the development of endoscopic sinus surgery for inflammatory sinus disease. Coronal thin section NCCT is the best means of demonstrating the anatomy of this area (see Fig. 11-61). Pertinent observations include: (1) the individual's sinonasal anatomy and the presence of any anatomic variants (hypoplastic maxillary sinus, concha bullosa, agger nasi air cells, Haller air cells, deviated septum, deviated uncinate process, prominent ethmoid bulla, paradoxic curvature of the middle turbinate); (2) the location of obstructed air cells; (3) the extent of the chronic or acute sinus disease and whether this pattern is consistent with the obstruction of the ostiomeatal complex; and (4) the presence of any earlier surgical alterations (e.g., Caldwell-Luc, internal or external ethmoidectomy, uncinectomy). Ostiomeatal complex obstruction may result from anatomic compression, mucosal inflammation, polyps, benign neoplasms, and SCCA. Mucoceles, indicated by sinus expansion and low-density mucus on CECT, or by concentric rings of variably desiccated mucus in an expanded sinus on MRI, are a complication of chronic sinus obstruction (Fig. 11-64). A mucopyocele only shows peripheral enhancement when it is infected, and is then called a pyomucocele.

Nasal Cavity

The nasal cavity is occasionally the site of symptomatic disease. Anatomic variants include choanal atresia, concha bullosa, paradoxical curvature of the middle turbinate, wide nasal cavity from a hypoplastic maxillary sinus, and septal deviation. The nasal mucosa of the turbinates may be asymmetric in thickness because of the normal nasal cycle or the presence of polyps or inflammation. Obstruction of the ostiomeatal complex and other sinuses may occur with benign (antrochoanal polyp, neural tumors, inverting papilloma) or malignant (SCC, adenocarcinoma, adenoid cystic carcinoma) tumors (Fig. 11-65). If a nasal mass is present, the extent of the mass within the nasal cavity, adjacent sinuses, or orbits, or involvement of the cribriform plate, may be determined by coronal CECT or sagittal and coronal MRI because this may affect the surgical approach and postoperative therapy.

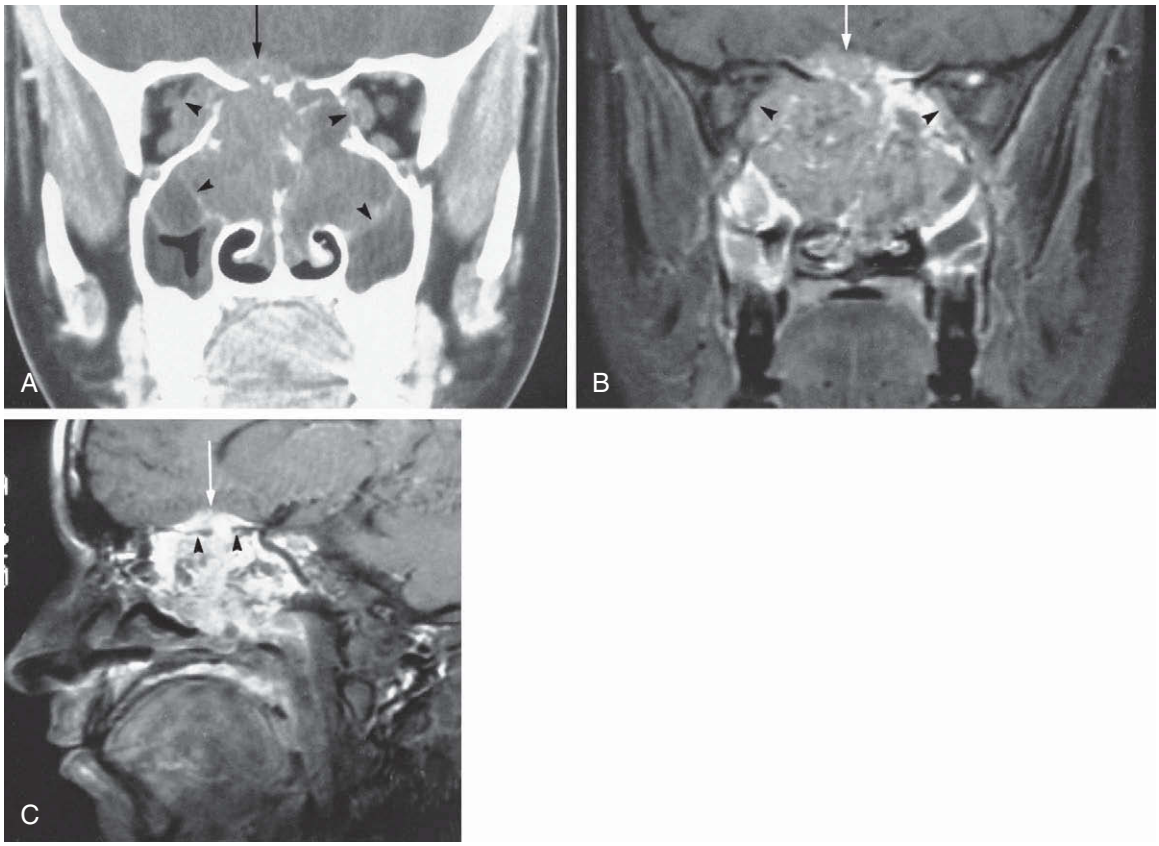

Figure 11-65. Invasive small cell carcinoma of cribriform plate and orbits. **A,** Coronal contrast-enhanced computed tomography shows (more clearly than magnetic resonance imaging) a mass centered in the posterior ethmoid sinuses with bone destruction of the cribriform plate *(arrow)* and medial orbits. The tumor has invaded both orbits and maxillary sinuses *(arrowheads)*. **B,** Anterior cranial fossa extension *(arrow)* through the cribriform plate and orbital invasion *(arrowheads)* are well seen on this coronal fat saturation postgadolinium T1-weighted image. **C,** Sagittal fat saturation postgadolinium T1WI depicts the anterior-posterior dimension of the tumor and extension of enhancing tumor *(arrow)* through the low-intensity cribriform plate and planum sphenoidale *(arrowheads)*.

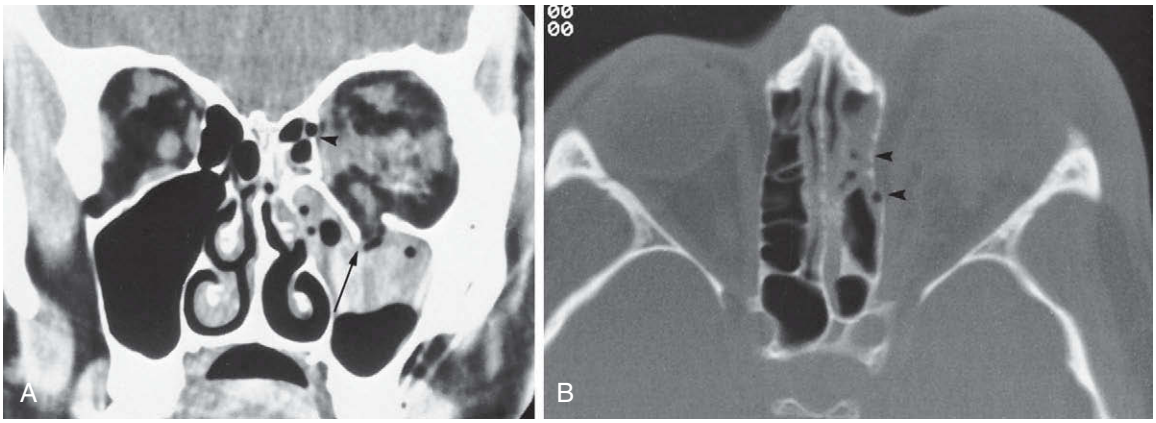

Figure 11-66. Medial and lateral orbital blowout fractures. **A,** Coronal noncontrast computed tomography (NCCT) with soft tissue windows shows an orbital blowout fracture with displacement of the floor *(arrow)*, distortion of the inferior rectus, and herniation of orbital fat through the orbital floor defect. Both intraconal hemorrhage and high-density maxillary sinus hemorrhagic air-fluid level are well demonstrated on these windows. Medial orbital blowout fracture *(arrowhead)* is suspected as well. **B,** Axial NCCT using bone windows shows opacified left anterior ethmoid air cells that help direct the observer to the displaced medial orbital fracture *(arrowheads)*.

Facial Trauma

Facial trauma is briefly included here because of the intimate relationship of the facial bones and sinuses. Thin-section axial and direct coronal NCCT is the ideal method for determining the full extent of facial trauma. One strategy for evaluating the extent of sinus trauma is to visually trace each bony outline on consecutive slices in both imaging planes, looking for fractures, normal fissures and canals, and displacements. However, the quickest way to locate sinus fractures is to search for indirect signs of fracture (Fig. 11-66): an air-fluid level, complete opacification of a sinus with blood, and the presence of gas outside the sinus (pneumocephalus, subcutaneous emphysema, infratemporal fossa, or orbital gas). Identification of the fractures allows determina-

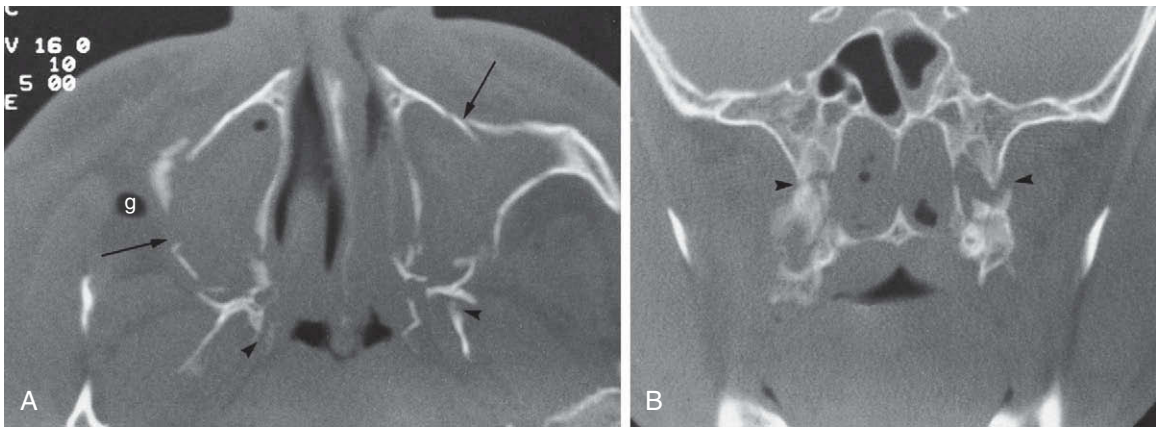

Figure 11-67. Facial fractures. **A,** Bilateral Le Fort type II fractures of the maxillary sinus anterior and posterior walls *(arrows)* and the pterygoid plates *(arrowheads)* appear as discontinuities or lucencies of the bone on this 3-mm axial noncontrast computed tomography (NCCT). Indirect signs of facial fracture are opacified maxillary sinuses, gas (g) in the right buccal fat pad, and premalar facial swelling. **B,** Coronal NCCT clearly demonstrates bilateral pterygoid plate fractures *(arrowheads)*.

tion of fracture classification: nasal, orbital blowout, trimalar or tripod, Le Fort (I, II, III, and complex), or nasoethmoidal complex fracture (Fig. 11-67). Assessment is made of the extent of soft tissue trauma, particularly the orbital soft tissues of the lens, globe, extraocular muscles, and optic nerve. Displaced orbital floor fractures may entrap fat or the extraocular muscles and result in enophthalmos or dysfunction of ocular motility.

Skull Base

Anatomically, the skull base can be divided into the anterior, middle, and posterior fossae. The lesser and greater wings of the sphenoid bone divide the anterior fossa from the middle fossa, while the petrous pyramid and mastoid portions of the temporal bone divide the middle and posterior fossae. The parietal and occipital lobes of the brain do not directly contact the skull base.

The skull base is formed from five bones: frontal, ethmoid, temporal, sphenoid, and occipital. The frontal and temporal bones are paired. Each of these bones can be subdivided into component bones. For example, the occipital bone has basioccipital, condylar, and squamosal portions. The skull base has its longest diameter in the AP plane, extending from the region of the crista galli to the posterior margin of the foramen magnum posteriorly. It is the thinnest in its superior-inferior direction, ranging between 3 and 5 mm in most areas, with the exception of the much thicker petrous temporal bone.

With CT, the skull base may be imaged using the axial or the coronal plane (only a modified coronal plane is possible because of limited gantry tilt). The coronal plane is excellent for delineating the superior inferior extent of a lesion. CT gives excellent visualization of bone detail, especially when bone algorithm techniques are used. In addition to the axial plane, MRI allows imaging both in a true coronal plane and in the sagittal plane, the latter especially useful for the study of midline lesions (e.g., chordoma). MRI also yields improved lesion contrast and conspicuity and more accurate delineation of lesion extent.

Using an anatomic approach, clinicians may classify skull base lesions as anterior, middle, or posterior fossa. They may then develop a unique differential for the medial and lateral portions of each fossa. Lesions may also be categorized as primary, those arising within the skull base itself, and secondary, those extending down from the cranial cavity above (endocranial lesions) or growing up from below (exocranial lesions). Endocranial masses are extracerebral and intracerebral lesions, whereas the exocranial lesions are secondary to extension superiorly from a disease process of the orbit, suprahyoid head and neck, cervical spine, and prevertebral muscles.

The skull base contains multiple foramina that allow the exit of cranial nerves and inflow and outflow of arteries and veins. These foramina also provide an access route for disease processes to spread from the cranial cavity to the infracalvarial structures and vice versa.[16] MRI performed after gadolinium infusion and with the use of fat suppression techniques allows sensitive detection of perineural spread, most readily seen with involvement of the fifth and seventh cranial nerves.[37]

Skull base fractures are readily detected with CT using thin slice sections and reformation techniques. Sinus air-fluid levels, sinus opacification, and clouding of the temporal bones may herald the presence of a fracture. Similarly, sinus opacification and fracture location may indicate the site of a CSF leak.

Inflammatory skull base lesions are now less common. Osteitis is seen as sclerosis of bone margins. Osteomyelitis usually involves all three skull tables and is characterized by irregular serpiginous lytic areas, occasionally with areas of bone sequestration present.

The osseous changes of neoplastic disease may be erosive, infiltrative, expansive, lytic, sclerotic, or of mixed density. Primary skull neoplastic lesions are uncommon. Benign conditions include osteoma, chondroma, giant cell tumor, cholesterol granuloma, and aneurysmal bone cyst (Fig. 11-68). Osteosarcoma, chondrosarcoma, fibrosarcoma, and rarely Ewing's sarcoma and lymphoma, are examples of malignant lesions. Metastatic lesions are more common than primary skull base lesions and frequently have an associated soft tissue component (Fig. 11-69). Osteoblastic metastases are most commonly caused by carcinoma of the prostate or breast; sclerotic changes may be seen occasionally in lymphoma (Fig. 11-70). Lytic lesions are more common than osteoblastic findings and are usually secondary to carcinoma of the lung, breast, kidney, or colon.

Intracerebral neoplastic processes may have associated osseous changes. Cerebral gliomas rarely cause local bone erosion or expansion; however, optic gliomas may cause expansion of the optic canal. Neuromas (nerve sheath tumors) may cause smooth expansion of skull base foramina: internal auditory canal (cranial nerve VIII), jugular foramen (cranial nerves IX, X, and XI), hypoglossal canal (cranial nerve XII), and lateral wall clivus and foramen rotundum (cranial nerve V). Paragangliomas cause irregular erosive changes in the skull base foramina (Fig. 11-71). A meningioma is often heralded by hyperostosis (bone sclerosis), especially common with a lesion of the middle fossa involving either the greater or lesser sphenoid wing. Chordoma, a tumor of notochordal remnants, typically causes destruction of the clivus (basisphenoid and basiocciput) with associated soft tissue mass and calcification.[38,39] Erosion of the sella floor and sella expansion are characteristic of pituitary adenomas.

Temporal Bone

Determination of temporal bone abnormality requires assessment of the external ear, middle ear, mastoid air cells, petrous apex, inner ear,

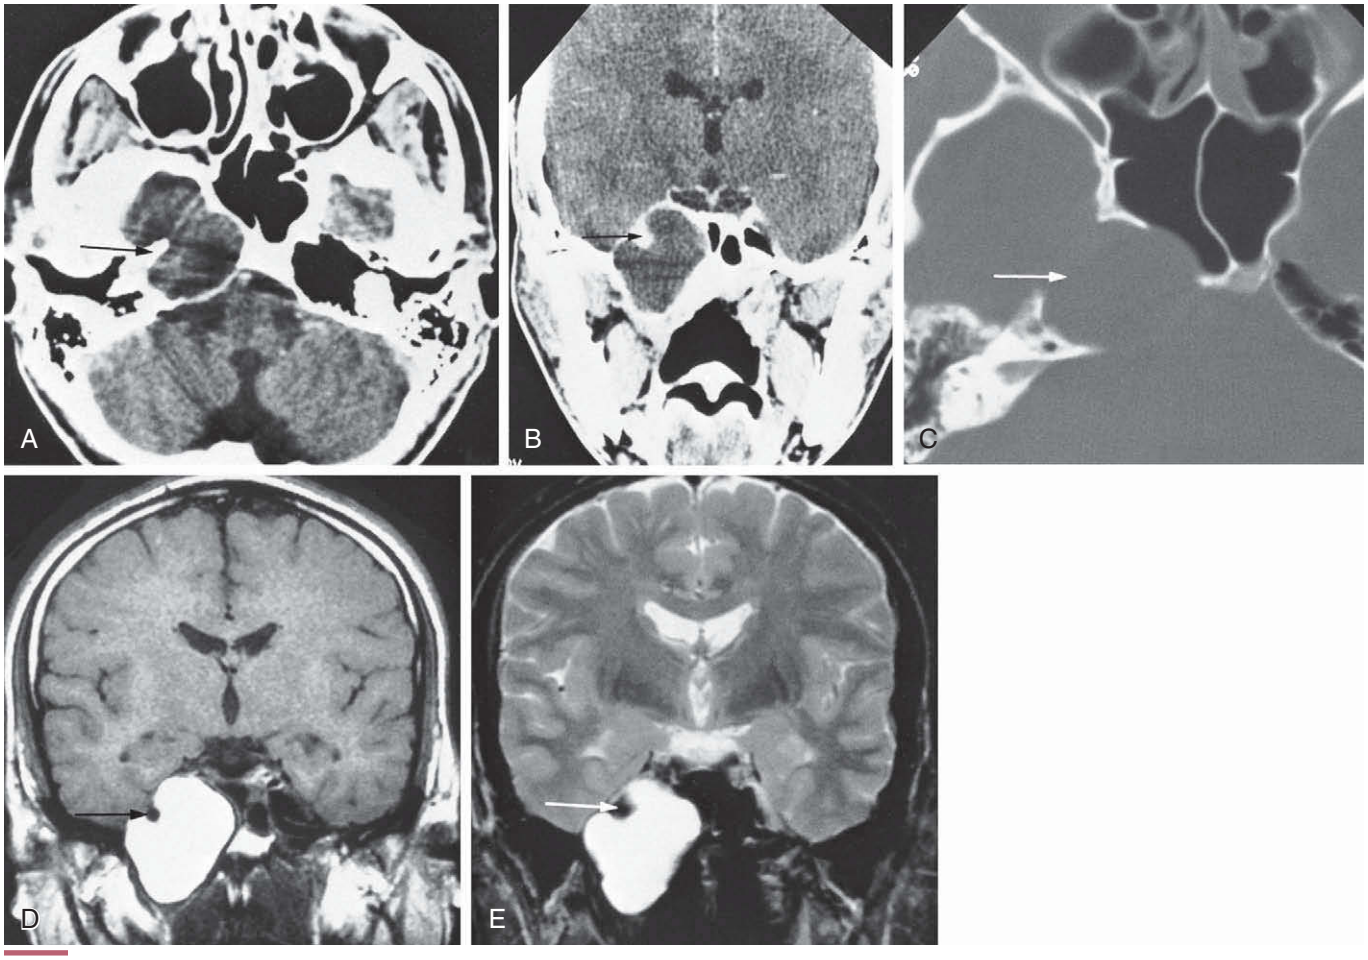

Figure 11-68. Cholesterol granuloma. **A** and **B,** Axial and coronal contrast-enhanced computed tomography (CECT) images demonstrate expansile lesion of the right petrous apex and greater wing of sphenoid. Lesion is homogeneously low density in nature. Displaced right internal carotid artery *(arrows)* lies in the lateral aspect of the lesion. **C,** Axial CECT bone algorithm image using bone windows demonstrates truncation of the anteromedial portion of the right petrous temporal bone *(arrow)* and adjacent posterolateral portion of the sphenoid bone. The lesion bulges into the right sphenoid sinus. **D,** Coronal T1-weighted image and, **E,** T2-weighted image demonstrate a lesion that is high intensity on both sequences, consistent with methemoglobin. Right internal carotid artery is noted in the midlateral portion of the lesion *(arrow)*. The lesion extends above and below the skull base and invaginates into the sphenoid sinus.

IAC, facial nerve canal, and vascular compartment (jugular foramen and carotid canal). The adjacent compartments into which an aggressive temporal bone lesion can spread, or from which a lesion can invade the temporal bone, include cerebellopontine angle (meningioma, acoustic schwannoma), middle cranial fossa (geniculate schwannoma, cholesteatoma), jugular foramen (schwannoma, paraganglioma, glomus tumor), skull base and clivus (chordoma), carotid space (aneurysm, schwannoma), parotid space (adenoid cystic carcinoma), and soft tissues of the external ear and scalp (SCC).

For the external ear and external auditory canal (EAC), the search for abnormality may be accomplished with either high-resolution CT or MRI. Abnormal development (external ear hypoplasia, fibrous or bony EAC atresia), soft tissue opacification (cerumen, EAC cholesteatoma, SCC), bone erosion (EAC cholesteatoma, mucormycosis, squamous cell carcinoma), bone formation (exostoses), or scutum erosion (par flaccida cholesteatoma) can easily be detected and their extent defined by CT. MRI may add additional information on soft tissue involvement below the skull base or on infiltration of the auricle and scalp.

The middle ear is best evaluated with high-resolution CT. Ossicular chain anomalies (fusion, dislocation, prosthesis, stapedial footplate sclerosis), air-fluid level (trauma, acute otitis media), soft tissue opacification (acute or chronic otitis media, cholesteatoma, trauma, chronic endotracheal or nasogastric intubation), and tympanic membrane thickening (otitis media) may all be characterized (Fig. 11-72). The radiographic approach to the mastoid air cells and petrous apex is similar to that of the paranasal sinuses, consisting of the evaluation of the mastoid and petrous apex soft tissue contents and the bony walls. Assessment is made of development or pneumatization of these regions (pneumatization or opacification by soft tissue), the bony septa and walls (hypoplasia or sclerosis from chronic otomastoiditis), the margins of the mastoid or petrous apex (expanded by a primary or secondary cholesteatoma [Fig. 11-73] or a cholesterol granuloma), or bone destruction (SCC, malignant fibrous histiocytoma, glomus tumor). MRI may complement CT for assessment of larger petrous apex or mastoid masses. A normal unpneumatized, fatty (marrow-filled) petrous apex is high signal on T1WI and low signal on T2WI, but a cholesterol granuloma is high signal on T1WI and T2WI from the methemoglobin (see Fig. 11-68). Mucus in an air cell is low intensity on T1WI, is very high intensity on T2WI, and enhances mildly with gadolinium. A primary cholesteatoma is similar to CSF in intensity, appearing low intensity on T1WI and moderately high signal on T2WI, and does not enhance with gadolinium. Postoperative findings encountered on CT and MRI include metallic ossicular prostheses, cochlear implants, and various types of mastoidectomies.

The inner ear structures are best assessed by high-resolution CT with attention to anatomic variants and bone density. A saccular ves-

tibule is one of the more common congenital anomalies. A cochlea with less than 2½ to 2¾ turns represents a Mondini malformation (Fig. 11-74). The basal turn of the cochlea and round window may be identified on both axial and coronal CT images. The horizontal (lateral) semicircular canal cortex may be eroded by a cholesteatoma. The oval window and foot plate of the stapes are thickened in stapedial otosclerosis, and the ring of the otic capsule is demineralized in labyrinthine otosclerosis (otospongiosis). The entire petrous bone may be abnormally low density with dysplasias such as osteogenesis imperfecta or sclerotic in osteopetrosis and Paget's disease. Inflammatory or neoplastic lesions may involve the cochlea and vestibule without obvious bony changes on CT; however, MRI with gadolinium-enhanced T1WI may show an enhancing lesion.

The IAC and facial nerve canals are best evaluated by high-resolution CT for bony detail and by gadolinium-enhanced MRI for the soft tissue abnormality. On CT, the findings might include widening (acoustic schwannoma, surgery) or narrowing (bone dysplasia, hyperostosis from a meningioma) of the IAC. The facial nerve canal may be traced along its entire course in both axial and coronal planes for areas of erosion (facial neuroma, paraganglioma, hemangioma) or abnormal position (anterior location of mastoid segment with EAC atresia). Gadolinium-enhanced MRI is the modality of choice for evaluating the seventh and eighth cranial nerves within the IAC and temporal bone (schwannomas of the facial nerve, of the vestibular nerve, or within the cochlea) or for demonstrating seventh cranial nerve inflammation (Bell's palsy) (Figs. 11-75 and 11-76). Note that the facial nerves may normally enhance mildly and usually symmetrically within the facial nerve canal. Asymmetric enhancement is more likely to be abnormal.

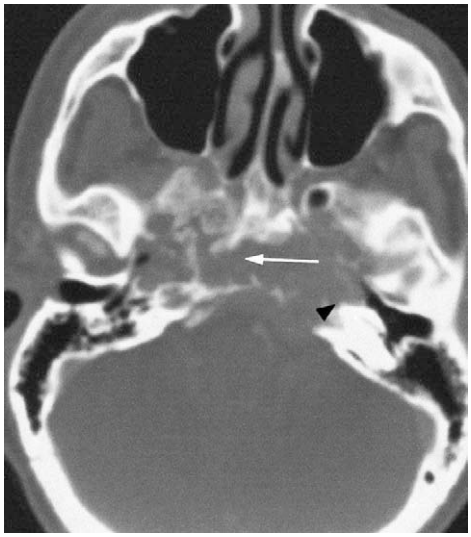

Figure 11-69. Skull base metastasis from adenocarcinoma of the breast. Axial noncontrast computed tomography demonstrates a metastatic tumor infiltrating and destroying a majority of the middle fossa. Clivus *(arrow)* and anteromedial left temporal bone *(arrowhead)* are especially affected.

Postoperative Neck and Face

A preoperative CECT or MRI is extremely helpful for interpreting the postoperative neck, skull base, or face for sites of concern and potential tumor recurrence. Likewise, a baseline CECT or MRI 3 to 6 months after surgery and radiation further improves the ability of imaging to detect posttreatment tumor recurrence. The posterior cervical space is the most frequently altered neck space, and part or all of its contents may be resected for staging and treatment of head and neck carcinoma. Note is made of missing structures.[40] A radical neck dissection (Fig. 11-77A) removes the sternocleidomastoid muscle, internal jugular vein, regional lymph nodes, and most of the fibrofatty tissue that comprises this space. Modified radical, functional, and supraomohyoid neck dissections remove less.

The oral cavity and face also are affected by surgery. Facial trauma is frequently treated by internal fixation with metallic screws and plates. Internal fixation also is performed as part of composite reactions where the mandible is split, or when the mandible is partially resected for invasion by tumor. Metal wires, screws, and plates may cause artifacts obscuring sites of posttraumatic CSF leak or potential tumor recurrence. Sinus and palate tumors may require resection of the maxilla, palate, orbital walls and soft tissue, and cribriform plate. The fat, muscle, or bone contained in free flaps, myocutaneous flaps, and osteocutaneous flaps placed in the surgical cavity further complicates image interpretation (see Fig. 11-77). Laryngeal surgery may remove parts or all of the larynx, often with placement of a tracheostomy. The remaining soft tissues of the collapsed visceral space are difficult to accurately evaluate.

Radiotherapy frequently causes an edematous pattern, characterized on CT by a streaky increase in the density of the subcutaneous, parapharyngeal, and posterior cervical space fat planes (Fig. 11-78A). On MRI it may have an increased signal on T2WI. The mucosal space of the pharynx and larynx may also develop swelling and edema,

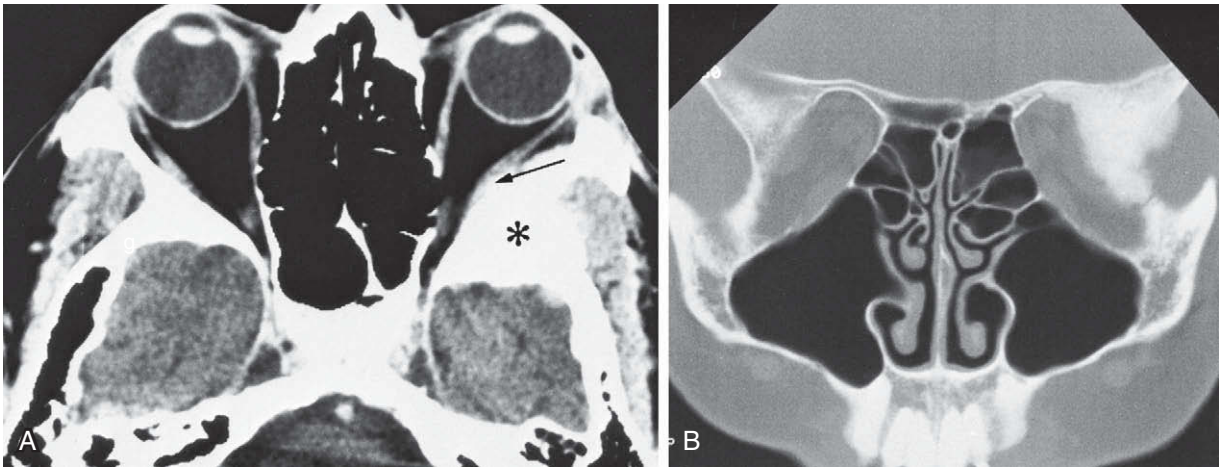

Figure 11-70. Metastatic prostate carcinoma to left orbit. **A,** Axial contrast-enhanced computed tomography (CECT) demonstrates sclerotic metastasis of the posterolateral margin of the left orbit *(asterisk)*. Small soft tissue component *(arrow)* lies deep to the hyperostosis, displacing the lateral rectus muscle medially. **B,** Coronal CECT with bone settings demonstrates a marked sclerotic reaction of the superior lateral portion of the left orbit. Intraorbital volume is decreased.

Figure 11-71. Glomus tumor (paraganglioma) of the right petrous temporal bone. Axial contrast-enhanced computed tomography with bone windows demonstrates an infiltrative destructive lesion of the middle and superior portions of the right petrous temporal bone *(arrow)*. Poorly defined margin of the lesion is characteristic of a glomus tumor. Soft tissue mass *(arrowheads)* is noted in the right cerebellopontine angle cistern and in the inferior portion of the right middle ear cavity *(asterisk)*. Previous right mastoidectomy has been performed.

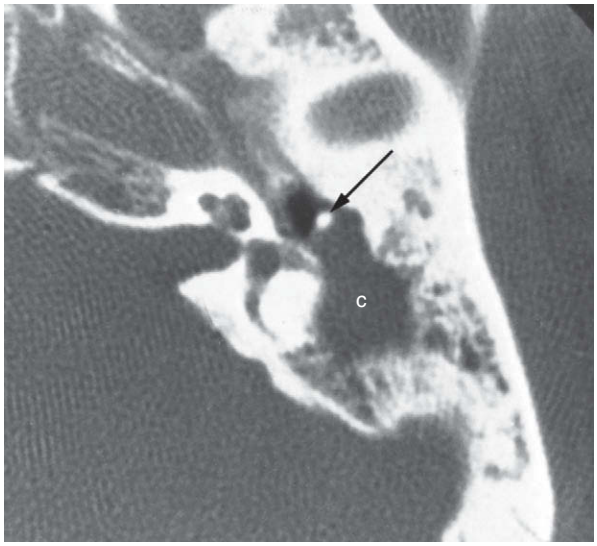

Figure 11-73. Pars flaccida cholesteatoma. Middle ear cholesteatoma (c) expands the mastoid antrum and epitympanic recess on this axial noncontrast computed tomography. The absence of incus and soft tissue abutting the head of malleus *(arrow)* confirm ossicular erosion.

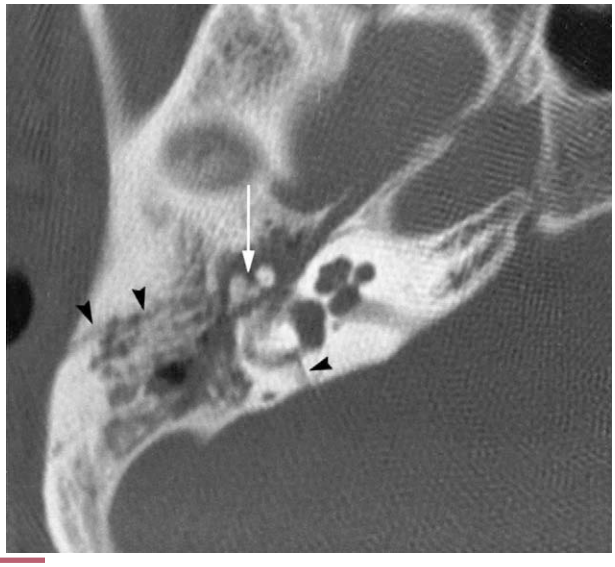

Figure 11-72. Transverse petrous fracture with ossicular dislocation. High-resolution 1.5-mm noncontrast computed tomography using a bone algorithm and bone windows shows a transverse petrous fracture *(arrowheads)* extending through the mastoid bone and semicircular canals. Ossicular dislocation of the head of malleus from its articulation with the fractured body of incus *(arrow)* is seen. Middle ear opacification also confirms presence of temporal bone trauma.

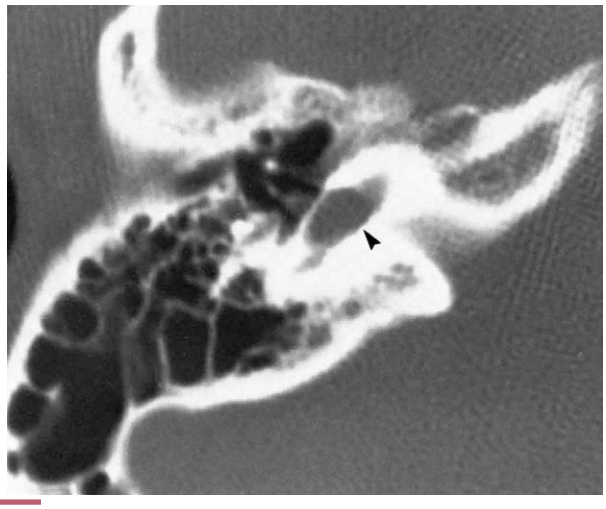

Figure 11-74. Mondini malformation. Saccular combined vestibule and cochlea *(arrowhead)* reveal a severe form of Mondini malformation on this axial noncontrast computed tomography.

appearing as diffuse mucosal thickening and enhancement on CECT, while MRI may show high signal on long TR sequences and on gadolinium-enhanced T1WI (see Fig. 11-78B). Postradiation edema, particularly of the larynx and pharynx, may mimic recurrent neoplasm for as long as 6 months to 7 years after radiotherapy.[41] Finally, treated lymph nodes may decrease in size or totally disappear, leaving a "dirty fat" appearance.

Recurrent tumor spread often produces strands or nodules of soft tissue density within or replacing the normal fat planes. However, CECT has difficulty detecting small (less than 1 cm) or mucosal based tumors, and reliably differentiating between recurrent carcinoma and fibrosis or edema. A new bulky, ring-enhancing mass, local tissue invasion, or further bone destruction is a strong sign of recurrent tumor. MRI is reportedly capable of distinguishing tumor from radiation-induced fibrosis in some cases. Posttreatment fibrosis or scarring is similar to or lower in signal than muscle on all sequences (particularly on T2WI), is usually linear, is not masslike, and may enhance mildly in a linear fashion. MRI is superior to CT (particularly NCCT) in discrimination of recurrent tumor from muscle and vascular structures. In the posttreatment neck, gadolinium-enhanced MRI may have the potential to identify tumor recurrence and allow separation of tumor from fibrosis because recurrent tumor may ring-enhance, a pattern not seen with scar. Finally, PET/CT is better able to differentiate the metabolically active tumor tissue from postoperative changes.

Figure 11-75. Acoustic schwannoma. Axial fat saturation postgadolinium T1-weighted image demonstrates a brightly enhancing right cerebellopontine angle mass with intracanalicular (characteristic of acoustic schwannoma) and extracanalicular components. Note the acute angle that the mass makes with the petrous ridge *(arrow)*.

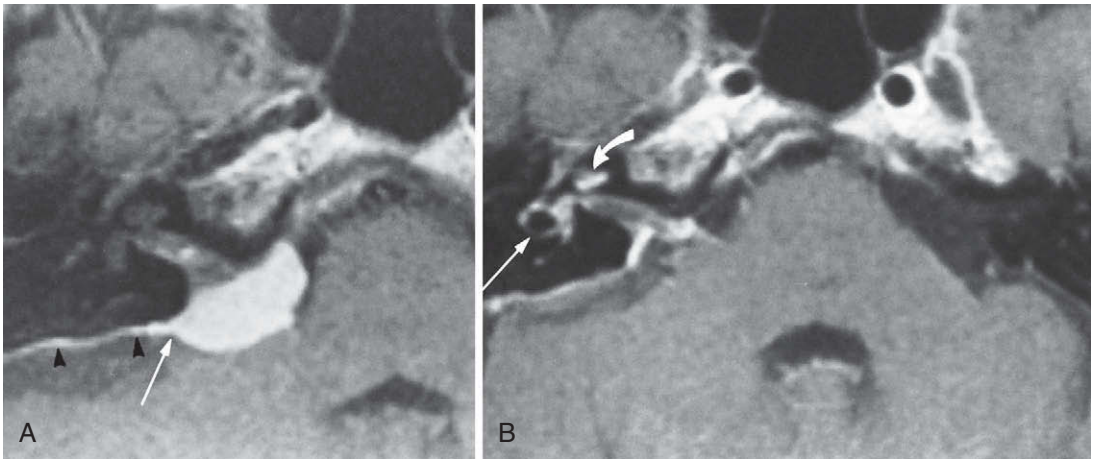

Figure 11-76. Magnetic resonance imaging (MRI) of internal auditory canal (IAC) and facial nerve. **A,** Axial postgadolinium T1-weighted image shows a broad-based brightly enhancing meningioma overlying the IAC. Note its obtuse angle *(arrow)* with the petrous ridge and dural "tail" extending posteriorly *(arrowhead)*, which are characteristic of a meningioma. **B,** In the same patient, postoperative labyrinthitis has developed on this follow-up axial postgadolinium T1-weighted images. Abnormal enhancement of the vestibule, semicircular canals *(straight arrow),* and cochlea *(curved arrow)* are new findings (which can only be observed by gadolinium-enhanced MRI).

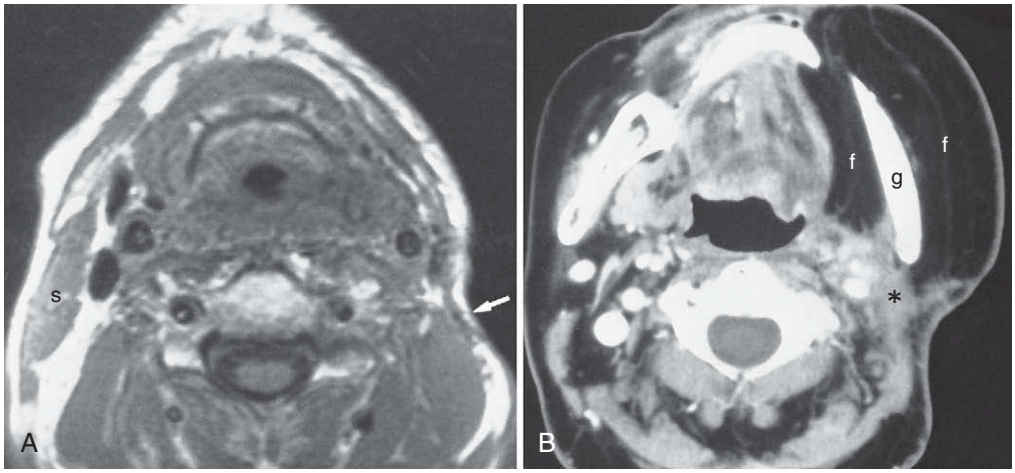

Figure 11-77. Postoperative appearance of neck. **A,** Axial T1-weighted image demonstrates an earlier left neck dissection *(arrow)* with removal of the sternocleidomastoid muscle (s) and posterior cervical space fat. **B,** Patient with an osteocutaneous flap, with thick fat (f) on deep and external margins of the mandibular graft (g), has developed a deep recurrent tumor *(asterisk)* around the carotid sheath.

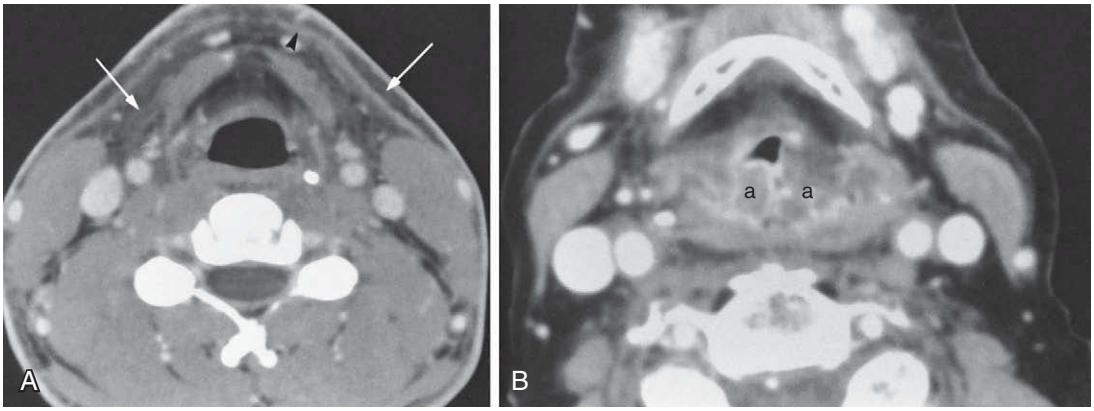

Figure 11-78. Radiation changes in neck. **A,** Axial contrast-enhanced computed tomography (CECT) demonstrates streaky densities in fat throughout the superficial cervical and anterior cervical spaces *(arrows)* and a thickening of the platysma muscle *(arrowhead)*. **B,** Different patient who had radiation therapy for glottic carcinoma has developed a thickening of the epiglottis and aryepiglottic folds (a) on this axial CECT. This finding may persist for many months after therapy.

CHAPTER TWELVE

Odontogenic Infections

James M. Christian

Key Points

- Almost all odontogenic infections are due to mixed bacterial flora, the most common of which are streptococci and oral anaerobes.
- Endodontic therapy or extraction of the tooth, surgical drainage of the abscess, and release of pressure to improve vascularity are all fundamental in management of odontogenic infections.
- The direction of spread of the infection from the tooth apex depends on the path of least resistance of the marrow considering the thickness of the overlying cortical bone and the relationship of the bone's site of perforation to the muscle attachment of the jaws.
- The factor that determines whether the sublingual or submandibular space is involved in spread of an odontogenic infection is the location of the perforation relative to the mylohyoid muscle attachment.
- The hallmark of infection in any or all of the secondary spaces of the mandible (the masticator space) and by extension, the deep neck spaces, is trismus.
- Evaluation and management of the airway is critical to the success of treating severe odontogenic infections.
- A careful history and a thorough physical examination, with the appropriate radiographic images, are paramount in diagnosing and treating patients with odontogenic infections.

Odontogenic infections are among the most frequently encountered infections afflicting humans, the etiology of which is almost always a carious tooth or a tooth suffering from periodontal disease. The vast majority of these infections are minor and acute, and some even drain through the tooth socket , because they are primarily due to chronic periodontal disease. Consequently, there is considerable interest in periodontitis—a chronic inflammatory disease (and by definition a chronic low-grade infection due to a microbial biofilm) of the tooth-supporting structures—as a potential risk factor in the morbidity and mortality of systemic conditions such as cardiovascular disease, diabetes mellitus, and premature birth. Research is ongoing to delve more deeply into these relationships.[1] Refer to the Suggested Readings for more information on periodontal disease. Another topic that frequently arises with reference to odontogenic infection is osteomyelitis, which is an inflammation of the cortical and cancellous bone. It can follow odontogenic infection that is not completely resolved and when appropriate attention is not paid to the jawbone itself on follow-up. Again, refer to the Suggested Readings for more information regarding osteomyelitis.

Odontogenic infections, whether acute or chronic, have been plaguing humanity for millennia, and there are many documented stories, engravings, artifacts, and the like to prove this point.[2] A great deal of pain and suffering continues to be a scourge, especially in populations that neglect dental care, do not have access to dental care, or ignore professional advice on proper oral hygiene. Extraction of the offending tooth usually results in resolution of the infection, even without antibiotics. However, some of these minor tooth-related infections occasionally become more serious and potentially life threatening, especially in immunocompromised patients. The need for more aggressive surgical and medical care is usually necessary then to prevent more disastrous results.

This chapter discusses the more acute odontogenic infections, focusing on diagnosis, clinical and radiographic presentation, microbiology, and treatment and management. Emphasis is on the pathogenesis, especially for the nondental practitioner, to provide a clearer understanding and ensure effective treatment is provided.

Microbiology of Odontogenic Infections

Odontogenic infections are usually caused by normal endogenous flora. The mouth contains many microenvironments, allowing for colonization of many bacterial species. Once this environment is established, which varies with factors such as age, immune status, type of diet, and preferred environment, it can and does change over a lifetime. Table 12-1 lists many of the common "normal" aerobic, facultative, and anaerobic species of bacteria (several fungal species, viruses, and even protozoans can also be found in the "normal oral flora"). In most patients, these normal oral bacteria are the cause of most odontogenic infections. Other organisms can be implicated, however, if there is a compromised host or unusual oral environment, such as that found in chronic osteomyelitis. Facultative streptococci are the most numerous group of organisms in the oral cavity and members of the viridans group are the most abundant; these are classically based on their type of hemolysis on agar. Noticeably absent from these normal organisms are the staphylococci, although they are present in nearly every mouth, but in small numbers. *Staphylococcus aureus*, in particular, is much more common in the nose and throat, and may participate in mixed odontogenic infections. Gram-negative anaerobes comprise much of the rest of the mouth's normal flora, and these organisms can increase in numbers, especially in patients with chronic periodontal disease.[3]

In a recent study describing the microbiology of head and neck infections of odontogenic origin by Rega and colleagues,[4] the most common bacteria isolated were viridans streptococci, *Prevotella*, staphylococci, and *Peptostreptococcus*. This finding has been consistent for many years, even as name changes (especially for *Bacteroides*) have taken place to better reflect more recent genetic information.[5-9]

Based on the results of many studies in the literature and much clinical anecdotal evidence, two important conclusions can be drawn

Table 12-1

Normal Mouth Flora

Aerobic Bacteria	Anaerobic Bacteria
Gram-positive Cocci	
Streptococcus	*Streptococcus* *Peptococcus* *Peptostreptococcus*
Gram-negative Cocci	
Neisseria	*Veillonella*
Gram-positive Bacilli	
Diphtheroids	*Clostridium* *Actinomyces* *Eubacterium* *Lactobacillus*
Gram-negative Bacilli	
Haemophilus *Eikenella*	*Prevotella (Bacteroides)* *Fusobacterium* *Porphyromonas*

Adapted from Peterson LJ. Odontogenic infections. In: Cummings CW, ed. *Otolaryngology Head and Neck Surgery.* Vol 2. 2nd ed. St. Louis: Mosby; 1993:1199.

regarding the microbiology of odontogenic infections: First, almost all odontogenic infections are due to mixed flora. Peterson states that the average number of different organisms is five, but can be as great as 10 or more.[10] Second, between one third and two thirds of these infections are primarily anaerobic,[4,10] which probably has to do with the timing of obtaining the cultures.

The most commonly implicated organisms in mixed infections are viridans streptococci, *Peptococcus, Peptostreptococcus, Eubacterium, Prevotella,* and *Fusobacterium*. Notably absent from this list are the enteric gram-negative cocci and rods, such as group D streptococci, *Escherichia coli, Pseudomonas*, and *Bacteroides fragilis*, among others. This fact has profound implications for treatment when any of these non-normal organisms are cultured from an odontogenic infection.

The anaerobic bacteria seen in odontogenic infections are not usually acknowledged to be pathogenic themselves. The most commonly isolated anaerobe is probably *Prevotella (Bacteroides)*. Entry of bacteria into deeper tissues to cause an infection is probably the result of invasive aerobic bacteria giving access through a necrotic dental pulp. The aerobes then serve as the initiators of the infection, preparing the local environment for anaerobic bacterial invasion and subsequent proliferation. The anaerobes then predominate because the reduction-oxidation potential favors anaerobic growth. The clinical picture is as follows: aerobic or facultative streptococci release exotoxins and lytic enzymes to cause a spreading cellulitis. As the infection progresses, a mixed streptococcal/anaerobic infection ensues. As the hypoxic state increases, the predominance of anaerobic bacteria becomes evident.

Implications of Microbiology for Antibiotic Therapy

For centuries, the primary treatment of odontogenic infections has been surgical, and it will continue to be so in the future. Endodontic therapy or extraction of the tooth, surgical drainage of the abscess, and release of pressure to improve vascularity are all fundamental in the management of these infections.

Antibiotics are a necessary adjunctive therapy in many of these infections to allow for faster and complete resolution. The choice of antibiotic should be based, at least initially, on the susceptibility of the organisms likely to be the cause of the infection. In an *uncomplicated infection,* an empirical choice can be made without the delay of obtaining a specimen for culture and sensitivity testing.

Two microbiologic factors must be kept in mind, however, when making this choice: first, the antibiotic must be effective against *Streptococcus*, because these bacteria are ubiquitous in odontogenic infections; second, the antibiotic should be effective against a wide range of anaerobes, because up to 90% of infections involve some of these bacteria. Fortunately, oral anaerobes are still very susceptible to available antibiotics.[11,12]

The following list summarizes the effectiveness of commonly used antibiotics for odontogenic infections:

- Orally administered drugs
  - Very effective: penicillin, clindamycin, metronidazole (for anaerobes only), amoxicillin/clavulanic acid
  - Effective: erythromycin, cephalexin, tetracycline
  - Less effective: sulfa, quinolones

- Parenterally administered drugs
  - Very effective: penicillin, clindamycin, metronidazole
  - Effective: cefazolin, cefoxitin, carbapenems
  - Not effective: gentamicin, tobramycin, amikacin, cephalosporin (third generation)

The very effective drugs can be used with confidence empirically to treat most odontogenic infections. The effective and less effective drugs are less predictable and should not be used as first-line drugs unless allergy dictates their use or specific culture and sensitivity data are subsequently available. The drugs listed as not effective are not effective against either *Streptococcus* or anaerobes. They should only be used in specific circumstances when indicated by culture results and then in combination with a beta-lactam antibiotic.

In certain infections, other antibiotics may be used. Drugs such as ampicillin, ticarcillin, piperacillin, azlocillin, mezlocillin, moxalactam, third-generation cephalosporins, and chloramphenicol are generally reserved because of their greater toxicity, excess expense, or extended spectra. However, these may be useful in a life-threatening situation, in which case an infectious disease control agency may become involved with the care.

Regarding recommendations for antibiotics, first, it is most useful to use a bactericidal antibiotic rather than a bacteriostatic, if available. The advantages of a bactericidal antibiotic are (1) less reliance on host resistance, (2) killing of the bacteria by the antibiotic itself, (3) faster results, and (4) greater flexibility with dosage intervals.[13] Second, use of the most narrow-spectrum antibiotic first should be considered to allow less opportunity for development of resistant strains. Third, the addition of metronidazole to a beta-lactam antibiotic can add a significant benefit in the treatment of odontogenic infections, especially those considered to be mostly anaerobic. As always, the treating clinician must follow the clinical course of the patient and make the appropriate adjustment in antibiotic therapy as circumstances warrant.[14-17]

Natural History of Odontogenic Infections

The usual cause of an odontogenic infection is necrosis of the pulp of a tooth, which is followed by bacterial invasion through the pulp chamber and into the deeper tissues. Necrosis of the pulp is the result of deep caries in the tooth, to which the pulp responds with an inflammatory response. Vasodilatation and edema cause pressure in the tooth and because the walls of the pulp canal are rigid and cannot expand, severe pain results. If left untreated, blood supply is lost and necrosis results, which then provides a perfect avenue for bacterial invasion into the bone and possibly deeper tissues.

Once the bacteria have invaded the bone, if left unchecked, the infection will spread equally in all directions, but ultimately will seek the path of least resistance until a cortical plate is encountered. During this time, pain continues until the patient seeks treatment, wherein endodontic therapy or extraction results in resolution of the symptoms and the infection.

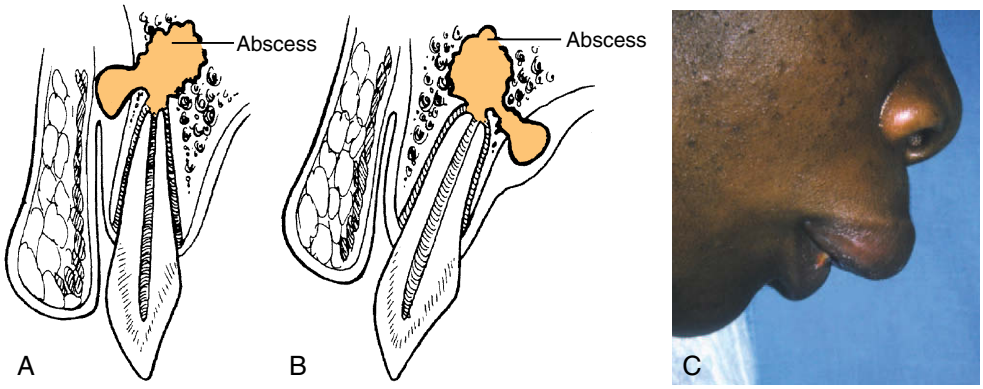

Figure 12-1. When the infection process is allowed to progress, it erodes through the nearest cortical plate. **A,** Tooth apex is near thin labial bone, so infection erodes onto labial side. **B,** Apex is near palatal side and erodes through that side. **C,** Patient with a lip abscess, reflecting **A.**

Direction of Spread of Infection

The direction of spread of the infection from the tooth apex depends on the path of least resistance, considering the thickness of the overlying cortical bone and the relationship of the bone's site of perforation to the muscle attachment of the jaws.

If no treatment is instituted, the infection erodes through the thinnest, nearest cortical plate of bone and into the overlying soft tissues (Fig. 12-1). Fig. 12-1A shows the root apex to be nearest the labial cortex; Fig. 12-1B shows the root apex to be nearest the palatal plate; Fig. 12-1C is a clinical photograph of a patient with a lip swelling, reflecting Fig. 12-1A. Clinical experience reveals that in the maxilla, Fig. 12-1A, is more common in that generally the labial-buccal cortex is thinner. If the root apex is centrally located, the infection erodes through the thinnest bone first, that is, the path of least resistance.

Once the bone has been perforated, local muscle attachments determine the location of the soft tissue abscess (Fig. 12-2). The most common pathway for the abscess is through the labial or buccal bone, occlusal to the muscle attachments, resulting in a vestibular swelling (Fig. 12-3). The vestibular abscess is seen as a fluctuant swelling, literally a "pus pocket," adjacent to the affected tooth or teeth. If no treatment is provided, this pouch of pus usually ruptures and a sinus tract or fistula is established. At this point, the patient's pain is relieved and he or she may believe that all is okay, especially because there are few, if any, systemic symptoms. However, if the tooth continues to be neglected, one of several things can happen. Slowly over time the bone involvement with the abscess can increase with more dissolution, possibly involving adjacent teeth. The patient may develop the classic "gum boil" or parulis, which is the body's attempt at healing the sinus tract with ever-increasing amounts of granulation tissue. Occasionally the tract becomes congested and the pain and swelling may briefly return, until the built-up pressure causes release and relief. This cycle may repeat many times. The one meaningful consequence of continued neglect is development of an osteomyelitis, which may be more severe and more difficult to eradicate. Another unusual possibility is development of an orocutaneous fistula, which is much more common when it occurs in a longstanding mandibular infection (Fig. 12-4).

If the infection perforates the bone above the muscle attachment (see Fig. 12-2, points 2, 4, and 5), fascial space involvement occurs. When this happens, the potential for more severe infection and more significant systemic symptoms becomes greater. A rare occurrence, in my experience, is an odontogenic infection creating a sinusitis, reflected in Fig. 12-2, point 6. The sinus membrane provides a modicum of protection to the spreading infection and allows the body's defenses to "wall off" the abscess, most commonly.

As previously stated, once the infection extends beyond the local muscle attachments, fascial space involvement is possible. Spread of infection along these potential spaces is determined by the presence of loose connective tissue. Fasciae develop in planes covering musculature that is subjected to movement. Surrounding or separating muscles, fascial planes offer an anatomic roadmap for infection to develop from the superficial to deep tissues of the face and neck. It is important to remember that these are potential spaces until separated by pus, blood, or dissection. Other features of these spaces are:

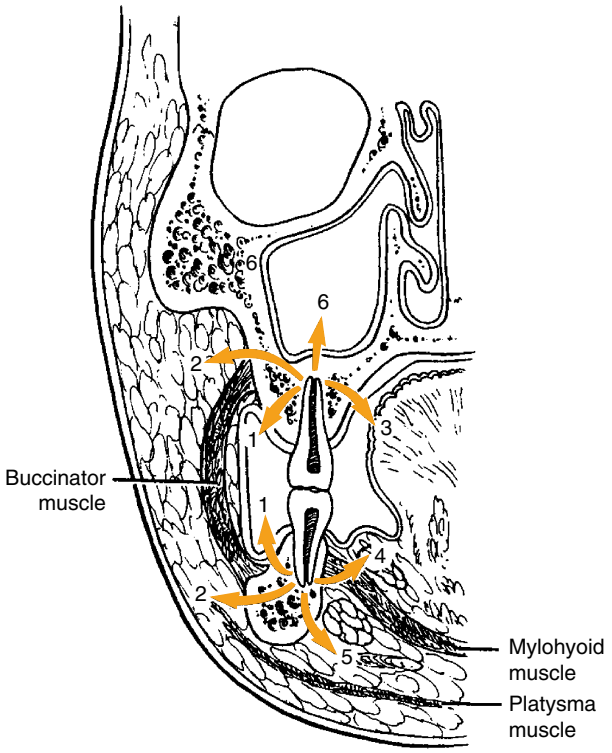

Figure 12-2. As infection erodes through bone, it can express itself in a variety of places, depending on thickness of overlying bone and relationship of muscle attachments to the site of perforation. This illustration notes six possible locations: 1, vestibule; 2, buccal space; 3, palate; 4, sublingual space; 5, submandibular space; and 6, maxillary sinus.

1. Antibiotic availability in pus-filled spaces is limited by poor vascularity.

2. Treatment of a fascial space infection depends on open incision and dependent drainage.

3. Fascial spaces are contiguous and infection can spread readily from one space to another; so it is important to open all primary and

Figure 12-3. Fluctuant swelling in the right maxillary vestibule.

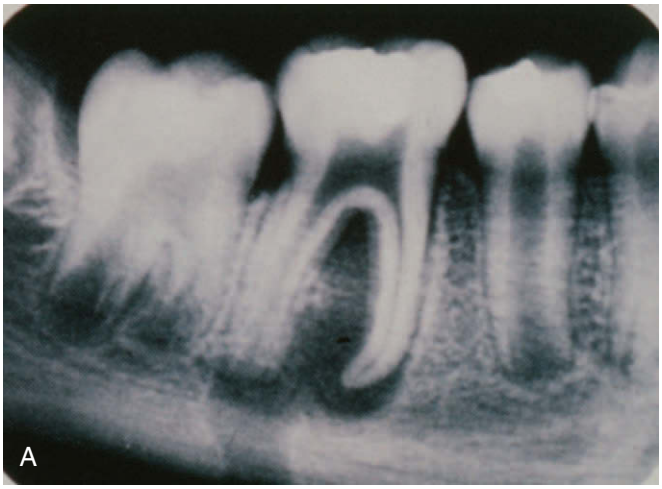

Figure 12-4. **A,** Periapical radiograph of a patient with an abscess on a mandibular molar which shows a tract through the inferior border of the mandible. **B,** Patient with an orocutaneous fistula, which may result from a longstanding infection caused by a molar infection similar to that in **A**. *(From Goldberg MH, Topazian RG. Odontogenic infections and deep fascial space infections of dental origin, Figure 8-2. In: Topazian RG, Goldberg MH, Hupp JR, eds.* Oral and Maxillofacial Infections. *4th ed. Philadelphia: WB Saunders; 2002:162.)*

Figure 12-5. Patient with a canine space abscess. Note the swelling and obliteration of the nasolabial fold. *(From Goldberg MH, Topazian RG. Odontogenic infections and deep fascial space infections of dental origin, Figure 8-9. In: Topazian RG, Goldberg MH, Hupp JR, eds.* Oral and Maxillofacial Infections. *4th ed. Philadelphia: WB Saunders; 2002:169.)*

secondary spaces; once opened, spaces need to have drains and possibly irrigation catheters placed.

4. Involved teeth should be extracted, ideally at the time of incision and drainage to ensure resolution of the infection; once a fascial space infection has occurred, it is prudent to extract the involved teeth rather than rely on endodontic treatment.[18]

It is my opinion that open incision and drainage is the best course of treatment for a fascial space infection, particularly when the mandibular spaces are involved. Although needle aspiration can remove pus, it usually delays recovery because dependent drainage is not accomplished and irrigation of the wound is not possible. Anaerobic bacteria can cause significant tissue destruction and this debris is better cleared with an open wound. Trismus also resolves more quickly and early return to function is a desirable end point. Clearly, clinical judgment and experience play a large role in this treatment decision.

Fascial Space Involvement

Maxillary Spaces

As previously stated, most maxillary tooth infections manifest as vestibular abscesses, more often on the labial-buccal surface, but occasionally on the palatal surface (especially if the palatal root of a maxillary molar is the cause). If the path of infection breaks out above the muscle attachments, then a space infection is possible. The two primary maxillary spaces that may be involved are the canine space and the buccal space.

The canine space becomes infected almost exclusively as a result of apical infection of the root of the maxillary canine tooth. The root must be long enough to ensure that the apex is superior to the insertion of the levator anguli oris muscle. The canine space is located between the anterior surface of the maxilla and the levator labii superioris. When

infected, there is usually swelling lateral to the nose and loss of the ipsilateral nasolabial fold. Drainage is most often accomplished with an intraoral stab incision (Fig. 12-5).

The buccal space becomes involved when the infection of maxillary molar teeth breaks out superior to the attachment of the buccinator muscle. The space itself lies between the buccinator muscle and the skin. All three maxillary molars (uncommon with the third molar) may cause infection in this space; rarely the premolar teeth do. It is an ovoid space, below the zygomatic arch and above the inferior border of the mandible. Infections in this space are dramatic in appearance and may cause trismus, although this is not a consistent finding and may be more of a limitation than actual muscle involvement. The buccal space may also be infected from the mandibular molar teeth, but this involvement is not common. Drainage can be intraoral, but dependent drainage is difficult to obtain. In longer standing buccal space infections, pointing usually occurs and an extraoral incision and drainage is necessary; unfortunately, this usually leaves a noticeable scar after healing (Fig. 12-6).

In addition to these two maxillary space involvements, maxillary odontogenic infections may ascend to cause orbital cellulitis or cavernous sinus thrombosis. These are rare complications in that most patients seek treatment before coming to these extremes. The clinical picture of both of these complications is similar regardless of cause. Early in the course, there is infraorbital edema due to blockage of lymph channels. Progression can then lead to significant swelling and redness of the eyelids, chemosis, and exophthalmos. Once the septum is breached, involvement of the orbital contents includes both vascular and neural components (Fig. 12-7).

Cavernous sinus thrombosis may also occur as a result of the superior spread of an odontogenic infection.[19] Spread to the cavernous sinus is hematogenous and may occur along an anterior or a posterior route (Fig. 12-8), because orbital veins lack valves, permitting blood flow in either direction. This allows contaminated venous drainage into the cavernous sinus. Fortunately this is a rare occurrence and most causes of cavernous sinus thrombosis are nonodontogenic. Signs and symptoms are like those of orbital cellulitis,[20] and are related to the structures in the cavernous sinus.

Mandibular Spaces

Again, most infected mandibular teeth manifest as vestibular abscesses, but these may advance to involve a variety of spaces. Three are designated as primary spaces: submental, sublingual, and submandibular; three are designated as secondary: masseteric, pterygomandibular, and temporal.

The primary spaces are those into which infection spreads directly from the teeth through bone. The submental space lies between the

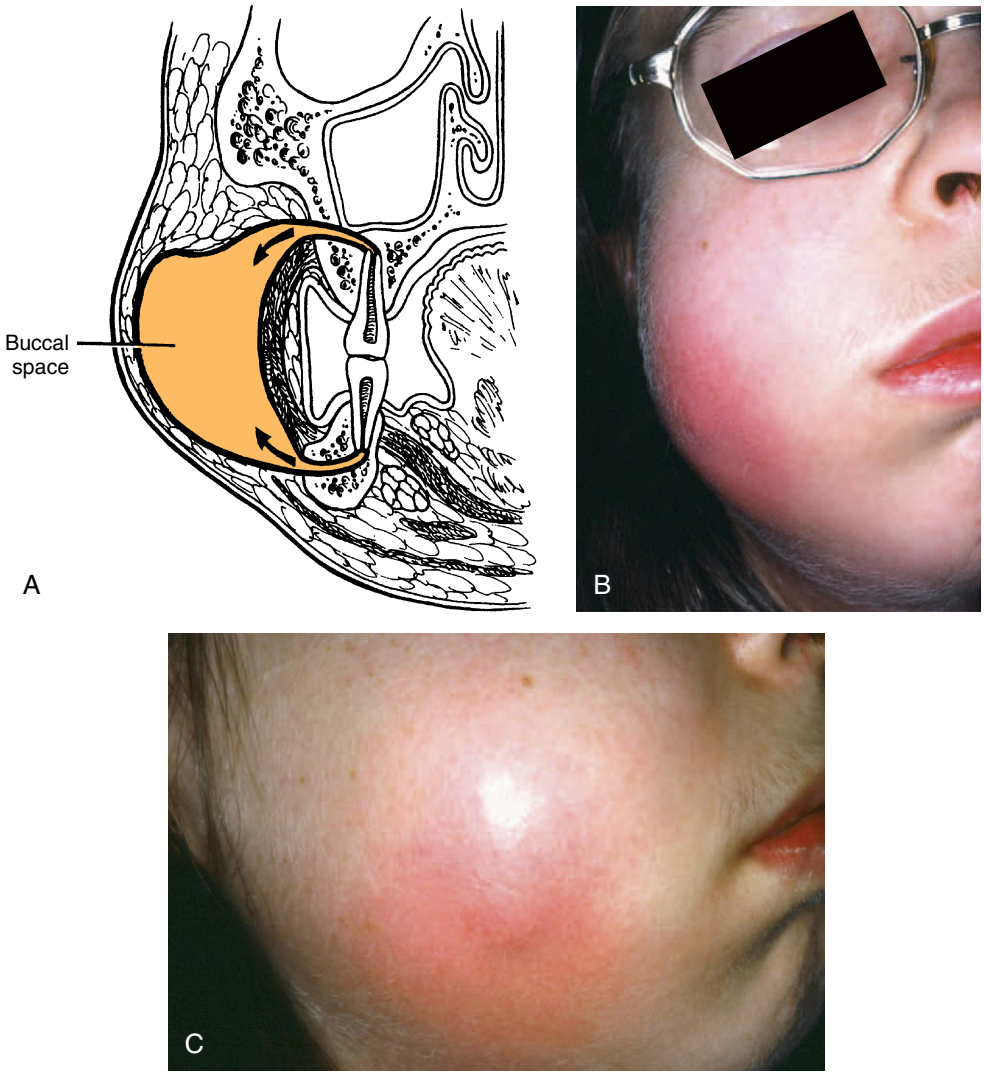

Figure 12-6. **A,** Buccal space lies between the buccinator muscle and the overlying skin and superficial fascia. This potential space may become involved by infection of maxillary and possibly mandibular molars. **B,** Dramatic buccal space infection with skin erythema and "pointing." **C,** Close-up of the "pointing" area.

Figure 12-7. **A,** Patient with multiple space infections and orbital cellulitis, which rapidly progressed to an orbital abscess. **B,** The patient in **A** hours later. Postseptal orbital abscess showing significant edema and chemosis. The globe was nonmobile and red. Urgent incision and drainage was needed.

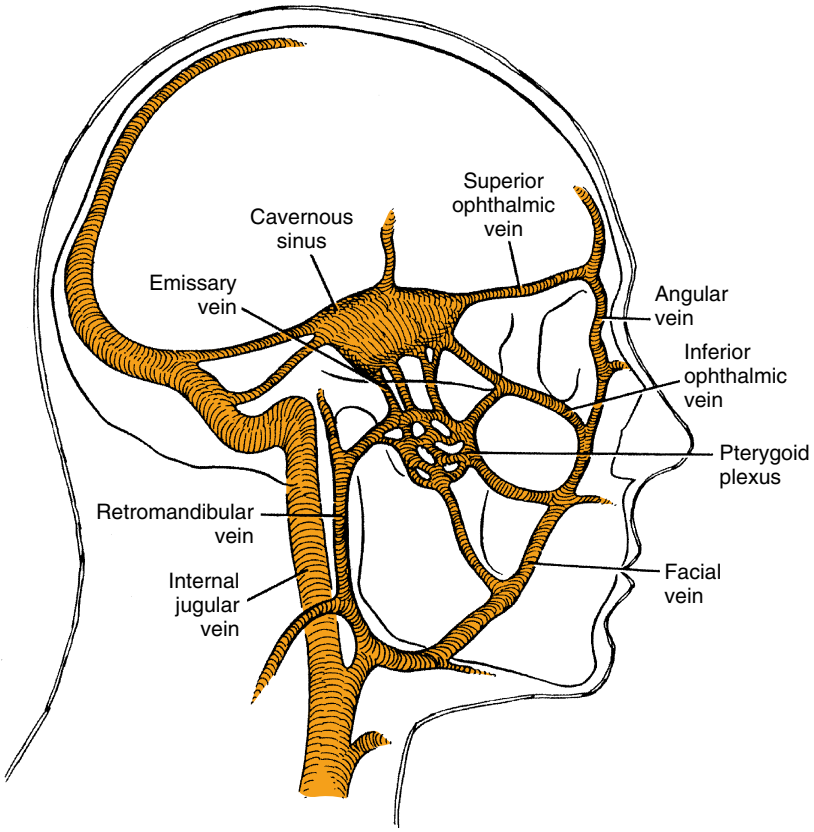

Figure 12-8. Hematogenous spread of infection from jaw to cavernous sinus may occur anteriorly via the inferior or superior ophthalmic vein or posteriorly via the emissary veins to the pterygoid plexus.

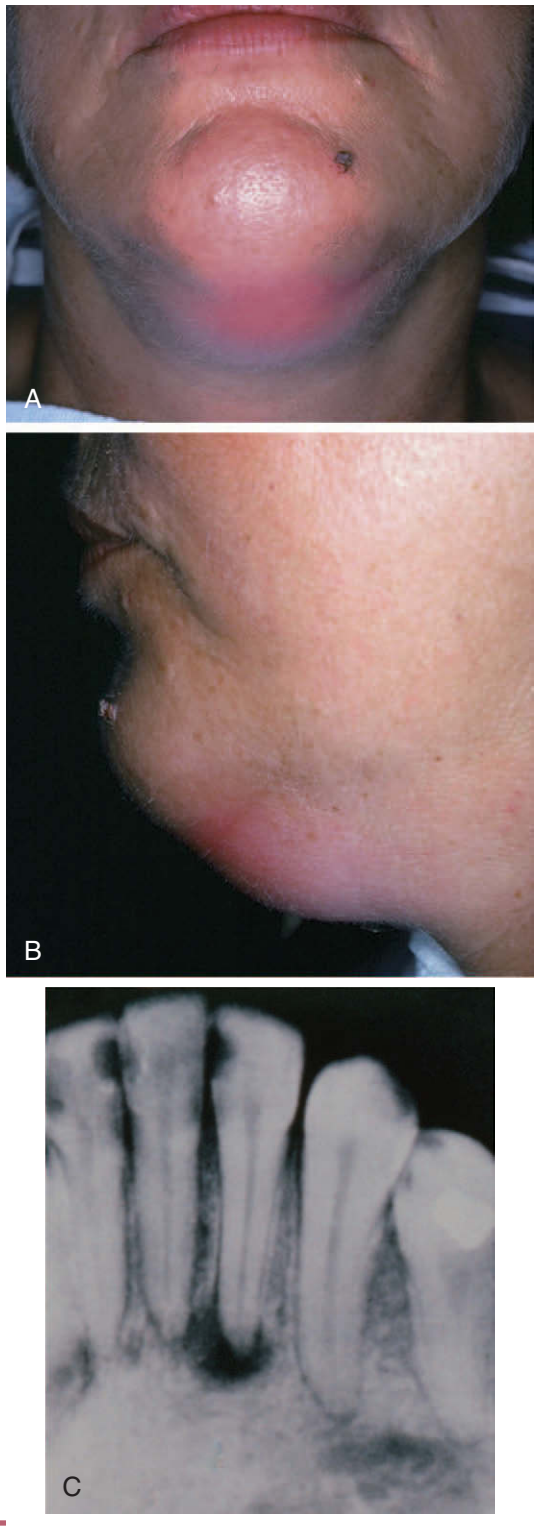

Figure 12-9. **A,** Patient with a submental space infection. **B,** Lateral view. **C,** Periapical radiograph of this patient showing an abscessed mandibular incisor, the result of which is the submental infection.

anterior bellies of the digastric muscles and between the mylohyoid muscle and the skin. This space is involved with infected mandibular incisors, whose roots are long enough to allow erosion apically to the attachment of the mentalis muscle. Isolated submental space infections are not common (Fig. 12-9).

The sublingual and submandibular spaces exit on the medial aspect of the mandible. They are usually involved because of lingual perforation of infection from the mandibular premolars and molars. The factor

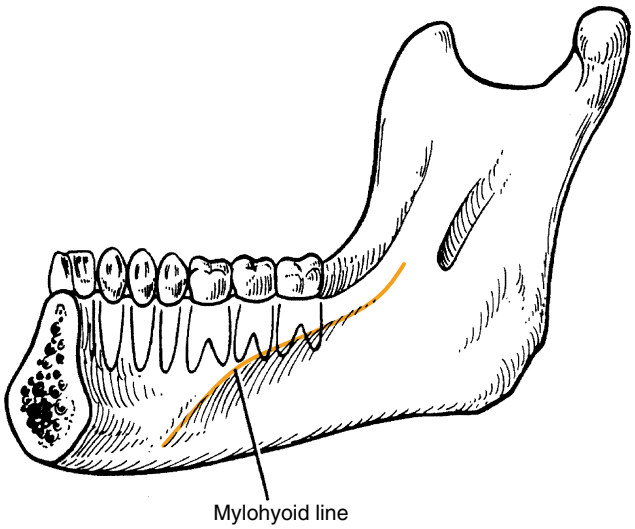

Figure 12-10. The mylohyoid line is the area of attachment of the mylohyoid muscle. Lingual cortical perforation by infection from premolars and first molar causes sublingual space infection, whereas perforation from third molar involves the submandibular space. Second molar may involve either or both spaces.

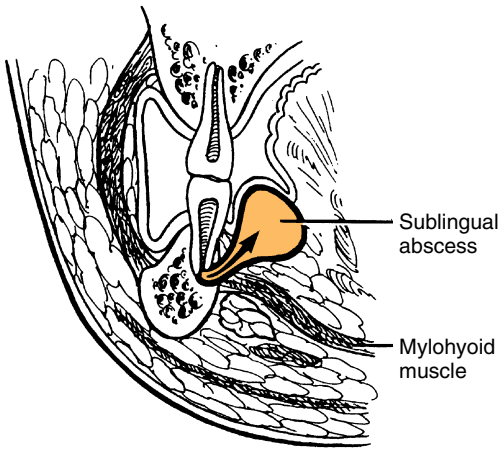

Figure 12-11. Sublingual space, which exists between the oral mucosa and the mylohyoid muscle. It is primarily involved by infection from mandibular premolars and first molar.

that determines whether the sublingual or submandibular space is involved is the location of the perforation relative to the mylohyoid muscle attachment (Fig. 12-10). If the location of the apex of the tooth is superior (premolars, first molar), the sublingual space is involved. Conversely, if the apices are inferior to the mylohyoid (second, third molar), the submandibular space is involved. However, the second molar may be sublingual or both, pending its root apex location.

The sublingual space is between the lingual oral mucosa and the mylohyoid muscle (Fig. 12-11). Its posterior boundary is open, so it communicates freely with the submandibular space and the secondary spaces located more posteriorly and superiorly. Clinically, there is little extraoral swelling, but there can be marked intraoral lingual swelling in the floor of the mouth, and if bilateral, the tongue will be elevated and swallowing becomes very difficult.

The submandibular space lies between the mylohyoid muscle and the skin (Fig. 12-12). Like the sublingual space, it has an open posterior boundary, so it can communicate easily with the secondary spaces as well. When this space becomes infected, the swelling begins at the inferior lateral border of the mandible and extends medially to the digastric area and posteriorly to the hyoid bone (Fig. 12-13). Clinically

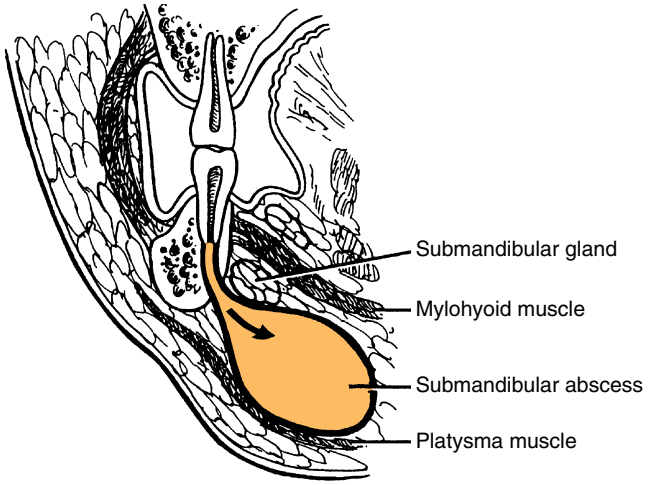

Figure 12-12. Submandibular space, which lies between mylohyoid muscle and the skin and superficial fascia. It is infected primarily by second and third molars.

Figure 12-13. Submandibular space infection, which has produced a large, indurated swelling of the submandibular space. This infection is beginning to "point."

this is a large potential space and the patient is likely to ignore initial swelling; it will not be until the infection has progressed substantially that the patient will seek care.

If all three primary spaces bilaterally become infected, the infection is known as *Ludwig's angina*. Ludwig's angina, described by Wilhelm Friedrich von Ludwig in 1836,[2] was not uncommon in the preantibiotic era and was a significant cause of death. It is characterized, even in the antibiotic era, as a rapid, *bilateral* gangrenous cellulitis of all *three* primary spaces. It can and usually does extend posteriorly to involve the secondary spaces. It causes gross swelling, elevation and displacement of the tongue, and tense brawny induration of the submandibular region superior to the hyoid bone (Fig. 12-14). There is usually minimal or no fluctuance because of the rapidity of the cellulitic process. The patient experiences severe trismus, drooling, inability to swallow, tachypnea, and dyspnea. Impending compromise of the airway produces marked anxiety. If not treated, the cellulitis can progress with alarming speed, producing upper airway obstruction and, ultimately, death. The usual cause is an odontogenic infection from a mandibular molar. Clearly virulent streptococci are involved, but ultimately, it is a mixed picture as usual.[21,22]

The three secondary spaces of the mandible are located posteriorly and superiorly to the tooth-bearing portion of the mandible in the angle-ramus area. They are called *secondary* spaces because they become infected by secondary spread of infection from other anterior spaces: buccal, sublingual, and submandibular. It is also not uncommon to cause infection in these secondary spaces by direct extension of the infection of the tissues surrounding a partially erupted third molar. The hallmark of infection in any or all of these secondary spaces of the mandible is *trismus* caused by muscle irritation and dysfunction due to the infection.

The masseteric space exists between the lateral aspect of the mandible and the masseter muscle (Fig. 12-15). This space is involved from posterior spread of a buccal space infection or from soft tissue infection around the third molar. When involved, the posteroinferior portion of the face swells, especially at the angle of the mandible (Fig. 12-16).

The pterygomandibular space (medial pterygoid space) lies between the medial aspect of the mandible and the medial pterygoid muscle (see Fig. 12-15). This space becomes involved from spread posteriorly of the sublingual and submandibular spaces and from soft tissue infection around the third molar. When this space is involved, there is little or no swelling extraorally, but there is significant trismus, a clue to the diagnosis.

The temporal space is posterior and superior to the masseteric (lateral) and pterygomandibular (medial) spaces (see Fig. 12-15). Bounded laterally by the temporalis fascia and medially by the skull, it is divided into two portions by the temporalis muscle: superficial and deep. Infection in these spaces is more uncommon, unless the infection is overwhelming. Involvement may occur occasionally with extension of a soft tissue infection around a maxillary third molar, in which case the infratemporal portion of this space may first become infected. This area is just the inferior portion of the temporal space and is contiguous with the deep compartment. Swelling is evident over the temporal area, and if the superficial compartment is singularly involved, the swelling can be dramatic.

Collectively, these three secondary spaces are known as the *masticator space*, since they are bounded by the muscles of mastication: masseter, medial pterygoid, and temporalis. These spaces communicate freely with one another, so it is most common to find multiple spaces involved in any one infection. Again, the singular diagnostic symptom of masticator space involvement is trismus (Fig. 12-17).

Cervical (Deep Neck) Spaces

Extension of odontogenic infection beyond the primary and secondary mandibular spaces is not common, again because most patients will have sought care prior to this happening. When it does occur, spread to the cervical or deep neck spaces may have serious, life-threatening sequelae. These sequelae may be the result of local complications, such as upper airway obstruction, or distant problems, such as mediastinitis.

Unfortunately, the deep neck spaces have a variety of names and descriptions, but three are relatively consistent throughout the literature: the lateral pharyngeal space, the retropharyngeal space, and the prevertebral space, or *danger space No. 4*. The layers of deep cervical fascia form and bind these three potential spaces.

The lateral pharyngeal space is classically described as having the shape of an inverted pyramid. The base is the skull base at the sphenoid bone, and the apex is at the hyoid bone. It is located between the medial pterygoid muscle laterally and the superior pharyngeal constrictor medially (Fig. 12-18). Anteriorly the boundary is the pterygomandibular raphe, around which it communicates with the spaces of the mandible. Posteromedially it extends to and is bounded by the prevertebral fascia and communicates freely with the retropharyngeal space. The

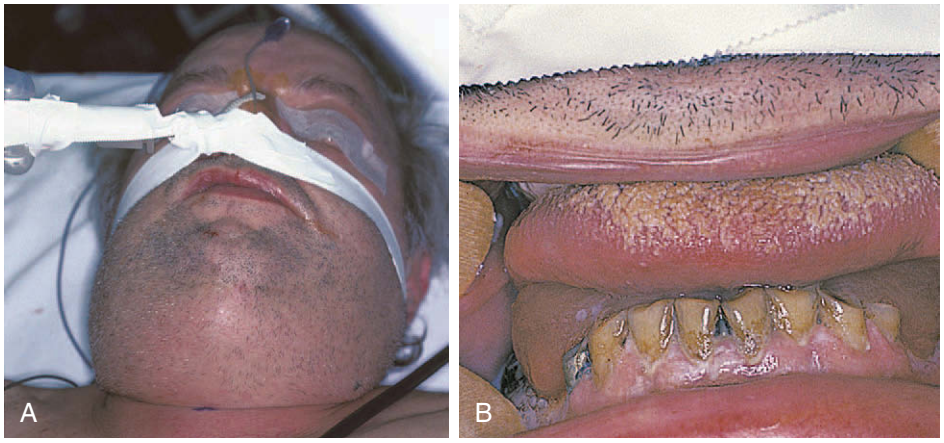

Figure 12-14. A patient with Ludwig's angina. **A,** Note the significant swelling of the bilateral upper neck, involving the bilateral submandibular spaces and the submental space. **B,** The bilateral sublingual spaces are also involved, with resultant obstruction of the oral airway by the tongue.

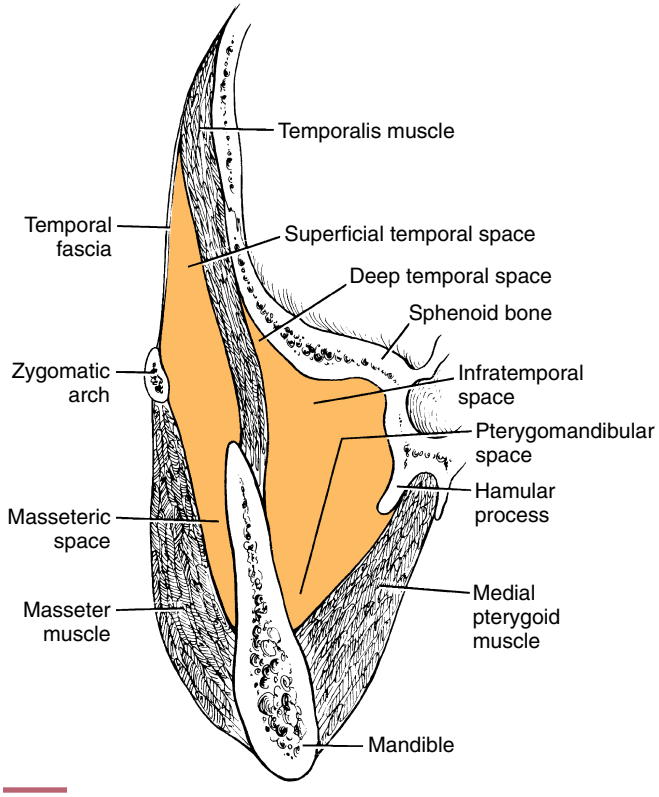

Figure 12-15. Spaces of the ramus of the mandible are bounded by the masseter, medial pterygoid, and temporalis muscles. The temporal space can be subdivided into superficial and deep, superiorly, and infratemporal, inferiorly.

Figure 12-16. Young patient with a masseteric space infection. Note the obliteration of the angle of the mandible.

styloid process and its attached muscles and fascia divide the lateral pharyngeal space into an anterior compartment, which contains muscles, and a posterior compartment, which contains the carotid sheath and cranial nerves.

When the lateral pharyngeal space is involved in an odontogenic infection, there is trismus, because there is extension from the mandibular secondary spaces. If it is severe, it may interfere with accurate diagnosis and treatment. Lateral neck swelling, especially beyond the angle of the mandible, is usually seen, and intraorally, the lateral pharyngeal wall, when visualized, bulges toward the midline. One can differentiate it from a primary peritonsillar abscess primarily because the latter rarely has significant trismus (Fig. 12-19).

Complications result from involvement of the lateral pharyngeal space. First, the odontogenic infection has become severe and may be progressing at a rapid rate. Second, direct effect of the infection on the contents of the space, particularly of the posterior compartment, can include thrombosis of the internal jugular vein, erosion into the carotid artery or its branches, and interference with cranial nerves IX to XII or the sympathetic chain. Third, the infection may progress to the retropharyngeal space.

The retropharyngeal space lies posteromedial to the lateral pharyngeal space. It is bounded anteriorly by the superior pharyngeal muscle and its investing fascia and posteriorly by the alar layer of

prevertebral fascia (see Fig. 12-18). The space begins at the skull base and extends inferiorly to the level of C7 or T1, where the alar and buccopharyngeal layers of fascia fuse (Fig. 12-20), at the level of the posterosuperior mediastinum.

When the infection has extended into the retropharyngeal space, the situation is grave and requires immediate attention. Trismus is severe in essentially all patients at this stage and evaluation of the retropharyngeal space is best performed by evaluation of a lateral radiograph of the neck and a computed tomography (CT) scan, as long as time is not delayed in obtaining one. Average widths of the prevertebral tissues have been well established.[23] The soft tissue shadow should be no more than 7 mm (average: 3.5 mm) at C2 and no more than 20 mm (average: 14 mm) at C6, that is, behind the trachea. The CT scan can be very valuable as well (Fig. 12-21).

Involvement of the retropharyngeal space may also include the prevertebral space, which is a potential space between the two layers of prevertebral fascia, the alar and prevertebral layers. It extends from the skull base inferiorly to the diaphragm. The space is also known as the *danger space No. 4.*[24]

Figure 12-17. Patient with a masticator space infection showing severe trismus.

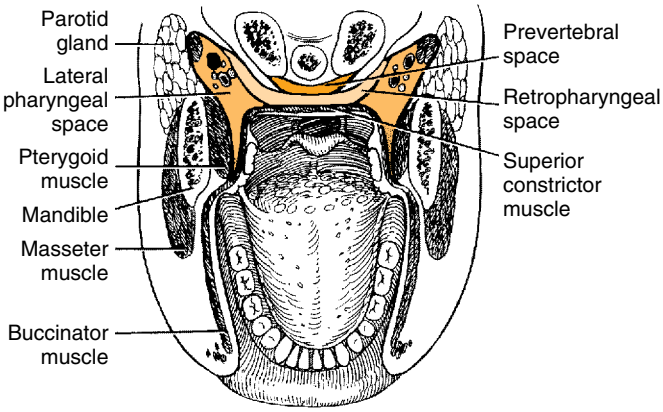

Figure 12-18. Lateral pharyngeal space, located between the medial pterygoid muscle laterally and superior pharyngeal constrictor medially. Retropharyngeal and prevertebral spaces lie between the pharynx and vertebral column. Retropharyngeal space lies between the superior constrictor muscle and alar portion of prevertebral fascia. Prevertebral space lies between the alar and prevertebral layers of prevertebral fascia.

Figure 12-19. **A,** Patient with all of the left masticator spaces and left lateral pharyngeal space infections. **B,** Bulging lateral pharyngeal wall past the midline in this patient; the tongue is retracted inferiorly. **C,** Computed tomography scan showing the lateral pharyngeal space abscess, similar to the patient shown in **A** and **B.** Note the extreme deviation of the airway.

With infection involvement of these deep neck spaces, the patient is seriously ill and is in grave danger of death. Three great potential complications exist: first, the upper airway is in danger of obstruction due to anterior displacement of the posterior pharyngeal wall into the oropharynx (see Fig. 12-21); second, spontaneous rupture of the abscess can result in aspiration, pneumonia, and asphyxiation or this rupture may be caused by attempts at insertion of an endotracheal tube to secure the airway; third, once the infection has gained access to the retropharyngeal spaces, the mediastinum may become infected also (see Fig. 12-20).

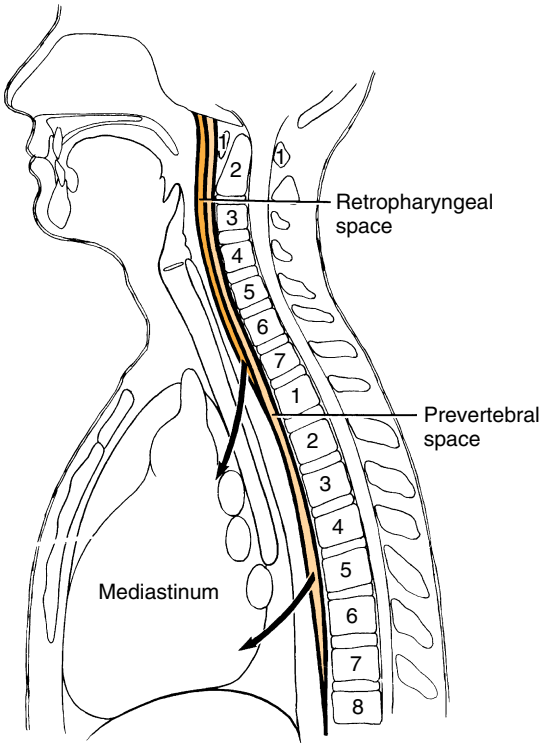

Figure 12-20. Diagram of the fascial spaces of the deep neck. If the retropharyngeal space is involved, the posterosuperior mediastinum may also become infected secondarily. If the prevertebral space is infected, the inferior boundary is the diaphragm, so the entire mediastinum is at risk.

Management of Odontogenic Infections

The principles of treating odontogenic infections are no different from the principles of managing any other infection. These principles are reviewed in the context of treating odontogenic infections that are serious enough to warrant hospitalization. Experience and common sense should dictate that it is better for the patient to be treated in the hospital setting, when a space infection has developed. The initial step, however, in any treatment is the history and physical examination.

History and Physical Examination

A careful history is the essential first step in managing these patients. Focusing on the patient's chief complaint will clue in the practitioner to the origin, extent, and severity of the presenting problem, such as history of tooth pain, presence or absence of fever, use of antibiotics, and any difficulty in opening the mouth or in swallowing. The initial assessment reveals the gravity of the illness, the need for hospitalization, and the possible urgent surgical intervention. Indications of possibly fatal infections are respiratory impairment, difficulty in swallowing, impaired vision and/or eye movement, lethargy, and a decreased level of consciousness. Toxicity is suggested by paleness, tachypnea and tachycardia, fever, shivering, and diaphoresis. Central nervous system impairment includes a decreased level of consciousness, evidence of meningeal irritation such as severe headache, stiff neck, and vomiting, eyelid edema, and ophthalmoplegia. The cardinal signs of inflammation are present to some degree in all patients with an odontogenic infection: rubor, calor, tumor, dolor, and loss of function. Their absence may indicate that the acute phase of infection is past and the infection is spreading to deeper tissues. It may also indicate that antibiotics are effective, but the overall examination of the patient is the key.

Fever is an important finding in a patient with an odontogenic infection, since elevation of the temperature represents systemic involvement by the infection. It is related to the release of endogenous pyrogen, interleukin-1, from inflammatory cells recruited by the body's defense system to fight the infection. Clearly, there are many variables that affect the temperature, but those elevations less than 102° F probably do not harm the patient and may contribute to the defense because elevated temperatures enhance phagocytic activity. Careful consideration should be given to the measurement of the temperature, because oral readings may be erratic; in children, measuring temperature using the external auditory canal is preferable.

Recording the vital signs is an integral part of the examination. In addition to the temperature, the blood pressure, respiratory rate, and

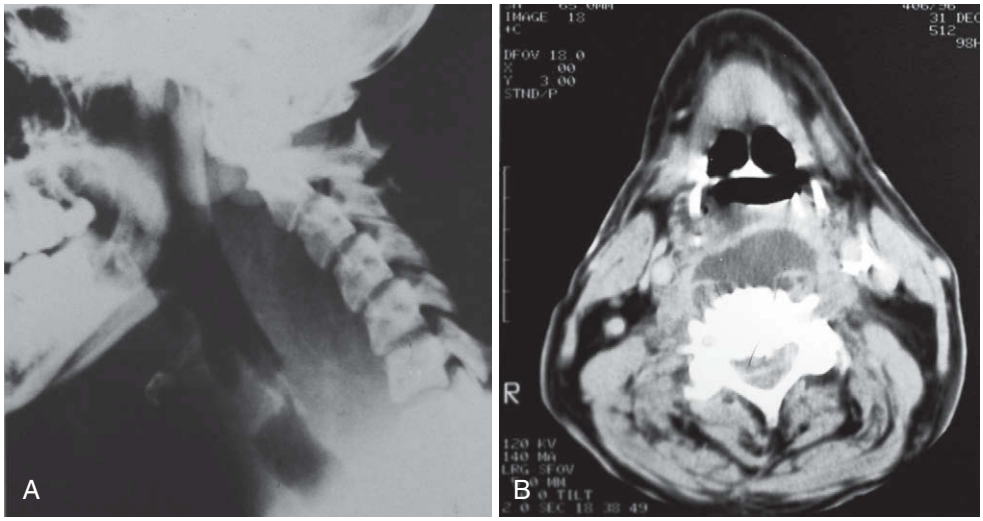

Figure 12-21. **A,** Retropharyngeal space is involved with the soft tissue becoming substantially thicker and width of the oropharyngeal air shadow decreasing. **B,** A retropharyngeal space abscess. Note the widening of the prevertebral region.

pulse can give clues to the extent of the systemic involvement as well. The pulse tends to increase 10 beats per minute for each 1°F of increased temperature, so tachycardia is important to recognize as a vital sign that accompanies fever in an infected patient.

The comprehensive examination should include a regional assessment with inspection, palpation, and percussion as warranted. It is advisable to begin extraorally by examining the skin of the face and neck for swelling, fluctuance, erythema, fistula formation, and crepitus; any lymphadenopathy should be noted. If trismus is present, this is a clue to space involvement and may limit the intraoral examination. Attention can then focus on the teeth and vestibules, noting caries, mobility, swellings, and purulent drainage. The floor of the mouth can be assessed for swelling, as well as the patient's ability to swallow. Ophthalmologic examination should include an assessment of extraocular muscle function and any preseptal or postseptal edema.

Inflammatory swellings in the face of adults represent odontogenic infection until proven otherwise. In children, this is not necessarily the case because there are several more common causes such as gingivostomatitis, sinus infections, and skin infections.

After a thorough history and physical examination, the clinician should proceed with imaging studies. Experience and the evaluation of the physical examination indicate whether plain films, such as a panoramic radiograph, are sufficient for diagnosis and treatment. In general, CT scans are recommended in addition to plain radiography, if fascial space infections have spread to the orbit or neck.[18]

Assessment and Support of Host Defenses

As discussed, odontogenic infections are almost always minor and are easily treated in the office. However, they become serious infections more commonly in patients who have some defense compromise, such as diabetes or immunosuppression. A careful, thoughtful review of the patient's defenses and immune system capabilities should be a routine part of the patient's evaluation.

Patients with moderate or severe odontogenic infections usually have severe pain and dysphagia, which usually results in a poorly hydrated, exhausted patient. Thus the infection itself produces a compromised host. Care must be taken to provide the proper antibiotics, proper analgesics, nutrition, and hydration for patients with these infections, hence the decision to admit the patient.

Airway Establishment

This is one of the most important considerations after admission of the patient. Fascial space involvement that can compromise the airway may be anterior, as in Ludwig's angina, or posterior, as in a deep neck infection. In either case, rapid severe compromise of the airway may occur. The surgeon must be keenly aware of this fact, carefully and frequently evaluating airway status to prevent fatal obstruction, and be prepared to take the patient to the operating room on an urgent or emergent basis.

In the uncomplicated odontogenic infection that involves the spaces of the mandible unilaterally, airway problems are rarely seen. If they are seen, nasal endotracheal intubation is the method of choice for airway establishment, with fiberoptic assistance as needed, especially if the patient has significant trismus. Consideration should be given to leaving the endotracheal tube in place for 2 to 3 days to ensure that acute obstruction does not occur in the time shortly after surgical decompression of the infection. These patients also have some rebound edema associated with the incision and drainage procedure.

In patients with Ludwig's angina, airway embarrassment is the primary cause of death. Once Ludwig's angina is diagnosed, it is imperative that the patient be monitored frequently and carefully for airway problems. These patients cannot lie flat and have difficulty in swallowing. If the decision is made to establish an artificial airway early, intubation with fiberoptic assistance (or blind nasal technique) can be attempted. These procedures should be carried out on awake, unparalyzed patients. Administration of neuromuscular blocking agents is not warranted because their administration may cause airway loss that cannot be regained. These cases require that an experienced anesthesiologist be present. If the decision to establish an artificial airway is delayed or cannot be accomplished, a tracheostomy or a cricothyroidotomy followed by a tracheostomy is the only option. An unhurried approach with a local anesthetic is preferred.[22]

If the infection involving a retropharyngeal space abscess is diagnosed with a radiographically enlarged soft tissue image or CT image, an artificial airway must be seriously considered. If the patient has only mild trismus and the anesthesiologist believes that direct laryngoscopy is possible, an endotracheal tube is preferred. However, if the patient has moderate or severe trismus, a fiberoptically assisted intubation is required. The major concern in this situation is rupturing the abscess while attempting to pass the endotracheal tube into the trachea, even under fiberoptic control. If such a rupture occurs, there is good likelihood of aspiration of pus into the bronchial tree, with all of the attendant sequelae. If there is no surety, even with an experienced anesthesiologist, then a planned tracheostomy (or cricothyroidotomy followed by a tracheostomy) should be carried out.

Identification of Bacteria

Identification of the causative microorganisms in an odontogenic infection is not usually a problem. As indicated earlier, the usual causes are *Streptococcus* and oral anaerobes. Because the data are so consistent among the various reports and the clinical experience of many surgeons, it is unnecessary to perform cultures for uncomplicated odontogenic infections in uncompromised patients. However, it is still appropriate to obtain cultures from patients who have undergone incision and drainage in the hospital setting, including the immunocompromised patients, in whom an unusual pattern of microorganisms may be harbored. Either aspiration with a large-bore needle before the surgical incision and drainage or capturing pus on the actual incision and drainage is sufficient. The specimen should be handled using both aerobic and anaerobic methods to ensure growth of all possible organisms.

Choice of Antibiotic

The drug of choice for odontogenic infections continues to be parenteral penicillin. Even for serious fascial space infections, including Ludwig's angina,[21] penicillin is preferred. Large doses of up to 20 million units daily for intravenous penicillin may be required for serious infections.

In the penicillin-allergic patient, clindamycin is the second drug of choice. It is quite effective against streptococci and anaerobes and has low toxicity. Although clindamycin may cause pseudomembranous colitis, it causes only about one third of the reported cases. (About one third of cases are caused by ampicillin/amoxicillin and one third by the cephalosporins.) The surgeon must be alert to this potential complication and prepared to treat it or to seek consultation. Metronidazole alone or in combination with penicillin is also a useful drug. It has minimal toxicity problems and is effective against anaerobes. Parenteral cephalosporins may be moderately useful. The first-generation cephalosporins have the same effects that penicillin does on the microbial population causing odontogenic infections. The second-generation drug cefoxitin is more active against the anaerobic bacteria but loses some of the antistreptococcal activity of the first-generation drugs. The third-generation cephalosporins are generally effective against anaerobes but also have decreased effectiveness against streptococci. Furthermore, they are expensive and have no clear additional benefit. Thus the second- and third-generation drugs are not highly desirable in most odontogenic infections. Ciprofloxacin and metronidazole in combination may be quite useful in the patient with a severe infection who has had an anaphylactoid reaction to penicillin.

In summary, high doses of parenteral antibiotics with a penicillin-like spectrum are usually effective in treating odontogenic infections. Specific culturing should be done for serious or nonresponsive infections and the results used accordingly.

Surgical Drainage and Decompression

Vestibular Infections

Odontogenic infections that are confined to the oral vestibule can usually be treated in a straightforward manner. These patients complain of mild to moderate pain and some soft tissue swelling, especially if there has not been a sinus tract established. There may be a mild, but

rarely severe, elevation of body temperature, because this is still a local phenomenon.

Treatment is primarily surgical with antibiotic therapy often used as an adjunct. Surgical treatment is extraction of the offending tooth (or endodontic therapy to remove the dental pulp of the tooth) and incision and drainage of the vestibular abscess. A small piece of Penrose drain is inserted to maintain drainage for 1 or 2 additional days. Antibiotic treatment is usually with penicillin. If the patient is allergic to penicillin, either erythromycin or clindamycin can be used effectively as alternatives. Antibiotic administration usually lasts for 7 to 10 days. Such patients can be managed on an outpatient basis. Resolution of the infection is rapid and usually without complications.

Jaw Space Infections

If the infection spreads to one of the fascial spaces surrounding the maxilla or mandible as described earlier, the treatment needs to be more aggressive.

The initial step after obtaining a history and completing a clinical and radiographic examination is to make a decision as to whether hospitalization is necessary. This decision is based on the presence and amount of swelling, the nature of the swelling (soft and doughy, indurated, or fluctuant) and the state of the body's defenses. Infections that appear as chronic abscesses, with or without an orocutaneous fistula present, without a major cellulitis component can be surgically drained in the office setting and the patient observed on an outpatient basis. Similarly, patients with early infections having a soft, doughy swelling and who are not yet dehydrated can be treated as outpatients with antibiotics and tooth extraction.

However, patients who have a moderately elevated temperature with an odontogenic cellulitis that is diffuse and indurated should be managed in the hospital setting. These are the patients who are dehydrated and have a significant amount of pain. Support of the host with hydration, intravenous antibiotics, and analgesics plays an important role in the overall therapy.

Surgical treatment should be considered early. If fluctuance is noted on the physical examination, the patient should be taken to the operating room and incision and drainage procedures performed. Aspiration of pus for aerobic and anaerobic cultures is accomplished first. Drainage of the canine and isolated sublingual spaces is usually performed with a transoral approach. After the incision is made, an exploration is carried out by blunt dissection to break up all loculation of pus, and the Penrose drains are inserted.

The buccal space can be drained transorally or extraorally, depending on the specific patient situation and the preference of the surgeon. Surgery from the mouth side is more difficult, with maintenance of dependent drainage becoming less predictable. Drainage from the cutaneous side is more likely if the infection has progressed to a "pointing area"; unfortunately, this leaves a scar.

The submental space is drained via a horizontal incision, which parallels the inferior border of the symphysis of the mandible (Fig. 12-22). The area between the anterior belly of the digastric muscles is explored posterior to the hyoid bone.

The buccal, submandibular, masseteric, pterygomandibular, and sublingual spaces can all be drained via a horizontal incision parallel and inferior to the angle of the mandible (see Fig. 12-22). An incision from as short as 0.5 cm to as long as 5 cm may be used. If the infection is a tense cellulitis that involves several mandibular spaces, a larger incision is indicated to relieve pressure. After the incision is made, blunt dissection is used to explore the involved spaces. The tip of the hemostat is advanced to hit bone at the inferior border of the mandible. It can then be directed laterally and medially. This medially directed exploration will allow for the medial pterygoid component (pterygomandibular space) to be drained, since it is the most commonly missed space. It can also be directed somewhat anteriorly to drain the submandibular space/sublingual space or a separate incision can be made more anteriorly at the inferior border. The inferior portion to the lateral pharyngeal space just medial to the pterygoid muscle can be explored by this approach as well. In severe infections, anterior (submental), posterior (submandibular), and superior (superficial temporal) incisions may all be required. Penrose drains are inserted to the extent of the dissection to facilitate drainage. Irrigation and suction catheters may be useful in more severe infections,[25] because anaerobic bacteria cause significant tissue damage and this debris needs to be flushed out of the wound. In infections drained by multiple incisions, through-and-through drains should be used, because intraoral incisions can also be of value to ensure thorough treatment.

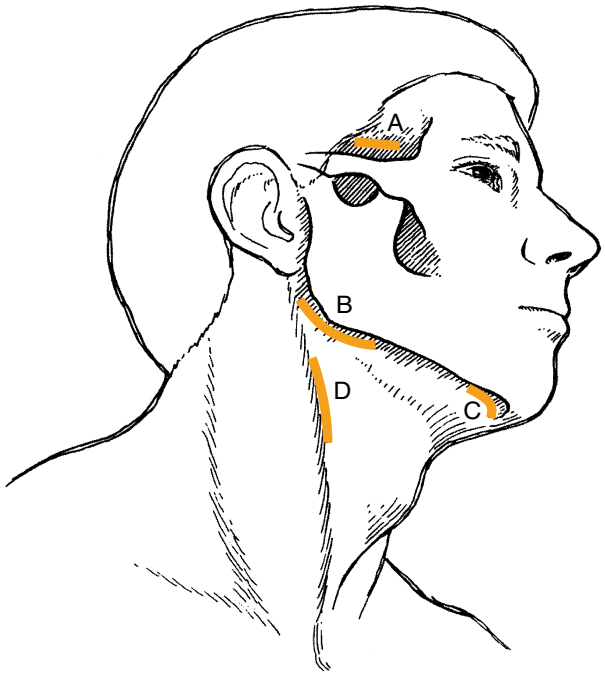

Figure 12-22. Typical incision and drainage sites for various fascial space infections. *A,* Superficial and deep temporal spaces. *B,* Submandibular, masseteric, and pterygomandibular spaces. *C,* Submental space. *D,* Lateral pharyngeal and retropharyngeal spaces.

Resolution of these infections depends on several factors: conditions of host defenses, seriousness of the original infection, appropriateness of antibiotic therapy, and extensiveness of surgical exploration. Of these, a failure to perform adequate surgical drainage is most likely to occur, especially if the patient reaches a plateau and does not continue to progress as expected. It may be necessary to repeat CT scans to identify an additional loculation that was not drained at the initial surgery. In the patient with severe cellulitis, overlying induration may prevent the clinical diagnosis of an abscess formation, especially if the patient was taken to the operating room before any scanning. Again additional surgery may be necessary.[26]

Deep Neck Spaces

Involvement of the deep cervical spaces as a result of odontogenic infection is an uncommon but life-threatening event. A large proportion of these deep neck infections are the result of odontogenic infections that have spread from the primary and secondary spaces of the mandible, because mandibular molars are the likely etiology. When deep cervical involvement does occur, usually beginning in the submandibular space and extending through the pterygomandibular space, the major diagnostic goal is to determine whether the lateral pharyngeal and retropharyngeal spaces are involved. The clinical examination, radiography (using anteroposterior [AP], and lateral soft tissue views of the neck; see Fig. 12-21A), and CT (see Fig. 12-21B) may all be required to make the diagnosis. Lateral and AP neck radiographs and CT scans may reveal the presence of gas in the soft tissue as well as soft tissue swelling. The presence of gas in the tissue in this setting signifies an anaerobic infection and indicates immediate and aggressive surgical therapy, because not only does pus need to be drained, but a continuing necrotizing fasciitis is also a concern.

Initial treatment of a patient suspected of having a deep neck infection requires immediate hospitalization, host support, maintenance of airway, IV antibiotic therapy, and incision and drainage of the involved spaces. Early surgical exploration, even in the absence of palpable fluctuance, is likely to produce more rapid and complete resolution of the infection with minimal mortality. As noted earlier, an artificial airway in these patients must usually be established, earlier rather than later. There must be no hesitation in accomplishing the necessary maneuver, whether it is fiberoptic intubation or tracheostomy. Large doses of parenteral antibiotic therapy must be started immediately as well. Penicillin with metronidazole is the preferred combination; clindamycin is an adequate alternative. If doubt exists concerning the bacterial cause of the infection, gentamicin or a third-generation cephalosporin may be added; in addition, it may be helpful early in the admission to obtain an infectious disease consult, if time permits.

Medical management with antibiotic therapy and host defense support may be used initially without surgery; however, a rapidly progressing infection of the neck should be explored. If gas emphysema, a foul-smelling discharge, or other signs indicating anaerobic infection exist, the indication for surgical intervention increases. If the infection continues to progress rapidly despite aggressive antibiotic therapy, surgical drainage becomes mandatory. If fluctuance is noted, pus should be drained immediately.[27-29]

Drainage of the lateral pharyngeal space is best accomplished by a combined transoral-extraoral approach. An incision is made lateral to the pterygomandibular raphe, and the space is explored by blunt dissection posterior and inferior to the angle of the mandible with a long Kelly hemostat. A skin incision is made over the clamp tip along the anterior border of the sternocleidomastoid muscle (see Fig. 12-22). Loculations of pus are disrupted by blunt dissection with the hemostat and by finger pressure. Through-and-through drains are placed.

The retropharyngeal space can be drained through transoral incision through the posterior pharyngeal mucosa. If this approach is used, a cuffed endotracheal or tracheostomy tube must be in place to prevent any aspiration of pus. An extraoral incision along the anterior border of the sternocleidomastoid muscle will facilitate dependent drainage. The space is explored by blunt dissection between the carotid sheath and pharyngeal constrictor muscle. Deep drains are placed as usual.

When surgical treatment was the only method of therapy (before the antibiotic era), early and aggressive surgery was essential to treat these infections and for survival. However, it is important to realize that, although aggressive antibiotic therapy may reduce the need for extensive surgical exploration in many patients, antibiotics rarely replace the need for surgery completely.

If surgery is emergent or even urgent, attention will not be immediately on the evident malnutrition of the patient. It is important in the postoperative period, then, to focus on correction of any deficiencies in intravascular volume status, electrolyte imbalances, and nutritional compromises. Oral pain, trismus, and swelling can be overcome by the administration of enteral nutrition for several days after the surgical procedure.

Acknowledgment

This chapter is dedicated to the memory of my former attending, teacher, and mentor, Dr. Larry J. Peterson, who I hope would approve of my update from the second edition.

CHAPTER THIRTEEN

Pharyngitis in Adults

Brian Nussenbaum

Carol R. Bradford

Key Points

- The most common cause (30% to 60%) of pharyngitis in adults is a self-limited viral infection that occurs as part of the common cold. Rhinovirus is the most common etiologic agent.
- Pharyngitis in adults is caused by a bacterial infection in approximately 5% to 10% of patients. This is different than in children, in whom bacterial pharyngitis accounts for 30% to 40% of cases.
- Group A beta hemolytic *Streptococcus pyogenes* (GABHS) is the pathogenic organism responsible for most cases of bacterial pharyngitis in adults.
- Prevention of rheumatic fever is possible if antibiotic therapy is started up to 10 days after the onset of symptoms, but antibiotic treatment does not appear to affect the incidence of acute poststreptococcal glomerulonephritis.
- Other more uncommon bacterial causes of acute pharyngitis include non–group A beta hemolytic streptococcus, *Arcanobacterium haemolyticum,* sexually transmitted organisms (gonorrhea, syphilis, and chlamydia), tuberculosis, tularemia, and diphtheria.
- Influenza continues to be a worldwide problem. Each year, influenza develops in 500 million people globally with approximately 150,000 people requiring hospitalization in the United States alone. In nonpandemic years, 20,000 to 40,000 deaths occur. In pandemic years, this number can reach 100,000 deaths annually. Influenza A rather than type B is responsible for most of the significant morbidity and mortality.
- Sore throat from Epstein-Barr virus is found in 82% of patients with infectious mononucleosis and is the most common complaint. Other symptoms may include abdominal discomfort, headache, stiff neck, and skin rash.
- Treatment for most patients with infectious mononucleosis consists of supportive care, rest, antipyretics, and analgesics. Patients should be advised to avoid contact sports until examination and abdominal ultrasonography confirms resolution of splenomegaly. Antivirals are not beneficial in uncomplicated infections. Antibiotics are indicated only for secondary bacterial infections. Steroids are indicated for complications related to impending upper airway obstruction, severe hemolytic anemia, severe thrombocytopenia, or persistent severe disease.
- *Candida* sp. can affect the oropharynx in the form of pseudomembranous candidiasis (thrush). The most common isolated organism is *Candida albicans* but other organisms (*C. glabrata, C. Tropicalis, C. dubliniensis, C. rugosa*, and *C. krusei*) are now emerging as causative agents, especially in immunocompromised patients and for those who have received previous radiotherapy.

Pharyngitis is defined as inflammation of the pharynx. The anatomic region of the pharynx invariably affected in adults is the oropharynx. The predominant symptom is sore throat, which overall is the third most common chief complaint to physicians in an office-based practice.[1] An infectious-related pharyngitis is just one of the many possible causes of sore throat in adults (Table 13-1). An accurate history and physical examination is critically important for determining the differential diagnosis for each individual patient. For instance, squamous cell carcinoma of the upper aerodigestive tract frequently presents with a history of chronic sore throat. Epiglottitis in adults commonly presents as a severe acute sore throat and odynophagia with a relatively normal oropharyngeal examination. More common conditions such as postnasal drip and laryngopharyngeal reflux can cause an irritative pharyngitis. Occupational[2,3] and environmental[4] exposures can also be associated with an irritative pharyngitis, which has been demonstrated in many different populations, most recently in the firefighters with World Trade Center cough.[5]

Pharyngitis in adults is caused by a bacterial infection in approximately 5% to 10% of patients.[6] This is different than in children, in whom bacterial pharyngitis accounts for 30% to 40% of cases.[6] Approximately 75% of adults presenting with a sore throat are prescribed antibiotics for a presumed bacterial pharyngitis even though this practice will only help a minority of patients.[7] This practice can be attributed to patients' expectations to receive an antibiotic and physicians' beliefs that patients will reconsult if antibiotics are not prescribed and be unsatisfied without a prescription. This inappropriate use of antibiotics has negative consequences for both individual patients and public health.

The focus of this chapter is the appropriate evaluation and management of different microbial causes of pharyngitis in adults. In this chapter, adults are assumed to be older than 15 years.

Bacterial Infection

Group A Beta Hemolytic *Streptococcus pyogenes*

GABHS is the pathogenic organism responsible for most cases of bacterial pharyngitis in adults.[8] Overall, however, GABHS only accounts for approximately 10% of adult cases of pharyngitis.[8] This organism is a gram-positive cocci that grows in chains. Its natural reservoir is the

Table 13-1

Etiologies for Sore Throat in Adults

Microbial-Related Pharyngitis:

Bacterial

Group A-beta hemolytic *Streptococcus pyogenes*
Groups C, G, and F streptococci
Arcanobacterium haemolyticum
Neisseria gonorrhoeae
Treponema pallidum
Chlamydia pneumoniae
Mycoplasma pneumoniae
Mycobacterium tuberculosis
Francisella tularensis
Corynebacterium diphtheriae
Yersinia enterocolitica
Yersinia pestis
Trichomonas vaginalis

Viral

Rhinovirus
Coronavirus
Parainfluenza
Influenza types A and B
Human immunodeficiency virus
Adenovirus
Epstein-Barr virus
Herpes simplex virus types 1 and 2
Cytomegalovirus

Fungal

Candida sp.

Protozoa

Toxoplasma gondii

Other Causes

Abscess (peritonsillar, parapharyngeal, retropharyngeal)
Epiglottitis
Cancer (squamous cell carcinoma, lymphoma)
Autoimmune (Behçet's disease, benign mucous membrane pemphigoid, sarcoidosis)
Laryngopharyngeal reflux
Postnasal drip
Eagle's syndrome
Glossopharyngeal neuralgia
Crohn's disease
Foreign body
Trauma
Medications
Environmental exposures/Air pollution

skin and upper aerodigestive tract mucosa of the nasopharynx and oropharynx. The organism is a pathogen only in humans. Less than 5% of adults are asymptomatic carriers.[9] Spread occurs mostly through aerosolized microdroplets, less commonly by direct contact, and rarely through ingestion of contaminated nonpasteurized milk or food. Infections are more common in the autumn and winter. The pathogenesis of GABHS infections is related to virulence factors intrinsic to the organism (cell wall, hyaluronic acid capsule, M proteins), secreted enzymes (streptolysin O, streptolysin S, DNases, hyaluronidase), secreted exotoxins (exotoxins A, B, and C), and host inflammatory mediators (interleukins 1/6, tissue necrosis factor, prostaglandins, bradykinin, nitric oxide, lysosomal enzymes, free radicals).[1]

The local tissues affected by GABHS pharyngitis include the palatine tonsils, uvula, soft palate, and posterior pharyngeal wall. Symptoms are usually rapid in onset and include severe sore throat, odynophagia, cervical lymphadenopathy, fevers, chills, malaise, headache, mild neck stiffness, and anorexia. Trismus, hoarseness, cough, conjunctivitis, diarrhea, rhinorrhea, and discrete ulcerative lesions are usually not present.[10] The pharynx typically has erythema, edema, and gray-white tonsillar exudates symmetrically involving the affected tissues. Petechiae may be present on the soft palate. The tonsils are commonly swollen, and the breath is characteristically foul. A scarlatiniform rash may be present.

If left untreated, infections are usually self-limited and consist of localized inflammation that resolves after 3 to 7 days. Patients are contagious during the acute illness and for approximately 1 week afterward. Prompt antibiotic treatment reduces the duration of symptoms (if treatment begins within 24 to 48 hours of symptom onset), reduces the period of contagiousness to 24 hours after beginning treatment, and likely decreases the incidence of suppurative complications. Prevention of rheumatic fever is possible if antibiotic therapy is started up to 10 days after the onset of symptoms. Interestingly, antibiotic treatment does not appear to affect the incidence of acute poststreptococcal glomerulonephritis.[8] Other possible manifestations include scarlet fever, toxic shock syndrome, necrotizing fasciitis, and bacteremic spread of infection to distant sites.

GABHS tonsillopharyngitis is difficult to accurately diagnose solely based on symptoms or signs because there is significant overlap with findings that are common to other causes of pharyngitis. In a population of young adults with sore throat, clinical grounds alone overestimated the occurrence of GABHS in 81% of the patients, and overdiagnosis commonly led to unnecessary treatment.[11] This is problematic because antibiotic treatment should be limited only to patients likely to have a GABHS infection.[12] Because of this diagnostic difficulty, scoring systems have been developed for predicting the likelihood of GABHS on clinical grounds alone. Patients can then be divided into high probability groups that should receive empirical antibiotic therapy, intermediate probability groups that should undergo further testing with a rapid antigen test and/or throat culture, and low probability groups that require only symptomatic therapy and appropriate follow-up.[1] Two clinical prediction scoring systems that have been tested and prospectively validated in adult populations are those described by Walsh and colleagues[13] and Centor and colleagues.[14] These scoring systems should not be used in patients who are immunocompromised, have complicated comorbidities, or have a history of rheumatic fever. Clinicians should also consider epidemiologic circumstances. For example, one should avoid using these scoring systems during an epidemic of acute rheumatic fever, in parents with school-aged children, or for adults with occupations that bring them into frequent contact with children.[15]

The Walsh scoring system uses an algorithm based on five items: (1) enlarged or tender cervical lymph nodes, (2) pharyngeal exudates, (3) recent exposure to GABHS, (4) recent cough, and (5) oral temperature greater than 101°F.[13] The Centor scoring system uses history of fever, anterior cervical adenopathy, tonsillar exudates, and absence of cough to generate a simple four-variable additive score.[14] The presence of three or four of the Centor criteria has a positive predictive value of 40% to 60%, whereas the absence of three or four criteria has a negative predictive value of 80%. The Centor criteria have been endorsed by the Centers for Disease Control and Prevention (CDC), the American Academy of Family Physicians (AAFP), and the American College of Physicians (ACP) for use in clinical practice guidelines for treatment of acute pharyngitis in adults.[15] These guidelines state that patients with 0 or 1 Centor criteria should receive no further testing or antibiotic treatment given the unlikely possibility of GABHS infection. For patients with two or more criteria, there are a few appropriate strategies: (1) test patients with two, three, or four criteria with a rapid antigen test and reserve antibiotics for those with a positive test; (2) test patients with two or three criteria with a rapid antigen test and limit antibiotic treatment to those with a positive test or with four criteria; or (3) use no diagnostic tests and limit antibiotic treatment to those with three or four criteria. The authors of these guidelines do not

include throat culture in their algorithm because of poor test-retest reliability, variable results depending on the technique of obtaining and performing the culture, and inability to distinguish acute infection from a carrier state.

After the above recommendations were published, a different viewpoint on the diagnosis and management of GABHS pharyngitis in adults was proposed by the Infectious Diseases Society of America (IDSA).[10,16] In an emergency department practice, the accuracy of the Centor score for predicting a positive GABHS throat culture was 32% to 56%. Based on these data, the IDSA noted that the application of this clinical scoring system alone would result in continued overprescription of antibiotics in adults with non-GABHS pharyngitis.[16] Given this consideration, the IDSA continues to support laboratory confirmation of clinically suspected cases of GABHS pharyngitis in adults. The American Heart Association (AHA) also still recommends laboratory confirmation.[17] In considering the sensitivity (80% to 90%) and specificity (>95%) of the more recently used rapid antigen detection tests, the low incidence of GABHS, and the very low risk of rheumatic fever in the adult population, the IDSA supports the use of rapid antigen tests alone without confirmation by throat culture as an acceptable alternative diagnostic strategy.[10] Even though several variables can affect the results, the IDSA still supports the use of throat culture on a sheep blood agar plate as the gold standard for documentation of the presence of GABHS in the upper respiratory tract and for the confirmation of acute GABHS pharyngitis. The sensitivity of throat culture is 90% to 95%. The use of antistreptococcal antibody titers has no role in the routine diagnosis of GABHS pharyngitis. A major problem in testing of adults with pharyngitis is that clinicians commonly fail to follow any guidelines, which leads to unnecessary treatment in many patients.[18]

Adults with GABHS pharyngitis should be treated with a dose and duration of an antibiotic that is likely to eradicate the organism from the pharynx. Penicillin remains the treatment of choice due to its proven efficacy, narrow spectrum, and low cost. No clinical isolate of GABHS has ever been documented to be resistant to penicillin.[10,15] Amoxicillin appears to be equally effective and is sometimes used as an alternative in children due to its improved taste. The oral course should be for 10 days. Benzathine penicillin can be alternatively used as a single intramuscular injection that provides bactericidal levels for 21 to 28 days. Erythromycin is an acceptable alternative for patients allergic to penicillin, but isolated reports of macrolide resistance (<5% of clinical isolates currently) have been reported in the United States. Clindamycin is an acceptable alternative for patients with both a penicillin allergy and a strain resistant to macrolides. Although studies have shown that cephalosporins, clindamycin, and azithromycin can effectively eradicate GABHS from the pharynx with treatment courses of 5 days or less, the IDSA does not support routine use of these shorter courses due to inadequacies with these studies, the broader spectrum of these antibiotics in comparison to penicillin, and increased cost.[10]

Many explanations for penicillin treatment failure have been proposed: (1) carrier state, (2) lack of compliance, (3) recurrent exposure, (4) in vivo copathogenicity of beta-lactamase-producing normal oral flora, (5) in vivo eradication of normal protective flora, (6) contaminated toothbrushes or orthodontic appliances, and (7) intracellular localization of the bacterium. These explanations are based on observational studies or are laboratory based without clinical confirmation rather than being based on type I or II evidence.[19]

Routine retesting is not recommended for asymptomatic patients after a complete course of treatment for GABHS pharyngitis.[10] This would be indicated only for special circumstances such as patients with a history of rheumatic fever, development of pharyngitis during an outbreak of acute rheumatic fever or poststreptococcal acute glomerulonephritis, or in families with "ping-pong" spread of infection. Patients with persistent symptoms with a repeat rapid antigen or throat culture positive for GABHS may be a carrier in the presence of viral infection, may have copathogens that produce beta-lactamase, may be noncompliant with the antibiotic regimen, or may have acquired a new infection with GABHS from family or community contacts. No tests can distinguish between a carrier in the presence of repeat viral pharyngitis versus bona fide GABHS pharyngitis, and eradication of the GABHS carrier state is rarely possible with penicillin. Clindamycin or amoxicillin-clavulanic acid should be used to treat patients with multiple, repeated, symptomatic episodes of laboratory proven GABHS.[10] Tonsillectomy should be considered when these episodes do not decrease in frequency despite appropriate antimicrobial therapy and no other etiology for the repeated episodes is evident. A randomized clinical trial performed in Finland of tonsillectomy versus observation for adults with documented recurrent episodes of streptococcal pharyngitis showed that tonsillectomy was beneficial for decreasing the number of episodes of further throat infections. The number needed to treat to prevent one recurrence was 5.[20]

Non–Group A Beta Hemolytic Streptococcal Infections

Groups C and G streptococci have been cultured from patients during episodes of acute pharyngitis.[6,8] These organisms are part of the normal upper respiratory tract flora, so differentiating colonization from infection is difficult. These organisms can be cultured in patients with acute pharyngitis with clinical symptoms and examination findings indistinguishable from those of GABHS.[8] Pharyngeal infection with groups C and G streptococci can cause acute glomerulonephritis but has never been shown to cause acute rheumatic fever.[8] Penicillin and clindamycin both provide effective eradication when necessary.

Arcanobacterium haemolyticum

Arcanobacterium haemolyticum is a nonmotile, beta-hemolytic, gram-positive bacillus that causes 0.5% to 2.5% of bacterial pharyngitis cases.[21] This organism also causes deep-seated infections such as pneumonia, meningitis, osteomyelitis, brain abscess, and peritonsillar abscess in both immunocompetent and immunocompromised patients.[22] In these complicated cases, sources from the tonsils, cutaneous wounds, or absence of an identifiable source have all been reported. Phospholipase D and hemolysin are secreted exotoxins believed to play a role in pathogenesis of infections.[23] The mode of transmission appears to be airborne.

A. haemolyticum is not part of the normal upper respiratory bacterial flora.[23] The maximum incidence in patients with acute pharyngitis is 2.5%, which is found in the young adult population 15 to 18 years old.[24] Other reports state that the peak incidence occurs in patients 10 to 30 years old.[23] Infection is rare in other patient populations. The throat symptoms vary from a mild pharyngitis to an exudative tonsillitis to a diphtheria-like illness to septicemia. A rash is present in 25% to 50% of patients and may be urticarial, macular, or maculopapular. The rash usually occurs on the trunk and extremities, with sparing of the palms, soles, and face. The rash can be the predominant presenting symptom, especially in cases with only mild pharyngitis symptoms. Other clinical features include fever (64%) and cervical lymphadenopathy (41%).[24]

Pharyngitis caused by *A. haemolyticum* is easily mistaken for GABHS or viral pharyngitis with an exanthem due to the overlap in symptoms. When suspected, throat culture needs to be performed using 5% human blood agar.[23] Using this culture medium, prominent hemolytic zones are formed within 24 hours by *A. haemolyticum*. Sheep blood agar is usually used for standard throat cultures because it is rapidly hemolyzed by GABHS, but *A. haemolyticum* only forms 0.5-mm colonies with a narrow rim of hemolysis by 48 hours using this culture medium. Because most clinical laboratories discard throat cultures after 48 hours, the diagnosis is commonly missed when using this method.

Oral penicillin was recommended for treatment in the past but bactericidal tests demonstrated increasing tolerance of this organism. Thus first-line antibiotic therapy for *A. haemolyticum* pharyngitis is erythromycin.[23] Interestingly though, many reported cases of deep-seated complicated infections have been successfully treated with high-dose intravenous penicillin alone.[22] Vancomycin, clindamycin, cephalexin, and gentamicin are also effective antimicrobials. *A. haemolyticum* is resistant to oxacillin and trimethoprim-sulfamethoxazole. Antibiotic sensitivity assays are recommended for all positive cultures.

Neisseria gonorrhoeae

Neisseria gonorrhoeae is a sexually transmitted organism that affects the anal-genital region but can also cause gingivitis, stomatitis, glossitis, and pharyngitis.[25] Gonococcal pharyngitis is an uncommon but

Figure 13-1. Traumatic pharyngitis as might be seen in patients presenting with oral manifestations of sexually transmitted diseases. *(Photo courtesy of Richard A. Chole, MD, PhD.)*

well-described manifestation. This infection usually occurs concomitantly with genital infection but rarely occurs as the only site of involvement. Fellatio is the high-risk behavior and thus the incidence of disease is highest in homosexual males and females.[8] Auto inoculation has also been postulated to be a possible mechanism of disease transmission to the oropharynx. In patients with genital gonorrhea, positive oropharyngeal cultures are found in 20% of homosexual males, 10% of females, and 3% of heterosexual males.[26] Combining these groups together, the overall reported incidence of positive oropharyngeal culture in patients with genital gonorrhea is 4% to 11%.[27] Interestingly, however, only 50% of these patients actually have acute pharyngitis symptoms.[26] For asymptomatic patients, evidence suggests that the presence of *N. gonorrhoeae* in the oropharynx may be self-limited.[28] This does not justify withholding treatment, however, because dissemination from the pharynx can still occur. Dissemination most commonly manifests as arthritis, septic joint, or dermatitis.[26]

Symptomatic patients usually present with findings suggestive of tonsillitis. The tonsils are enlarged with a white-yellow exudate arising from the crypts.[25] There may be evidence of oropharyngeal trauma particularly on the soft palate or uvula (Fig. 13-1). Fever (8%) and lymphadenopathy (9%) are uncommon findings. Organisms are found within the cellular debris at the base of crypts.[27] Because of this, it is recommended to obtain Gram stain and culture specimens from deep within the crypts. A typical Gram stain reveals intracellular gram-negative diplococci. This finding should be confirmed by culture on modified Thayer-Martin medium because the pharynx can be colonized by other *Neisseria* species. Sensitivity and specificity of culture has been reported to be 47% and 100% for detection of *N. gonorrhoeae* in the pharynx.[29] The ligase chain reaction, a test based on DNA amplification, has a sensitivity of 95% and specificity of 98% for detecting pharyngeal gonorrhea.[29] This test is not currently approved, however, by the U.S. Food and Drug Administration for use in extragenital testing.

Recommended treatment is with a single dose of intramuscular ceftriaxone.[8,30] Alternative antibiotic regimens include a single intramuscular dose of cefotaxime or a single oral dose of ciprofloxacin or levofloxacin. Combined treatment for *Chlamydia trachomatis* should be given in all cases because this organism is not reliably identified in throat cultures but still coexists in 45% of cases.[30] Treatment for *C. trachomatis* consists of a single oral dose of azithromycin as first choice therapy or, alternatively, a 7-day course of doxycycline.[30]

Treponema pallidum

Treponema pallidum is the spirochete that is the causative agent of syphilis. Primary syphilis can present with manifestations in the oral region in patients with the risk factor of orogenital contact. The most common finding is an ulcer and the most common affected site is the lip followed by the tongue and tonsil.[31] Oral involvement during the primary stage is painless, however, and does not present as pharyngitis. If left untreated, a latent period begins and secondary syphilis subsequently presents up to 6 months later. Secondary syphilis mainly presents with systemic symptoms but oropharyngeal complaints may also be prominent.[31] Symptoms include headache, malaise, low-grade fever, sore throat, rhinorrhea, neck mass, and rash.[32,33] Physical examination of the pharynx reveals oval, red maculopapules, and patches. Initially, these lesions are rich in spirochetes and highly infectious. The tonsils (unilateral or bilateral) may be enlarged and red. Nontender lymphadenopathy can be present in the cervical and other regions. A nonpruritic papular or maculopapular rash involving the palms and soles is characteristic of secondary syphilis.[31,32] Symptoms and signs of secondary syphilis can last for 3 to 12 weeks and disease then enters a latent phase if still left untreated.[31,33] At this point, about one third are cured without any specific treatment, another one third remain latent (no lesions but persistent positive serologic tests), and the remainder progress to the tertiary phase.

Diagnosis during suspected cases of secondary syphilis is made using microscopy or serologic tests.[32] Gram stain cannot detect this bacterium. Spirochetes can be detected by darkfield microscopy but *T. pallidum* cannot be distinguished from *Treponema microdentium*, a commensal in the oral cavity, using this technique.[31] Warthin Starry stain can detect *T. pallidum* in tissue specimens, although detection may not be possible late in the course of disease.[32] Nonspecific (RPR) and specific (FTA-ABS, TPHA) serologic tests are positive and the treponemal-specific tests remain positive even after adequate treatment.

Treatment for primary or secondary syphilis is with a single intramuscular dose of benzathine penicillin G.[30] Alternative therapy is with doxycycline or ceftriaxone but longer courses are required to provide a cure.

Chlamydia pneumoniae

Chlamydia pneumoniae is a gram-negative obligate intracellular organism. It exists in two forms. The elementary body is the infectious metabolically inactive extracellular form and the reticulate body is the noninfectious metabolically active intracellular form. The elemental body gets endocytosed and then changes into the reticulate body, which subsequently forms the characteristic intracytoplasmic inclusions. Approximately 36 hours later, the reticulate body condenses back into the elemental body, which undergoes release by cytolysis or exocytosis at 48 hours. The hallmark of infection is prolonged subclinical infection. The only known reservoir is humans and disease is transmitted through an airborne route.

Chlamydia pneumoniae infection in adults most commonly causes pneumonia and bronchitis.[34] Sore throat and hoarseness are usual complaints among these patients, and these symptoms may be prominent enough to be the presenting complaint. Cases of *C. pneumoniae* that produce pharyngitis without apparent lower respiratory tract involvement are rare.[35] In fact, this organism's role as a causative agent in primary cases of pharyngitis has been questioned. The diagnosis is difficult to confirm because *C. pneumoniae* is not easy to isolate by culture, enzyme immunoassay (EIA) is not sensitive, and polymerase chain reaction (PCR)/DNA amplification kits for reliable detection are still in the developmental stage. Serologic evidence of *C. pneumoniae* infection was found in 8.5% of adults presenting with acute pharyngitis,[36] but follow-up data suggested that the criteria for serologic diagnosis are not specific in that 19% of asymptomatic, healthy, culture, and PCR-negative adults also fulfilled the serologic criteria for acute *C. pneumoniae* infection.[37]

C. pneumoniae is susceptible to tetracyclines, macrolides, and fluoroquinolones but resistant to sulfonamides. Two- to 3-week courses of therapy are needed to eradicate the organism.

Mycoplasma pneumoniae

Mycoplasma pneumoniae is estimated to be responsible for 15% to 20% of cases of community-acquired pneumonia.[38] The greatest proportion of patients with pneumonia caused by *M. pneumoniae* is in the 15- to 19-year-old age group. This organism likely does not cause an isolated pharyngitis. Rather, sore throat, nasal congestion, and coryza accompany the pneumonia. Other symptoms include cough, fever, chills, and malaise. Bullous myringitis is not a common concomitant finding

during episodes of pneumonia. Involvement of other organ systems can occur and be associated with significant morbidity and death. Stevens-Johnson syndrome, hemolytic anemia, disseminated intravascular coagulation, pericarditis, myocarditis, meningitis, transverse myelitis, and Guillain-Barré syndrome have all been described.

Diagnosis of infection from *M. pneumoniae* cannot be made on clinical grounds alone. Chest radiographs usually show bronchopneumonia involving one or more lobes with or without a small pleural effusion. Complete blood count is usually normal, but 50% to 60% of patients have an increase in cold agglutinin titers.[39] This usually occurs after the second week of illness and normalizes 6 weeks later. Isolation by culture is possible but not practical due to the slow and fastidious growth of the organism. A complement-fixation test and enzyme immunoassay are available serologic tests that assist with diagnosis. These tests are limited, however, by the inability to establish an early diagnosis. The complement fixation antibodies do not rise until 2 to 4 weeks after infection and IgM antibodies do not rise until 1 week after infection. Antigen detection techniques and a PCR test are both being developed and tested, possibly providing an accurate method for physicians to make a prompt diagnosis.

Treatment is effective with tetracyclines, macrolides, and quinolones. Beta-lactam antibiotics are not effective.

Mycobacterium tuberculosis

In endemic populations, reactivation of tuberculosis can rarely present in the tonsils with or without concomitant pulmonary involvement.[40,41] All patients with tonsil involvement present with sore throat and most also have cervical lymphadenopathy. The rarity of this finding, however, even in patients with known tuberculosis who complain of sore throat is demonstrated in a study performed by Amin and Dawlatly.[42] These authors studied the tonsil tissue in 14 patients with pulmonary tuberculosis who also complained of sore throat. No granulomas were pathologically demonstrated in any of the specimens. The Armed Forces Institute of Pathology reviewed 22 cases of tonsils with granulomatous inflammation, which represented 0.08% (22 of 26,386 cases) of all tonsil and adenoid cases examined from 1940 to 1999.[43] Only three cases of tonsillar tuberculosis were diagnosed. Other etiologies found in the 21 patients with follow-up included sarcoidosis (n = 7), Hodgkin's disease (n = 2), squamous cell carcinoma (n = 1), toxoplasmosis (n = 1), and idiopathic (n = 7).

When affected by tuberculosis, the oropharyngeal examination reveals hypertrophic tonsils with ulceration and white exudates.[40] The tonsil tissue pathologically reveals caseating granulomas or granulomatous inflammation with organisms frequently seen on Ziehl-Neelsen stain. Mycobacterial culture is also necessary. A purified protein derivative (PPD) skin test will be positive unless the patient is immunosuppressed or has an overwhelming infection. Medical management with antituberculous agents is the recommended therapy. The diagnosis of tonsillar tuberculosis may be difficult to distinguish from sarcoidosis if the Ziehl-Neelsen stain is negative because both diseases are characterized by granulomatous inflammation, pulmonary disease, and lymphadenopathy.[43] It is important in this situation to make a definitive diagnosis rather than treating as a presumed case of sarcoidosis because corticosteroids can be harmful if the patient actually has tuberculosis.

Francisella tularensis

Francisella tularensis is a gram-negative bacillus and is the causative agent of tularemia. Tularemia occurs both sporadically and in epidemics in the United States.[44] There are two subtypes: Jellison type A, which is the more virulent and common biotype in North America, and Jellison type B, which is more common in Europe and Asia.[45] *F. tularensis* is a zoonotic organism that survives in rodents, ticks, raccoons, rabbits, calves, cats, and dogs. Ticks are the primary reservoir. Transmission occurs through blood-sucking arthropods and insects, ingestion of contaminated food or water, or inhalation of dust contaminated by feces of infected arthropods.[44,45] In some cases, the exact source of infection is still unclear even after thorough questioning. Person-to-person transmission is rare and not epidemiologically important.[44]

Luotonen and colleagues studied 127 patients with tularemia manifestations in the head and neck region.[46] This accounted for 11.5% of all patients treated at their institution for tularemia. Disease presented in three forms: glandular, ulceroglandular, and oropharyngeal. The oropharyngeal form accounted for 25% of the head and neck cases. Seventy percent of patients with the oropharyngeal form were older than 15 years. Identified sources of infection in these cases included contaminated hare meat and strawberries. Because the source for this form of tularemia is contaminated food or water, other family members are often infected also.[44]

The oropharyngeal form presents with fevers, chills, malaise, sore throat, and painful neck mass.[45,46] Signs include an acutely ill appearance, fever, pharyngeal erythema, exudative tonsillitis, and tender lymphadenopathy. The lymphadenopathy can suppurate during the course of illness. The clinical presentation can be easily confused with acute infectious mononucleosis, especially because there can be a false-positive Monospot test and atypical lymphocytes can be present on peripheral blood smear.[46] Cases can also easily be confused with GABHS pharyngitis and only discovered after failure of penicillin therapy.

Diagnosis is best determined by serum hemagglutination titers. A fourfold increase in titer or a titer greater than 1:160 at any time is considered sufficient for diagnosis given the clinical suspicion of disease.[44] These titers are usually within diagnostic range by 16 days after disease onset but not before 11 days. A PCR test has recently been described that may allow for earlier diagnosis in highly suspect cases.[47] No other laboratory tests are specific for this disease. Culture is usually not helpful because the organism is fastidious and grows poorly in vitro.

F. tularensis is resistant to beta-lactam antibiotics. Aminoglycosides, macrolides, fluoroquinolones, and tetracyclines are effective choices for antimicrobial therapy. A source from water resources or foods should be sought in order to avoid further cases in the local population.

Corynebacterium diphtheriae

Diphtheria is an example of an infectious disease that has almost been eradicated by the application of microbiologic and public health principles. The worldwide incidence decreased markedly with the administration of diphtheria toxoid shortly after World War II. It is currently a rare disease in the United States with fewer than five cases per year being diagnosed since 1980.[48] This disease has not been fully defeated, however. In 1994, epidemic diphtheria reemerged in the New Independent States (former Soviet Union) causing approximately 50,000 cases and 1800 deaths.[49] Outbreaks can also occur in immunized populations because adults can have serum antitoxin levels below the protective level.[50]

Corynebacterium diphtheriae is a nonmotile, gram-positive pleomorphic bacillus. Toxigenic strains are pathogenic and toxin production is mediated by a bacteriophage. The diphtheria exotoxin inhibits protein synthesis in mammalian cells by inactivating elongation factor 2. Antitoxin neutralizes circulating toxin but is ineffective once cell penetration has occurred.

Transmission occurs through infected secretions from the nose, throat, eyes, or skin lesions. Entry occurs through the mouth or nose and the organism initially remains localized to the mucosal surfaces of the upper respiratory tract. Local inflammation and toxin-mediated tissue necrosis causes formation of a fibrinous, patchy, adherent, gray-black pseudomembrane. The location of pseudomembranes can be nasal, tonsillar, pharyngeal, laryngeal, laryngotracheal, conjunctival, genital, or cutaneous. More than one area can be affected, but the oropharynx is the most commonly involved site. Attempts to remove a pseudomembrane characteristically causes bleeding from the underlying tissue. Sore throat and low-grade fever usually begin 1 to 2 days before development of the pseudomembrane. The severity of local symptoms is variable. Symptoms may be mild and resolve with sloughing of the pseudomembrane in 7 to 10 days. Alternatively, symptoms may be severe and life threatening if disease extends into or primarily involves the larynx, or if the pseudomembrane is aspirated after sloughing. A "bull-neck" appearance caused by marked swelling of cervical lymph nodes and extensive infiltration of the neck soft tissues typically develops in patients. This can cause external compression on the larynx with subsequent airway obstruction.

Toxin effects at distant sites cause myocarditis, neuritis, and acute tubular necrosis. Myocarditis is associated with delayed administration

of antitoxin and typically occurs just as the local disease is improving at 2 weeks after onset. Peripheral neuritis occurs 3 to 7 weeks later, usually affecting motor rather than sensory nerves, and commonly affecting the soft palate and pharyngeal muscles.

Definitive diagnosis is based on isolation of the organism. The pseudomembrane should be cultured and the laboratory should inoculate Loeffler's, tellurite, and blood agar media. Finding GABHS does not rule out the possibility of diphtheria because this organism can be co-cultured in 30% of cases.[51] Smears taken from organisms growing on Loeffler's medium characteristically show club-shaped organisms forming sharp angles with each other. This morphology is reminiscent of a "Chinese character" appearance. Recovered diphtheria should be tested for toxigenicity. This is performed using the guinea pig neutralization test or Elek's test. Elek's test is based on a commercially available antiserum and testing whether a precipitin reaction forms when this antiserum is placed on growing colonies.

Treatment consists of both the antitoxin and antibiotics. Outcome depends on the location and extent of the pseudomembrane, the patient's immunization status, and how quickly the antitoxin is administered. The antitoxin should be given as soon as possible because it can only inactivate toxin that has not already entered cells. The antitoxin is a hyperimmune antiserum of equine origin, so tests for sensitivity to horse serum should be performed before administration. The recommended dose is dependent on location of disease and duration of illness.[52] Antibiotics are needed to eradicate the organism. The recommended antibiotics are penicillin or erythromycin. Alternatively, *C. diphtheriae* is also sensitive to tetracycline, clindamycin, and rifampin. Supportive care is important because most patients have difficulty swallowing and some patients require intubation or tracheostomy to avoid upper airway obstruction. Booster vaccination should be given during the recovery period and serial electrocardiograms should be obtained for early detection of cardiac complications. Disease eradication should be documented by two negative cultures after completing treatment.

The patient's immunization history is important information in determining suspicion of disease because recent immunization or booster injection would make disease highly unlikely. Diphtheria toxoid booster injection is recommended every 10 years in adults. This is especially important for people that travel to epidemic or endemic areas. Immunized patients can still be carriers for the organism since the vaccination is directed solely against the toxin. When carriers are detected, treatment should consist of a course of antibiotics and a toxoid booster injection if none was administered during the previous year.

Yersinia enterocolitica

Yersinia enterocolitica is a motile, gram-negative bacillus that is a well-described cause of enteric infections. Pharyngitis symptoms occur in 20% to 30% of these patients with enteritis and, more recently, *Y. enterocolitica* has been described to cause pharyngitis in the absence of enteritis.[53] During a milk-borne outbreak, 14 of 172 patients with culture-documented *Y. enterocolitica* had pharyngitis without enteritis. All patients were adults with a median age of 38.5 years old. This contrasted with the patients affected by enteritis whose median age was 5 years old. Findings consistent among affected patients included exudative tonsillitis, tender cervical adenopathy, fever, and elevated leukocyte count (mean 16,000/mm^3). All patients demonstrated *Y. enterocolitica* on blood agar or MacConkey's agar from a throat specimen without any other identified organisms and showed a serologic response to the outbreak strain.

Although this organism does not commonly cause pharyngitis, prompt recognition is important because delayed diagnosis can lead to airway obstruction, bacteremia, sepsis, and death.[54] The treating physician should be suspicious in cases of exudative pharyngitis with continued symptoms, positive examination findings, and leukocytosis despite appropriate treatment for the more common causes of bacterial or viral pharyngitis. Throat culture or rapid antigen test for GABHS and serologic tests for infectious mononucleosis are negative. Patients with beta-thalassemia are at particularly high risk for development of *Y. enterocolitica* infection.[55] The organism is sensitive to tetracyclines, aminoglycosides, third generation cephalosporins, and trimethoprim-sulfamethoxazole. Penicillin, ampicillin, and first generation cephalosporins do not effectively treat this organism.

Viral Infection

Common Cold (Rhinovirus, Coronavirus, Parainfluenza Virus)

The most common cause (30% to 60%) of pharyngitis in adults is a self-limited viral infection that occurs as part of the common cold.[6] The average adult gets two to four colds each year, accounting for close to 20% of patients who present with an acute illness to health care providers.[56] Rhinovirus is the most common etiologic agent of the common cold.[8] Coronavirus and parainfluenza virus are less commonly implicated. Before the identification of a novel coronavirus as the cause of severe acute respiratory syndrome (SARS), the only illness that coronaviruses were thought to cause in humans was the common cold.[57] Interestingly, upper respiratory symptoms such as sore throat and rhinorrhea occur in a minority (13% to 25%) of patients with SARS.[57] Rather than showing hyperemia or edema, examination of the oropharynx reveals drying of the mucosa.[58] Lymphadenopathy is also typically absent in SARS.

Rhinovirus is a single-stranded RNA virus in the picornavirus family. More than 100 serotypes of rhinovirus exist. It is transmitted through large particle aerosols that initially affect the ciliated nasal epithelium. The virus does not directly invade the nasal epithelium, but rather causes an acute inflammatory reaction. Inflammatory mediators subsequently cause edema and hyperemia of the nasal mucosa that extends into the pharynx.

Presenting symptoms of the common cold may overlap with those of GABHS pharyngitis, but the sore throat is usually not severe and odynophagia is unusual. Patients usually complain of nasal symptoms (rhinorrhea, nasal stuffiness) that precede the throat symptoms. A nonproductive cough, hoarseness, and low-grade fever may also be present. The nasal mucosa is typically edematous and the oropharynx has mild erythema. Specific virologic diagnosis is unnecessary for most patients because it usually does not affect the management. Computed tomography (CT) scan of the paranasal sinuses cannot reliably distinguish patients with the common cold from those with acute bacterial sinusitis because imaging abnormalities are frequently found in both conditions.[59] The common cold most commonly causes CT scan abnormalities of the maxillary sinuses (87%), followed in frequency by occlusion of the ethmoid infundibulum (77%), abnormalities of the ethmoid sinuses (65%), abnormalities of the sphenoid sinuses (39%), and abnormalities of the frontal sinuses (32%). Imaging findings are usually bilateral. When associated with the common cold, most sinus CT abnormalities either markedly improve or resolve by 2 weeks after onset. Treatment for the common cold is symptomatic and consists of rest, oral hydration, and over-the-counter cold medications for relief of symptoms. Most healthy adults recover within 1 week. Antibiotics are not routinely used and are only indicated for secondary acute bacterial sinusitis, which occurs in 0.5% to 5% of cases.[59]

Influenza Virus

Influenza is a single-stranded RNA virus in the orthomyxovirus family. Three types (A, B, and C) have been identified but only types A and B cause widespread outbreaks.[60] Influenza A viruses are further classified into subtypes based on antigenic differences between the hemagglutinin and neuraminidase surface glycoproteins.[61] Disease is transmitted through an airborne route from respiratory droplets. Virus invades the respiratory epithelium, initially in the tracheobronchial tree but later throughout the whole respiratory tract. The hemagglutinin glycoprotein on the surface of the virus facilitates attachment to respiratory epithelial cells by binding to sialic acid receptors. The neuraminidase glycoprotein facilitates the release of progeny virions by catalyzing the cleavage of glycosidic linkages to sialic acid.

In North America, influenza presents as outbreaks in the late fall or winter. This disease is a worldwide problem, however. Each year, influenza develops in 500 million people globally with approximately 150,000 people requiring hospitalization in the United States alone.[60] This disease is also deadly. The pandemic of 1918 killed 20 million

people. In nonpandemic years, 20,000 to 40,000 deaths occur.[60] In pandemic years, this can reach 100,000 deaths annually. There is a variation in severity of disease based on several factors. Influenza A rather than type B is responsible for most of the significant morbidity and mortality. Very young patients are at higher risk for influenza-related hospitalization. Patients older than 50 years are at higher risk for complications. Patients with underlying comorbidities such as immunosuppression, cardiopulmonary disease, or diabetes are also at higher risk for a complicated disease course. Death is usually caused by a primary viral or secondary bacterial pneumonia. Bacterial organisms that cause pneumonia in these patients are community-acquired pathogens, *Staphylococcus aureus*, and group B *Streptococcus*.[60]

Patients present with abrupt onset of fever, headache, and myalgias. Sore throat, malaise, chills, sweats, nonproductive cough, and rhinorrhea shortly follow. The sore throat can be severe. Examination of the oropharynx typically reveals mild hyperemia and edema without exudates. Lymphadenopathy is an uncommon finding.

In uncomplicated infections, symptoms usually resolve after 3 to 5 days. Supportive therapy is indicated during this time period. Antiviral therapies with M2 ion channel blockers (amantadine) or neuraminidase inhibitors (zanamivir or oseltamivir) are currently available. Amantadine can reduce the duration of symptoms by about 1 day when started within 2 days of the onset of symptoms.[61,62] This medication has limitations, however, including rapid development of drug-resistant viral strains, lack of activity against influenza B, side effects (insomnia, light-headedness, hallucinations, dizziness, headaches, nausea, vomiting), and unproven efficacy for decreasing complications in high-risk populations. The neuraminidase inhibitors are effective against influenza type A and B and decrease symptoms by 1 to 2.5 days when started within 2 days of developing symptoms.[61,63] These drugs have also been shown to reduce complications in high-risk populations.[47] Current treatment recommendations for neuraminidase inhibitors include patients at high risk for complications or with severe disease.[60,61] Treatment should also be considered for patients not at high risk but when disease is diagnosed early.

With the availability of new treatments that need to be started early in the disease course in order to be beneficial, it is now more desirable to make a prompt, accurate diagnosis. The FDA has approved a few rapid diagnostic tests that give results in less than 15 minutes. Compared with throat culture (the gold standard for laboratory diagnosis), the sensitivity and specificity of these tests range from 62% to 73% and 80% to 99%, respectively.[62] Samples should be obtained from the nose rather than from the throat.

The best treatment for disease is prevention with the inactivated influenza vaccine that is prepared yearly based on the anticipated strains likely to appear during the flu season. Vaccination is 70% to 100% effective when the viruses in the vaccine and the viruses in the epidemic have been well matched antigenically.[61] The FDA has recently approved an intranasal vaccine with live attenuated virus as an alternative to the traditional inactivated injected vaccine.[62] This vaccine more accurately mimics natural infection and thus may provide a broader and more durable immunologic response. This vaccine can be used in healthy patients from 5 to 49 years old. Because this vaccine contains live influenza viruses, it should not be used in patients or close contacts of patients with chronic illnesses or immunodeficiency. The CDC recommends routine vaccination for people older than 50 years of age and encourages vaccination of children between 6 and 24 months old.[62] Other populations in whom vaccination is recommended are residents and employees of long-term care facilities, patients with chronic cardiopulmonary disease, patients with metabolic disease or immunosuppression, women in the second or third trimester of pregnancy during influenza season, health care personnel, and providers of home care to high-risk patients.[60] For high-risk patients who did not receive vaccination or who received vaccine in poor-match years, amantadine, zanamivir, or oseltamivir can be effective as prophylaxis against disease.[61,62,64] When used for this indication, medication must be taken daily for the duration of influenza risk in the community. During prolonged courses, the development of drug-resistant strains frequently occurs with amantadine and is a concern with the neuraminidase inhibitors.[65] Long-term use of amantadine is also difficult due to the side effects (listed earlier).

Human Immunodeficiency Virus

Acute human immunodeficiency virus (HIV) type 1 infection causes a mononucleosis-like syndrome in 40% to 90% of patients, which starts days to weeks after exposure.[66] This febrile illness is called acute retroviral syndrome (ARS). Due to the nonspecific signs and symptoms, even patients at risk for HIV are frequently not promptly diagnosed. Thus ARS should be included in the differential diagnosis in any patient with a fever of unknown origin and risk factors for HIV exposure.

The time course from mucosal breach to initial viremia is 4 to 11 days.[66] Symptoms related to ARS are caused by the robust immune response to replicating virus. The most common symptoms and signs include fever (median maximum temperature 38.9°C), lethargy, skin rash, myalgia, headache, pharyngitis, cervical adenopathy, and arthralgia.[67] Pharyngitis occurs in 50% to 70% of patients and usually appears as hypertrophy of the tissues of Waldeyer's ring without exudates. Other oral manifestations that are less commonly observed include ulcers (29%) and candidiasis (17%).[68]

Diagnosis is dependent upon laboratory tests. Complete blood count (CBC) may reveal lymphopenia or thrombocytopenia.[69] Atypical lymphocytes and a decreased CD4 cell count are usually not observed at this time. Because antibodies to HIV appear approximately 4 weeks after infection, enzyme-linked immunoassay (ELISA) and Western blot tests are also negative at this time. A quantitative plasma HIV-1 RNA level, tested by PCR, is necessary to make a timely diagnosis. This level will be greater than 50,000 copies per milliliter.[66,69] The high viral titer associated with ARS is reflective of the initial burst of viremia with wide dissemination of virus and seeding of lymphatic organs. If a quantitative plasma HIV-1 RNA level cannot be obtained, then detection of viral p24 antigen is an alternative test that can be used to make the diagnosis.

The natural history of ARS is resolution of signs and symptoms along with the viremia within 14 days after onset.[69] Disease progression to other HIV manifestations or AIDS ultimately occurs. Although data are limited regarding long-term benefits of early treatment, immediate and sustained therapy with antiretroviral medications may limit the extent of viral dissemination, restrict damage to the immune system, protect antigen-presenting cells, and reduce the chance of disease progression.[66] Patient compliance with sustained treatment is important because inconsistent adherence can cause viral resistance, which can limit future treatment options.

In patients with AIDS, persistent ulcers in the oropharynx can be caused by herpes simplex virus, cytomegalovirus, *Cryptococcus*, histoplasmosis, mycobacterial organisms, and lymphoma.[70] In many cases, however, no identifiable etiology is determined after exhaustive microbiologic, serologic, and pathologic tests. The pathogenesis of these ulcers is unclear but has been postulated to be immunogenic[71] and possibly related to the relative increase of CD8-positive cytotoxic T cells in the local tissues.[70] These ulcers progressively enlarge, have destructive behavior, and are extremely painful. There is a propensity for these ulcers to manifest in the tonsillar fossa, floor of the mouth, and epiglottis.[72] The pain associated with these ulcers causes significant odynophagia that can lead to malnutrition and wasting. Patients with these ulcers typically have advanced immunosuppression with a median CD4 count of 25 cells per cubic millimeter.[71]

Injected[72] and systemic[70] steroids have shown success for treating these AIDS-related ulcers. Friedman and colleagues showed that intralesional injections of triamcinolone acetonide completely healed 51% of the 36 treated ulcers by 4 weeks and 72% by 8 weeks.[72] For the 10 patients without complete clinical resolution, six still had marked symptomatic improvement. In other studies, preliminary data suggested that thalidomide was effective and a multicenter, double-blinded, randomized, placebo-controlled study was subsequently performed.[71] This study revealed complete healing in 55% of the patients in the thalidomide-treated group as opposed to 7% in the placebo-treated group. This was highly statistically significant. The median time to complete healing was 3.5 weeks. Most of the patients in the thalidomide group without a complete response had at least a partial response. Quality of life measures were performed on these patients and showed reduced pain and improved ability to eat.

Adenovirus

Adenovirus is a double-stranded DNA virus in the Adenoviridae family. Although adenovirus is well known as a causative agent of pharyngitis with conjunctivitis (pharyngoconjunctival fever) in children, serotypes 3, 4, 7, and 21 cause outbreaks of febrile respiratory illness in military recruits,[73,74] immunocompromised adults (particularly recipients of hematopoietic stem cell grafts),[75] and rarely in healthy young adult civilians.[76] Military recruits appear to be at particular risk because of crowding and physical stress associated with basic training. Before the availability of vaccines, adenoviral outbreaks occurred frequently in military recruits, affecting up to 10% of recruits and causing as much as 70% of all cases of respiratory disease.[77] This had significant implications on military readiness in that basic training was disrupted by an average of 3 days for each affected recruit.[77] Outbreaks also overwhelmed medical resources and caused significant economic loss. Beginning in 1971, live oral vaccines against serotypes 4 and 7 became available for use in the military and were administered to all male recruits from October to March of each year. This was changed to year-round immunizations in 1984 due to recurring outbreaks in the late spring and early fall. This intervention had a dramatic effect, reducing adenovirus-specific disease rates by 95% to 99%. The manufacturer of this vaccine stopped production in 1995, however, due to the inability to continue "good manufacturing practice" in existing facilities and stores of vaccine against serotypes 4 and 7 were depleted in 1998 and 1999, respectively. Outbreaks have now reemerged as a threat to the health of military recruits.[73,74,77]

In adults, adenovirus causes pharyngitis as part of a febrile respiratory illness. Sore throat is reported in 71% of patients. Adenovirus directly invades the pharyngeal mucosa and has a cytopathic effect. Thus, the sore throat is typically more severe than the common cold. Other associated symptoms include nasal congestion, dry cough, myalgia, headache, nausea, vomiting, and diarrhea. The average oral temperature was 38.9°C in one military outbreak.[77] Examination reveals an exudative pharyngitis that is difficult to distinguish from GABHS pharyngitis. More than half of affected patients received antibiotics at some point during their illness due to concern for a bacterial pharyngitis or respiratory infection.[77]

Adenoviral infection can be confirmed by culture from a throat swab. The culture specimen is grown on various cell lines in vitro and a cytolytic effect is observed. Immunofluorescence using an antiadenovirus monoclonal antibody is performed to confirm the diagnosis. Acute and convalescent serum can also be tested for antibody titers. PCR is a rapid, sensitive test for detecting adenoviral DNA in nasopharyngeal aspirates or serum.[78] In immunocompromised patients, detection of adenoviral DNA in serum precedes the development of severe systemic infections.[75]

Disease is usually self-limited and symptomatic treatment suffices for most cases. The average duration of symptoms is 10 days.[77] Significant morbidity and mortality can occur, however, in immunocompromised patients[75,79] and rarely in previously healthy young adults.[80] Infection can cause pneumonia, secondary bacterial infections, and more rarely meningitis, encephalitis, cystitis, nephritis, colitis, and death. For these severe adenoviral infections, there are no approved antiviral agents or antiviral therapies with proven efficacy. There are case reports and small case series supporting the possible benefits of ribavirin, cidofovir, ganciclovir, leukocyte transfusion, and intravenous immunoglobulin.[79]

Epstein-Barr Virus

Epstein-Barr virus (EBV) is a double-stranded DNA virus in the herpesviridae family. The virus remains ubiquitous in humans by remaining latent in B lymphocytes and intermittently replicating in oropharyngeal epithelial cells to enable transmission through saliva. Blood transfusion is more rarely the mode of transmission. Worldwide, 80% to 90% of adults are seropositive for EBV.[81] Nearly all children in developing countries seroconvert by 6 years old. But in industrialized countries, about 30% of cases occur during adolescence or early adulthood. In this population, 50% of patients seroconvert without development of an overt illness.[81]

EBV is the causative agent of infectious mononucleosis (IM). The initial route of infection occurs through the lymphoid tissues and pharyngeal epithelial cells. There is an initial incubation period of 3 to 7 weeks. A prodrome of malaise, fever, and chills is followed 1 to 2 weeks later by sore throat, fever, anorexia, and lymphadenopathy (especially cervical). Sore throat is found in 82% of patients with IM and is the most common complaint. Other symptoms may include abdominal discomfort, headache, stiff neck, and skin rash.

Figure 13-2. Infectious mononucleosis showing the characteristic exudative tonsillitis with tonsillar hypertrophy. *(Photo courtesy of Richard A. Chole, MD, PhD.)*

Examination of the oropharynx reveals an exudative pharyngitis with erythema and tonsillar hypertrophy (Fig. 13-2). Other findings may include diffuse lymphoid hyperplasia of Waldeyer's ring, petechiae at the hard palate–soft palate junction, and ulcers on the pharyngeal and epiglottic mucosa.[82] Prominent cervical adenopathy is commonly present. Splenomegaly and hepatomegaly are found in 50% and 15% of cases, respectively. Periorbital edema is found in up to 30% of cases.[81]

Infectious mononucleosis causes an absolute lymphocytosis with more than 10% atypical lymphocytes. A vigorous cytotoxic T-cell response to EBV accounts for the lymphocytosis and causes many of the associated symptoms. Finding atypical lymphocytes on a peripheral blood smear may be consistent with a clinical impression of IM but is not specific for this illness. Toxoplasmosis, cytomegalovirus, acute HIV-infection, hepatitis A, tularemia, and rubella can also be associated with this finding. Cytomegalovirus can cause a mononucleosis-like illness but typically the sore throat is much less prominent. Other serologic findings may include neutropenia (50% to 80%), thrombocytopenia (25% to 50%), and asymptomatic elevated transaminases (50% to 80%).[83]

Immunologic studies include the heterophile antibody test and EBV-specific antibody tests.[81] Heterophile antibodies are closely associated with primary EBV infection but they are not produced as an immune-specific response to EBV expressed antigens. Heterophile antibodies form the basis of the currently used Monospot test. Between 70% and 90% of adults with IM have a positive Monospot test, but this is usually detectable for a short time period beginning 2 to 3 weeks after the onset of pharyngitis and fever. EBV-specific antibody studies can accurately diagnose acute IM in Monospot-negative patients when there is still a strong clinical suspicion for this illness. EBV-specific antibodies to viral capsid antigen (VCA) are present at the onset of clinical symptoms as opposed to Epstein-Barr nuclear antigen (EBNA) antibodies that are present only during convalescent IM or with previous exposure.

Although most cases of acute IM have a self-limited course without significant sequelae, there is a wide range of complications that are well described.[83] Secondary bacterial infections, usually GABHS pharyngitis, occur in up to 30% of cases. A progressive upper airway obstructive symptom from lymphoid hyperplasia and severe tonsillitis occur in less than 5% of patients but is one of the most frequent reasons for hospitalization. Hepatitis as manifested by elevated transaminases is a common finding but jaundice occurs in only 5% of cases and ascities or fulminant liver failure occurs more rarely. Severe neurologic complications occur in 1% to 5% of patients and can manifest as

Figure 13-3. Viral pharyngitis with a herpes virus showing reddening of the tonsils. *(Photo courtesy of Richard A. Chole, MD, PhD.)*

meningitis, encephalitis, cranial neuropathies (especially VII), transverse myelitis, and Guillain-Barré syndrome. Other rare complications include spontaneous splenic rupture, hemolytic anemia, myocarditis, and psychosis.

Treatment for most affected patients consists of supportive care, rest, antipyretics, and analgesics. Patients should be advised to avoid contact sports until examination and abdominal ultrasonography confirms resolution of splenomegaly.[81] Antivirals are not beneficial in uncomplicated infections. Antibiotics are indicated only for secondary bacterial infections. Ampicillin or amoxicillin should not be used because these antibiotics cause a maculopapular rash in 95% of patients with IM.[83] Other beta-lactam antibiotics can cause a rash in 40% to 60% of patients with IM, so alternative antibiotics should be used. Steroids are indicated for complications related to impending upper airway obstruction, severe hemolytic anemia, severe thrombocytopenia, or persistent severe disease. Other airway interventions such as placement of a nasopharyngeal tube, endotracheal intubation, or tracheostomy are rarely necessary.

Herpes Simplex Virus

Herpes simplex virus (HSV) is a double-stranded DNA virus in the herpesviridae family. HSV type 1 (HSV-1) and type 2 (HSV-2) are distinguished by antigenicity. HSV-1 is usually associated with disease in the head and neck region, although HSV-2 has also been described to cause disease in this area.[84] Direct contact with oral secretions is the principal mode of HSV-1 transmission. Primary HSV infection has been increasingly recognized as a prevalent cause of acute pharyngitis among college students, where it accounts for approximately 6% of cases.[85] Immunosuppressed patients are also at particular risk.

Primary HSV-1 infection is characterized by pharyngitis with or without gingivostomatitis. Recurrent herpes labialis is a manifestation of reactivation rather than primary infection. The symptoms and physical examination signs are not easily distinguishable from GABHS pharyngitis as reflected by the frequent presumptive treatment with antibiotics.[85] Symptoms include sore throat, fever, malaise, and lymphadenopathy. Findings in the oropharynx include reddening and hypertrophy of the tonsils with an overlying exudates (Fig. 13-3).[82] Enlarged, tender cervical nodes are frequently present. Although the predominant symptoms and findings are associated with pharyngitis, 34% have at least one herpes-like lesion (painful, shallow ulcer) of the oral cavity or oropharynx.[85]

Diagnosis can be obtained by viral culture with confirmation using immunofluorescence. If present, vesicles contain the highest concentration of virus within the first few days of illness. Multinucleated giant cells seen in a Tzanck smear from cells obtained from the base of an ulcer indicate infection with a herpesvirus but further tests need to be performed to identify which virus within that family. Serologic tests for neutralizing antibodies have been described but may not be reliable for diagnosing primary infection.[86]

There is a paucity of data for treatment of primary HSV pharyngeal infections with antivirals. Patients could potentially benefit from effective treatment because 14% require hospitalization and 40% seek further medical attention for their symptoms after the initial evaluation.[85] Extrapolating from the beneficial effects during primary episodes of HSV genital infections, antivirals can potentially decrease symptoms if prescribed early. This needs to be studied in further detail. Unfortunately, there are currently no accurate tests for rapid diagnosis. Until such a test is available, it seems reasonable to consider antiviral therapy until culture results return in high-risk groups with severe pharyngitis symptoms and in patients with suggestive findings who do not present during an influenza outbreak and have no serologic evidence for infectious mononucleosis.[85]

Fungal Infection

Candida sp.

Candida sp. are fungi that can affect the oropharynx in the form of pseudomembranous candidiasis (thrush).[87] The most common isolated organism is *Candida albicans* but other organisms (*C. glabrata*, *C. tropicalis*, *C. dubliniensis*, *C. rugosa*, and *C.* krusei) are emerging as causative agents.[87,88] Because *C. albicans* is a normal commensal of the oral cavity, oropharyngeal candidiasis (OPC) is considered an opportunistic infection and is the most frequent opportunistic infection found in symptomatic HIV-positive patients.[89] In patients receiving radiation for head and neck cancer, *Candida* can be isolated in 73% of patients and cause infection in 27%.[90] Other populations at risk for disease include patients with xerostomia (prior radiation to head and neck area, Sjögren's syndrome, side effects from medications), use of steroid inhalers or broad-spectrum antibiotics, immunosuppression, diabetes mellitus, Cushing's syndrome, terminally ill conditions, and a high carbohydrate diet.[87]

Patients with OPC complain of oral discomfort, burning, altered taste sensation, and dysphagia. White pseudomembranes consisting of desquamated epithelial cells, fibrin, and fungal hyphae can be scraped off to expose the underlying mucosa that appears erythematous. Other areas that can be involved in addition to the oropharynx include the buccal mucosa, hard palate, soft palate, tongue, larynx, hypopharynx, and esophagus. Clinical symptoms and findings are not significantly different if OPC is caused by *C. albicans* or a non-*albicans Candida*. The diagnosis can be confirmed by KOH preparation or positive culture. Cultures can use an oral swab or a swish sample of 10 mL of normal saline instilled in the mouth for 10 seconds and then collected in a sterile container.[88]

Disease manifestations are usually local but rarely can become systemic and cause significant morbidity and mortality. Initial therapy for uncomplicated OPC includes improving oral hygiene and use of topical antifungals.[87] Patients with a refractory or recurrent infection or at high risk for systemic disease should be treated with systemic antifungals. Fluconazole is the predominant medication used to treat OPC because the predominant organism, *C. albicans*, has consistently shown sensitivity to the drug and it is generally well tolerated. With increased use, however, development of resistance to fluconazole has become a growing concern. Resistance is usually correlated to the degree of immunosuppression and the total dose of drug.[91] Itraconazole is an alternative effective antifungal and should be used for fluconazole-resistant strains.[87]

A resistant *C. albicans* infection, a non-*albicans Candida* infection, or a mixed infection should be suspected in patients without a clinical cure after a 14-day course of fluconazole (100 mg/day).[88] Mixed infections can be difficult initially to detect because *C. albicans* can predominate on the initial culture. Several non-*albicans Candida* species have elevated minimal inhibitory concentrations to fluconazole and require increased dosage (as high as 800 mg/day) to achieve a cure.[88,92] Additionally, treatment of mixed OPC infections of *C. albicans* and non-*albicans Candida* often require higher doses or longer courses of fluconazole to eradicate the infection.[93] Some *Candida* species such as *C. krusei* are resistant to fluconazole. Patients should have a repeat culture performed. Use of chromogenic media and antifungal susceptibility testing are helpful in these situations.

Prophylaxis for patients at high risk for relapse of OPC has been considered. Such populations include HIV-infected patients, bone marrow transplant patients, patients with chemotherapy-induced neutropenia, and patients receiving radiation for head and neck cancer. Fluconazole appears to be better than nystatin in this regard.[87] To assess the efficacy of prophylaxis, a randomized controlled trial comparing fluconazole (150 milligrams once weekly) to placebo was performed in a population of HIV-infected patients with an episode of documented OPC that responded to a 7 day course of fluconazole (200 milligrams per day).[89] The end-points of the study were third relapse of OPC, occurrence of an adverse drug reaction, development of resistance, or a total duration in the study of 18 months. This study revealed fewer relapses of OPC in the fluconazole-treated group. Importantly, development of resistant *Candida* was rarely observed and was not significantly different between the groups. Although this study proved that weekly fluconazole effectively decreased OPC relapses, the authors still recommend caution with long-term prophylaxis due to the inherent risk of developing resistance. Because of this concern, it has been suggested by others that antifungal prophylaxis be limited to patients not only at high-risk for relapses of OPC but also at high-risk for invasive fungal infections.[93] The optimal antifungal to be used in these situations is still under investigation.[94-96]

CHAPTER FOURTEEN

Deep Neck Space Infections

Eric R. Oliver

M. Boyd Gillespie

Key Points

- Methicillin-resistant *Staphylococcus aureus* is an increasingly common cause of deep neck space infections.
- Ultrasound will likely be applied more frequently for the diagnosis and management of deep neck space infections.
- Evaluation and maintenance of the airway are the first steps in management of deep neck space infections.
- Conservative management of deep neck space infections can often be used prior to surgical intervention.

Infections of the deep spaces of the neck often present a true clinical challenge. Although antibiotics have reduced their incidence, deep neck space infections remain a relevant health problem. The complex anatomic organization of the neck makes diagnosis and precise localization of deep infections difficult. Clinical suspicion remains critical in that many deep neck infections are not evident on palpation or visual inspection. Although improved imaging and medical protocols exist, surgical intervention remains a critical component of successful management.

Etiology

Infectious and inflammatory conditions of the upper aerodigestive tract are the primary instigators of deep neck infections. Multiple retrospective studies have revealed dental infections as the most common starting point, followed by oropharyngeal infections.[1-7] Acute bacterial tonsillitis and pharyngitis remain as leading causes in children. Suppuration of lymph nodes after an episode of cervical lymphadenitis may progress to a neck abscess. In the pediatric population, acute rhinosinusitis is a common cause of retropharyngeal lymphadenitis. Oral surgical procedures and endoscopic instrumentation may iatrogenically incite an upper airway infection or traumatize the pharyngoesophageal lumen. Sialadenitis, with or without ductal obstruction, can precipitate infectious spread. A foreign body trapped within the upper aerodigestive tract may initiate infection, while penetrating cervicofacial trauma can both introduce pathogens and serve as a conduit between adjacent spaces. Superficial infections, such as skin cellulitis, may spread along fascial planes. Needle injection associated with intravenous drug use introduces pathogens to the neck in a similar fashion as penetrating trauma. Congenital or acquired lesions such as branchial cleft cysts, thyroglossal duct cysts, or laryngoceles may become infected, with resulting spread. Acute mastoiditis may progress to a Bezold abscess with subsequent spread. Necrotic malignant lymph nodes can form an abscess. Immunocompromised patients must raise the index of suspicion for more virulent or atypical pathogens. Although the etiologic factors are many, a thorough search for the cause often reveals no clear source.

Wherever the starting point, the infection may spread from its portal of entry to other regions of the neck through the lymphatic system, arterial or venous channels, or direct extension between spaces and along fascial planes. The inflammatory process may plateau as a soft tissue phlegmon upon presentation, or culminate in a deep focal abscess, which usually demands surgical intervention.

Microbiology

The microbiology of deep neck space infections most often yields a mixture of aerobic and anaerobic organisms, usually representative of the oropharyngeal flora. Retrospective microbiologic analyses consistently demonstrate polymicrobial isolates.[2,7-11] The commonly cultured organisms, which often reflect the microbiology of odontogenic infections, are *Streptococcus viridans, Staphylococcus epidermidis, Staphylococcus aureus,* group A beta-hemolytic *Streptococcus (Streptococcus pyogenes), Bacteroides, Fusobacterium,* and *Peptostreptococcus* species. Cultures occasionally reveal *Neisseria, Pseudomonas, Escherichia,* and *Haemophilus* species. The proportion of community-acquired methicillin-resistant *Staphylococcus aureus* (MRSA)-associated neck space infections is significantly increasing in some regions of the United States, especially in pediatric populations.[12,13] One retrospective review concluded that MRSA is more likely to infect younger patients, but that a medial abscess location was less likely for both MRSA and methicillin-sensitive *S. aureus* infections.[13]

Atypical organisms may also initiate a deep neck infection. Actinomyces are endogenous saprophytic organisms of the oral cavity and tonsil. The most common site of cervicofacial actinomycosis is in the vicinity of the angle of the mandible, and this pathogen may cross fascial planes in its route of spread. A granulomatous reaction with central abscess formation and necrosis with "sulfur granules" is characteristic. Tuberculous and nontuberculous infection of the head and neck most commonly presents with cervical lymphadenopathy. Histopathologically, caseating necrotizing granulomatous inflammation is present. Cat scratch disease, caused by the pleomorphic gram-negative bacillus *Bartonella henselae*, manifests with large, tender cervical lymph nodes. Late lesions may form an abscess. Management of atypical neck space infections often leans toward nonsurgical management, because incision and drainage procedures may result in a chronic wound or fistulous tract.

Anatomy

Accurate diagnosis and application of timely treatment requires an understanding of the complex anatomic organization of the neck spaces. Fascial planes divide the neck into true and potential spaces.

The two main fascial divisions of the neck are the superficial cervical fascia and the deep cervical fascia, which further divides into three layers.

Superficial Cervical Fascia

The superficial cervical fascia, deep to the dermis, envelops the platysma and muscles of facial expression. It incorporates the superficial musculoaponeurotic system and extends from the zygoma to the axillae, clavicles, and deltopectoral region. Deep to the platysma, a potential space separates the superficial and deep cervical fasciae. This space houses adipose tissue, sensory nerves, and blood vessels, such as the anterior and external jugular veins, and facilitates free movement of the skin.

Deep Cervical Fascia

The deep cervical fascia is divided into three layers: the superficial, middle, and deep. The superficial layer of deep cervical fascia, or investing fascia, surrounds the neck. Posteriorly it attaches to the superior nuchal line, the ligamentum nuchae of the cervical vertebrae, and the mastoid process. As it transmits anteriorly, it splits and re-fuses to surround the trapezius and sternocleidomastoid muscles. Anterosuperiorly, this layer attaches to the inferior zygomatic arch. As it proceeds inferiorly, it splits to enclose the parotid gland, forming the parotid fascia superficially, and extends along the temporal bone to the carotid canal deeply. It envelops the muscles of mastication and covers the submandibular gland. This layer also forms the stylomandibular ligament, which separates the parotid from the submandibular gland. Inferiorly the investing fascia attaches to the hyoid, clavicle, acromion, and spine of the scapula, but first splits to encompass the intermediate tendon of the omohyoid and form the suprasternal space. The superficial layer of deep cervical fascia contributes to the lateral aspect of the carotid sheath.

The middle layer of deep cervical fascia, or visceral fascia, is composed of a muscular and visceral division. The muscular division surrounds the strap muscles (sternohyoid, sternothyroid, thyrohyoid, omohyoid). The visceral division surrounds the buccinator, pharyngeal constrictor muscles, larynx, trachea, esophagus, thyroid, and parathyroid glands. The visceral division forms a pretracheal fascia that overlies the trachea. The visceral division also contributes the buccopharyngeal fascia posterior to the esophagus, which separates the esophagus from the deep layer of deep cervical fascia and forms the anterior border of the retropharyngeal space. The buccopharyngeal fascia forms two raphae: (1) one in the posterior midline that adheres to the alar layer of the deep layer, and (2) the pterygomandibular raphe of the lateral pharynx. The middle layer also contributes to the medial aspect of the carotid sheath.

The deep layer of deep cervical fascia, or prevertebral fascia, divides into two layers: the prevertebral and alar layers. The prevertebral layer envelops the paraspinous muscles and cervical vertebrae, lying anterior to the vertebral bodies from the skull base to the coccyx, and attaching laterally to the transverse processes. It covers the scalene muscles and forms the floor of the posterior triangle. As it courses anteromedially, it contributes to the posterior carotid sheath and splits to form the alar layer. The alar layer lies between the prevertebral layer and the buccopharyngeal fascia of the visceral middle layer. The alar fascia separates the retropharyngeal and danger spaces and covers the cervical sympathetic trunk.

The carotid sheath extends from the skull base to the thorax, and is a confluence of each layer of deep fascia. The sheath contains the common carotid artery, internal jugular vein, vagus nerve, and ansa cervicalis.

Neck Spaces

The above fasciae and the structures within the neck form real and potential spaces. Many of these compartments openly communicate with each other, and some spaces are contiguous with distant regions of the body, offering a route of rapid transit for infections. The neck spaces can be organized by their location: the face (buccal, canine, masticator, parotid), suprahyoid neck (peritonsillar, submandibular, sublingual, parapharyngeal), infrahyoid neck (anterior visceral), and along the length of the neck (retropharyngeal, danger, prevertebral, carotid).

Parapharyngeal Space

Also called the *lateral pharyngeal* or *pharyngomaxillary space*, the parapharyngeal space is an inverted pyramid with its superior base at the skull base and its inferior apex at the junction of the posterior belly of the digastric muscle and greater cornu of the hyoid bone. The pterygomandibular raphe and medial pterygoid muscle bound the space anteriorly, while the prevertebral fascia bounds it posteriorly. The superior constrictor, tensor, and levator veli palatini muscles form the medial boundary, and the parotid gland, mandible, and lateral pterygoid muscle bound it laterally.

The styloid process divides the space into two compartments: the prestyloid compartment, which is anterior to the styloid process, and the post-styloid compartment, which is posterior to the process. The prestyloid compartment contains fat, muscle (styloglossus and stylopharyngeus), lymph nodes, deep lobe of the parotid, internal maxillary artery, inferior alveolar, lingual, and auriculotemporal nerves. The post-styloid compartment contains neurovascular structures: carotid artery, internal jugular vein, sympathetic chain, and cranial nerves IX, X, XI, and XII.

The parapharyngeal space provides a central connection for the major deep neck spaces. It connects posteromedially with the retropharyngeal space, inferiorly with the submandibular space, and laterally with the masticator space. The carotid sheath courses through the space into the mediastinum. Lateral extension from the peritonsillar space directly invades the parapharyngeal space.

Submandibular and Sublingual Spaces

These two spaces are best discussed together, because they functionally comprise a single space. The mucosa of the floor of the mouth forms the superior border of the submandibular space, and the digastric muscle and hyoid bone form the inferior. Anteriorly, the mylohyoid muscle and anterior belly of digastric bound the submandibular space, with the posterior belly of the digastric and stylomandibular ligament serving as its posterior borders. The hyoglossus, mylohyoid, styloglossus, genioglossus, and geniohyoid muscles are medial, with the platysma and mandible being lateral.

The mylohyoid muscle divides the submandibular space into a superior sublingual compartment and an inferior submaxillary compartment. This sublingual compartment is also called the *sublingual space,* and contains the sublingual gland and Wharton's duct. The supramylohyoid sublingual space is lateral to the geniohyoid and genioglossus muscles. The sublingual space openly connects to the submaxillary compartment around the free posterior edge of the mylohyoid. The inframylohyoid submaxillary compartment, sometimes itself called the *submandibular space,* connects to its corresponding space contralaterally and contains the submandibular gland and lymph nodes.

The relationship of the mylohyoid to the tooth apices, the mylohyoid line, determines the most likely route of odontogenic infectious spread. The teeth apices anterior to the second molar lie superior to the mylohyoid line and thus involve the sublingual space. Infections of the second and third molars initially involve the submandibular or parapharyngeal space, because their roots extend below the mylohyoid line.

Retropharyngeal Space

The retropharyngeal space, extending from the skull base to the mediastinum at the tracheal bifurcation, refers to the lymph node and connective tissue containing potential space between the middle and deep layers of deep cervical fasciae. The space lies anterior to the alar fascia of the deep layer and posterior to the buccopharyngeal fascia of the middle layer that lines the posterior pharynx and esophagus. The carotid sheath is lateral to the space. It typically becomes involved by direct spread from the parapharyngeal space, or lymphatic spread from the paranasal sinuses or nasopharyngeal region, primarily in children.

Danger Space

The danger space, so named because of the potential for rapid inferior spread of infection to the posterior mediastinum through its loose

areolar tissue, extends from the skull base to the diaphragm. This potential space lies between the retropharyngeal and prevertebral spaces. The deep layer of deep cervical fascia subdivisions bound this space. The alar layer forms its anterior border, and the prevertebral layer forms its posterior border. Laterally, the transverse processes of the vertebrae enclose the danger space. The sympathetic trunk courses through this space. Infectious infiltration from the retropharyngeal, parapharyngeal, or prevertebral spaces are the primary routes to the danger space.

Prevertebral Space

The prevertebral space is enclosed by the prevertebral fascia, vertebral bodies and transverse processes, and extends from the clivus of the skull base to the coccyx. It is a compact potential space that contains dense areolar tissue and lies posterior to the danger space. In addition to the paraspinous, prevertebral, and scalene muscles, it contains the vertebral artery and vein, brachial plexus, and phrenic nerve. The main pathways of spread to the prevertebral space are from infection of the vertebral bodies and penetrating injuries. Tuberculosis of the spine may breach the space and form a Pott's abscess.

Masticator Space

The superficial layer of deep cervical fascia defines the masticator space upon splitting at the inferior border of the mandible to cover the medial pterygoid and masseter muscles. Next, the fascia continues superiorly to cover the inferior tendon of the temporalis muscle and incorporate with the superficial temporalis fascia. It contains the mandible and muscles of mastication (masseter, temporalis, medial pterygoid, lateral pterygoid). The masticator space also contains the third portion of the trigeminal nerve, which enters through the foramen ovale, the internal maxillary artery, and much of the buccal fat pad. This space occupies a position anterolateral to the parapharyngeal space.

The masticator space is also further divided into subspaces: the masseteric space between the masseter muscle and ramus of mandible, the pterygoid space between the pterygoid muscles and ramus, the superficial temporal space between the superficial temporal fascia and temporalis muscle, and the deep temporal space between the deep temporal fascia and temporal bone. Transmission of infection into the masticator space is most commonly from the third mandibular molars.

Peritonsillar Space

The peritonsillar space consists of loose connective tissue between the capsule of the palatine tonsil and the superior constrictor muscle. The anterior and posterior tonsillar pillars contribute to its anterior and posterior borders, respectively. The posterior tongue forms the inferior boundary. Peritonsillar infections may readily spread to the parapharyngeal space.

Parotid Space

The superficial layer of deep cervical fascia forms the parotid space as it splits to surround the parotid gland. However, the fascia, which does not enclose the superomedial aspect of the gland, permits communication with the prestyloid compartment of the parapharyngeal space. The space also contains the facial nerve, external carotid artery, and posterior facial vein. It occupies a position lateral to the parapharyngeal space.

Carotid Space

The carotid, or visceral vascular, space is the potential space within the carotid sheath containing the carotid artery, internal jugular vein, vagus nerve, and sympathetic plexus. Infection from the surrounding parapharyngeal space, penetrating trauma, or intravenous drug use may potentiate spread into this space.

Anterior Visceral Space

The visceral division of the middle layer of deep cervical fascia encloses the anterior visceral space, or pretracheal space, which lies immediately anterior to the trachea. It extends from the thyroid cartilage to the superior mediastinum. It contains the pharynx, esophagus, larynx, trachea, and thyroid gland. Perforation of the anterior esophageal wall by endoscopic instrumentation, foreign bodies, or trauma may introduce infection to this space.

Clinical Evaluation

History

The symptoms of deep neck space infection are determined by both the generalized inflammatory process as well as localizing symptoms at the site of infection. Inflammatory symptoms such as pain, fever, swelling, and redness are common. Symptoms such as dysphagia, odynophagia, drooling, "hot potato" voice, hoarseness, dyspnea, trismus, and ear pain offer further clues about the location of the inflammatory process as well as its potential severity. The onset and duration of symptoms should be elicited. Recent events such as dental work, upper airway surgery or intubation, intravenous drug use, sinusitis, pharyngitis, otitis, or blunt or penetrating soft tissue trauma that preceded worsening symptoms should be identified in order to formulate a differential of likely microorganisms and common pathways of spread.

The past medical history should be reviewed to account for antibiotic allergies and immunodeficiency status. Patients with a history of human immunodeficiency virus, hepatitis, diabetes, collagen vascular diseases, hematologic malignancy, and recent chemotherapy or steroid use are at increased risk of atypical pathogens and rapidly progressive disease.

Physical Examination

A complete head and neck physical examination is required in all patients with a potential deep neck space infection. Palpation of the neck and face may identify localizing tenderness or fluctuance as well as crepitus caused by airway trauma or gas-producing organisms. Otoscopic examination of the ear and nasal passages can rapidly reveal edema, purulence, drainage, and tenderness, as well as ruling out obstructing foreign bodies. Examination of the oral cavity and oropharynx is facilitated by the use of a headlight, which frees up the hands for bimanual examination. Difficulty with mouth opening indicates that inflammation has already spread into the parapharyngeal, pterygoid, or masseteric spaces. An odontogenic source of infection should be considered in the presence of alveolar swelling and decayed, loose, tender, or broken teeth. The floor of the mouth should be assessed for visible edema, which may cause posterior deflection of the oral tongue. Stensen's and Wharton's ducts should be assessed for purulent discharge and palpated for obstructing stones.

Visualization of the oropharynx is necessary to assess for asymmetric lateral or posterior wall swelling, and/or deviation of the uvula. Unilateral pharyngeal wall swelling in the absence of associated inflammatory symptoms such as fever and mucosal erythema should raise the possibility of parapharyngeal tumors, which should not be biopsied or incised without further evaluation. A unilaterally enlarged, irregular, or ulcerated tonsil, especially in the setting of prolonged exposure to tobacco and alcohol, may indicate the presence of tonsillar malignancy.

A complete cranial nerve examination is recommended. Infections of the upper dentition, paranasal sinuses, facial soft tissues, and parotid place the orbits at increased risk due to retrograde flow through the facial and ophthalmic veins. Edematous eyelids must be manually separated in order to assess the underlying globe. Reduced mobility of the globe and/or an absent papillary light reflex indicates orbital inflammation or abscess that requires urgent attention to save the eye.

Awake flexible fiberoptic evaluation of the upper airway is indicated in most cases of suspected deep neck space infections and is mandatory if the patient has hoarseness, dyspnea, stridor, or dysphagia or odynophagia without obvious cause on oropharyngeal examination. Normal pulse oximetry results do not eliminate the need for direct airway evaluation because the oxygen saturation is a poor proxy for airway status and typically does not fall until the airway is completely occluded. The presence of a patent, midline, noninflamed airway should be documented before the patient is transported for radiographic evaluation to prevent an airway emergency while the patient is supine in the radiology suite. Direct evaluation of the airway identifies patients who may be difficult to intubate by standard technique if surgery is required.

Laboratory Evaluation

Blood Tests

An initial complete blood count typically demonstrates leukocytosis in cases of deep neck infection. A lack of a leukocytic response may indicate viral illness, immunodeficiency, or a condition such as a tumor, which can be confused with deep neck infection. Daily measures of the white blood cell count may be helpful in monitoring a patient's response to treatment such as intravenous antibiotics or surgical drainage. Intravenous steroids are often necessary to reduce upper airway inflammation in deep neck infection and should not be withheld out of concern that steroid-related leukocytosis will make it difficult to monitor treatment response. A basic electrolyte panel should also be obtained to assess glucose level, bodily hydration, and renal function in case general anesthesia becomes necessary during treatment.

Imaging Studies

Plain Film Radiography

Radiographic imaging plays a critical role in evaluation of suspected deep neck infections. Plain film technology is inexpensive, rapid, and widely available, and it provides excellent information in select circumstances. In cases of suspected dental origin, plain film radiography or a Panorex of the jaw can help identify dental sources of infection if not already obvious on physical examination. Translucencies at the apex of the dental root are a common finding with dental-related abscess. Lateral neck films are useful for quickly evaluating the upper aerodigestive tract in cases of suspected retropharyngeal abscess or supraglottitis. Presence of an air-fluid level or greater than 5 mm of thickening in a child or greater than 7 mm of thickening in an adult of the prevertebral tissue at C2 indicate retropharyngeal infection until proven otherwise. Thickening of the epiglottis, commonly known as "thumbprint sign," and arytenoids indicate likely supraglottitis with urgent need for direct airway evaluation in a controlled setting with tracheotomy capabilities. Chest radiography is indicated in cases of dyspnea, tachycardia, or cough to rule out aspiration or mediastinitis.

Computed Tomography

Computed tomography (CT) scans of the head and neck are a critical component in the evaluation of deep neck infection because physical examination alone can misidentify the involved space and the number of involved spaces in 70% of cases.[14] CT scans with intravenous contrast provide excellent visualization of most bony and soft tissue structures of the head and neck. The intravenous contrast allows visualization of the great neck vessels and enhancement of areas of inflammation. CT scans are valuable in determining whether the infection is contained within the lymph nodes or has spread beyond into the fascial planes of the head and neck. Although CT is excellent for identifying the presence of deep neck infection, it cannot reliably differentiate between the generalized edema of phlegmon versus purulent abscess because both commonly appear as hypodense collections with peripheral enhancement (Fig. 14-1). The decision to explore the neck therefore should be made on clinical grounds with the expectation that pus will not be found in up to 25% of explorations.[15] Metastatic adenopathy most commonly from a tonsillar primary should be ruled out clinically because this may mimic neck abscess on CT scan, or may contain abscess if secondarily infected (Fig. 14-2).[16,17] The CT scan provides valuable information about which neck spaces require exploration and drainage at the time of surgery. The use of intravenous contrast is contraindicated in most patients with iodine or contrast dye allergy and in patients with compromised renal function. Therefore other imaging modalities are indicated when intravenous contrast cannot be used.

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) is not routinely used for suspected deep neck infections, but it should be considered in select circumstances when it is superior to CT. In addition, MRI scanning is time consuming and less likely to be tolerated by a patient who is in pain or is having trouble swallowing or maintaining an airway while supine. MRI scans may provide additional detail to CT in infections involving the intracranial cavity, parotid, and prevertebral space. Evaluation of the major vessels of the head and neck is occasionally indicated if there is suspicion of suppurative thrombi of major head and neck vessels such as the sigmoid sinus, internal jugular vein, or cavernous sinus, or if infection followed trauma to the neck such as an intravenous needle stick. MR angiography with venous flow-through provides excellent evaluation of thrombi and pseudoaneurysm, but invasive angiographic techniques may be needed for stenting or balloon occlusion in rare cases of infected pseudoaneurysms.

Ultrasonography

Ultrasonography is used extensively in the evaluation of both benign and malignant lesions of the head and neck in Europe, but has been largely limited to the evaluation of thyroid lesions in the United States. It is likely this modality will be used more in the future to evaluate neck infections because portable ultrasounds are becoming more readily

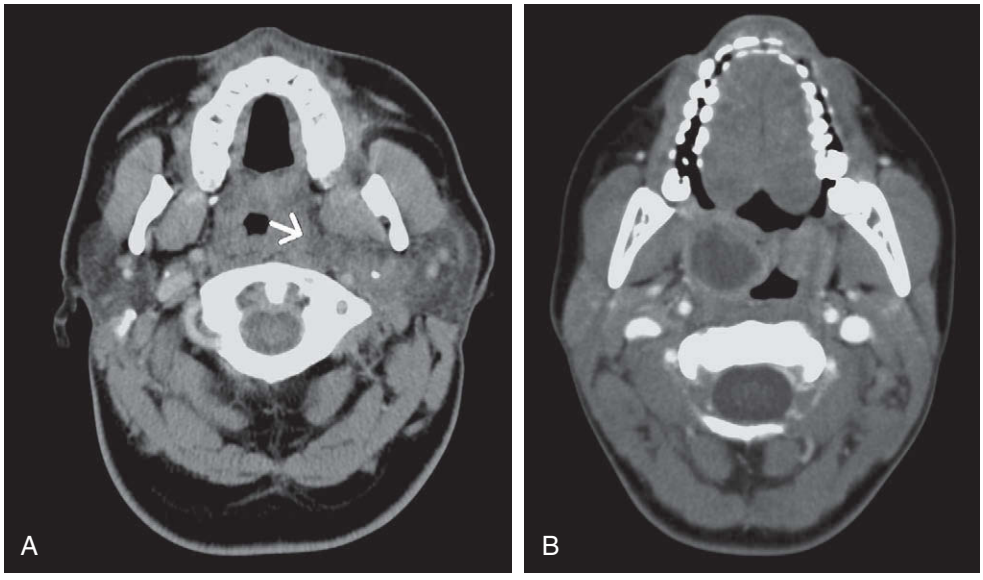

Figure 14-1. Computed tomography scans of deep neck infections may indicate inflammatory phlegmon (*arrow*) without obvious abscess early in the course of deep neck infection **(A)** or a mature infection with abscess formation **(B).**

Figure 14-2. A hypopharynx carcinoma initially diagnosed as a retropharyngeal abscess.

available in emergency departments and outpatient clinics. The noninvasive nature of ultrasound makes it an attractive imaging modality for pediatric patients, and the lack of radiation reduces concerns about potential long-term harm. Most ultrasonography practitioners are adept at using the ultrasound to perform fine-needle aspiration, which may be helpful to obtain culture or provide therapeutic drainage.[18] Ultrasound may be limited in cases of significant neck edema or phlegmon, or when the infection involves spaces beyond the focal range of the technology. Even though the fluid levels of abscesses can be seen by ultrasound if they are large and superficial enough, lack of visualization does not rule out the possibility of abscess due to its limitations on serial evaluation of multiple cross-sectional spaces that are better seen on CT.

Treatment

Medical Management

Airway Management

The initial management of any patient with a known or suspected deep neck infection is securing a safe airway. Loss of airway has traditionally been the major source of mortality from deep neck infection.[19] Airway complications should be anticipated in all cases of deep neck infection and especially infections involving the floor of the mouth, the parapharyngeal space, and the retropharyngeal space. Fiberoptic evaluation of the upper airway at the time of initial evaluation often identifies an evolving airway complication before it occurs. Pulse oximetry monitoring is helpful if interpreted in the proper context, but a normal oximetry should not provide false security in a patient who appears to be in airway distress. Patients with airway compromise should not be transported out of an intensive care suite for prolonged radiographic testing until the airway is secure. Intravenous access should be obtained to allow rapid administration of medications and anesthetic agents when needed. First-line airway therapy includes use of an oxygenated face tent with cool mist humidity, intravenous steroids, and epinephrine nebulizers. If the patient has mild airway symptoms and the examination reveals mild edema with less than 50% obstruction at the glottic or supraglottic level, the patient often responds to medical therapy alone while under direct observation in the emergency suite or intensive care unit.

Urgent airway intervention is necessary if there are greater levels of stridor and dyspnea, usually accompanied by airway obstruction of more than 50%. Effective communication between the consulting otolaryngologist and critical care/anesthesiology personnel is critical. The otolaryngologist needs to convey the results of the initial airway evaluation with the anesthesiologist and be actively involved in intubation planning. In general, an awake fiberoptic intubation can be successfully performed if the airway is visualized to be large enough to allow the passage of the average flexible bronchoscope (5 to 6 mm). Airway preparation with lidocaine nebulizers and lidocaine jelly–lubricated nasal trumpets with or without light sedation allows most adult patients to be intubated comfortably while awake. The patient should be sitting upright, and strong suction should be available to clear airway secretions to improve visualization. A tracheotomy set should be available in the room in case a surgical airway is required. An elective tracheotomy may be considered if extubation is not anticipated within 24 to 48 hours, or if surgical drainage procedures are likely to result in significant or prolonged airway edema. In such situations, elective tracheotomy has been associated with reduced hospital days and reduced costs compared to prolonged intubation.[20] An awake tracheotomy should be planned in cases where minimal or no airway lumen is visualized. Increasing peak airway pressures and frothy airway secretions following successful intubation may indicate the onset of postobstructive pulmonary edema, which typically resolves with positive pressure mechanical ventilation and judicious use of intravenous diuretics.

Fluid Resuscitation

Poor fluid intake is common when neck infection causes significant dysphagia, odynophagia, or trismus. Dehydration is especially common in infections of the peritonsillar and retropharyngeal spaces, and may be the main etiology of sialadenitis-related infections of the parotid space. Signs of fluid deficit include tachycardia, dry and pasty mucous membranes, and decreased skin turgor. Even so, most patients benefit from timely infusion of 1 to 2 L of isotonic intravenous fluids. Providing adequate fluid resuscitation before surgical intervention reduces the severity of anesthesia-related hypotension.

Antibiotic Therapy

Prophylactic antibiotics given before dental, oral, and head and neck procedures may reduce the risk of deep neck infection. Prophylaxis should consist of an oral or intravenous dose of a beta-lactamase–resistant penicillin or clindamycin given within 30 minutes of procedures on nonsterile body cavities, or a first-generation cephalosporin (e.g., cephalexin) or clindamycin for neck incisions in a sterile field. Prophylaxis is mandatory for any patient with a history of heart murmur, rheumatic valve disease, or vascular or joint prosthetic devices.

Deep neck infections require timely treatment with intravenous antibiotics at the time of diagnosis due to the rapidly progressive nature of these infections. Culture is not required before empiric antibiotic therapy because broad-spectrum coverage is usually necessary; most cases involve mixed flora of gram-positive cocci and gram-negative rods with or without anaerobes.[21] Antibiotic coverage may need to be expanded in cases of otologic or sinus infection or nosocomial infections in which *Pseudomonas* is more common, whereas expanded anaerobic coverage is often necessary for fulminate odontogenic infections.

Fluids obtained from aspiration or incision and drainage should be sent for culture due to the increasing rate of resistant organisms in the at-large community. Culture and sensitivity information is especially valuable in the setting of hospital-acquired infections or an immunocompromised host. Due to increasing rates of MRSA in the community, it is likely that more deep neck infection will be caused by this organism in the future. A detailed history and physical examination often identifies patients at risk for atypical infections, which should be confirmed by staining and culturing aspirated fluids or tissue biopsy samples. The choice of antibiotic therapy is typically dictated by the clinical scenario and by culture and sensitivity findings (Table 14-1).

Intravenous antibiotic therapy without surgical intervention may be sufficient therapy in certain circumstances.[22] If a patient is clinically stable and if imaging studies demonstrate inflammation without likely

Table 14-1

First-Line Antibiotic Alternatives for Deep Neck Infection

Community-Acquired Infection (gram-positive cocci; gram-negative rods; anaerobes) Alternatives

- Ampicillin-sulbactam 1.5 to 3 g. IV every 6 hours
- Clindamycin *(if penicillin allergic)* 600 to 900 mg IV every 8 hours

Compromised Patients/Nosocomial Infection (*Pseudomonas*; Methicillin-Resistant *Staphylococcus aureus*)

Pseudomonal and Gram-Negative Alternatives

- Ticarcillin-clavulanate 3 g IV every 6 hours
- Piperacillin-tazobactam 3 g IV every 6 hours
- Imipenem-cilastatin 500 mg IV every 6 hours
- Ciprofloxacin *(if penicillin allergic)* 400 mg IV every 12 hours
- Levofloxacin *(if penicillin allergic)* 750 mg IV every 24 hours

Methicillin-Resistant *Staphylococcus aureus*

- Clindamycin 600 to 900 mg IV every 8 hours, plus vancomycin 1 g IV every 12 hours

Necrotizing Fasciitis (Mixed Gram-Positive and Expanded Anaerobes)

- Ceftriaxone 2 g IV every 8 hours, plus clindamycin 600 to 900 mg IV every 8 hours, plus metronidazole 500 mg IV every 6 hours

Figure 14-3. An infected thyroglossal duct cyst that responded to needle aspiration followed by excision several weeks later.

abscess or an abscess contained within a lymph node, then a 48- to 72-hour trial of empiric intravenous antibiotic therapy is appropriate. A trial of empiric antibiotics is recommended in almost all stable pediatric cases because even sizable collections may respond favorably to intravenous antibiotics and steroids alone.[23] In general, the patient should be given nothing by mouth and closely monitored for changes in clinical status and elevation in white blood cell count. Repeat imaging and/or surgical intervention is necessary in cases that fail to improve or worsen during the observation period. If significant clinical improvement is noted with intravenous antibiotics after 48 to 72 hours, therapy is continued for 24 hours beyond normalization of symptoms followed by a 2-week course of an equivalent oral antibiotic. Patients requiring surgery usually need 48 to 72 hours of intravenous antibiotics postoperatively before being discharged home on oral therapy.

Surgical Management

Surgical drainage is indicated in most cases of deep neck infection. Surgical drainage is necessary under the following circumstances: (1) air-fluid level in the neck or evidence of gas-producing organisms; (2) abscess visualized in the fascial spaces of the head and neck; (3) threatened airway compromise from abscess or phlegmon; (4) failure to respond to 48 to 72 hours of empiric intravenous antibiotic therapy. The main goals of surgical intervention include providing a fluid or tissue sample for tissue staining and culture and sensitivity testing, and providing therapeutic irrigation of the infected body cavity while establishing a stable external drainage pathway to prevent the reaccumulation of abscess.

Needle Aspiration

Needle aspiration without incision often suffices for small abscesses contained within the confines of a lymph node or when an acute infection is caused by suspected congenital cysts or fibrotic pseudocysts (Fig. 14-3). Recurrent infection is common in head and neck cysts; therefore complete surgical excision should be planned after the acute inflammation subsides. For adults, aspiration can be performed at the bedside when the neck mass is palpable and the patient cooperative. Children younger than 12 years of age typically require conscious sedation to prevent errant aspiration. Applying lidocaine ointment to the skin surface for 20 minutes before the aspiration aids in patient comfort. Lidocaine injections often hurt as much as the therapeutic aspiration itself and may obliterate the palpable contours of the mass, making the aspiration more difficult. Slow advancement of a 16- or 18-gauge intravenous catheter on a control syringe while applying negative pressure usually allows localization of the abscess. The needle can be removed from the catheter and the catheter flushed with 1 to 2 mL of sterile saline when the pus is too thick to fully aspirate. Image-guided techniques using ultrasound or CT are being increasingly used when the initial unguided fine-needle aspiration is unsuccessful or the mass is nonpalpable.[24,25] Image guidance also allows placement of small pigtail catheters using Seldinger technique for drainage and flushing.

Transoral Incision and Drainage

The peritonsillar space can be accessed transorally in a cooperative adult without significant trismus. The procedure is often more likely to succeed and be more comfortable to the patient if intravenous fluid rehydration, pain medication, antibiotics, and steroids are administered at least an hour before the procedure. Following application of topical anesthetic spray, 1 to 2 mL of 1% lidocaine with 1:100,000 epinephrine is injected into the mucosa of the lateral soft palate. An initial attempt to drain the space by aspiration is reasonable and helps locate the abscess pocket. If the space cannot be decompressed with aspiration alone, a 1- to 2-cm incision is performed through the mucosa and submucosa along the normal curvature and 1 cm behind the edge of the anterior tonsillar pillar. Gentle vertical spreading of the incision with a hemostat will access the peritonsillar space and allow egress of the abscess. Irrigation with sterile saline using a 20-mL syringe and 18-gauge angiocatheter can easily be performed through the incision. The patient can be discharged home on oral pain medication and antibiotics with outpatient follow-up arranged within 48 to 72 hours. Tonsillectomy at a later date is an option for patients with a history of peritonsillar abscess, recurrent or chronic tonsillitis, or obstructive symptoms from tonsillar hypertrophy. Approximately 16% of adults and 7% of children will experience a recurrent peritonsillar abscess at a later date after an initial episode.[4] Alternatively, acute "quinsy" tonsillectomy at the time of presentation can be considered in cases of recurrent peritonsillar abscess, recurrent acute tonsillitis, or if a general anesthetic is needed due to patient discomfort or poor exposure. Acute

tonsillectomy may be more difficult and bloody than nonacute tonsillectomy due to the surrounding inflammation; therefore the surgeon should have access to adequate lighting, suction, electrocautery, tonsil packs, and suture.

Transoral incision and drainage is also a preferred method of surgery for select deep neck space infections. Odontogenic infections limited to the alveolus may respond to removal of the offending tooth to drain the infected root, although neck incision is necessary when infection has spread beyond the alveolar tissues. A neck incision with dependent drainage of the bilateral floor of the mouth through the mylohyoid muscle is mandatory in cases of Ludwig's angina to reduce the risk of airway obstruction. The buccal space can be accessed via transoral incision of the buccal mucosa with blunt dissection parallel to the facial nerve through the buccinators muscle. The masticator space can be entered by incision of the retromolar trigone with blunt dissection through the masseter. After drainage and irrigation, a ½-inch Penrose drain or gauze wick can be placed through the incision and secured with a silk suture if ongoing drainage is deemed necessary. Otherwise, the wound can be left open to close secondarily or closed loosely with interrupted Vicryl or chromic suture.

The retropharyngeal space is often best entered transorally, especially because many infections in this space originate from the adenoids and are located in the high oropharynx or nasopharynx, which is difficult to access through the neck. After securing the airway and inserting a tonsil gag, transmucosal needle aspiration of the likely site of infection is performed. Once the abscess pocket is identified, the overlying mucosa is incised and blunt dissection used to enter the pocket. Caution should be exercised when dissecting beyond the lateral pharyngeal walls to prevent inadvertent injury to the carotid artery. Drains are typically not placed due to the potential for drain aspiration and potential difficulties with drain removal. If a drain or wick is placed, it can be brought out through the mouth and taped securely to the face. Alternatively, a small ellipse of mucosa and submucosa can be excised at the site of incision to slow the healing process and allow several days of drainage before wound contraction.

Transcervical Incision and Drainage

Transcervical incision and drainage is the traditional surgical approach to deep neck space infection. The location of the incision is dictated by the neck spaces that require exploration. If the skin above a neck abscess has become fluctuant, adequate drainage can often be achieved under local anesthesia with or without sedation via an incision oriented along the relaxed skin tension lines. In general, the deep neck spaces can be accessed by one of three potential incisions that provide both excellent anatomic exposure as well as cosmetic healing. The preauricular parotid incision with neck extension allows access to the parotid and temporal spaces. A horizontal neck incision in a natural skin crease provides access to the masticator, parapharyngeal, pterygoid, submandibular, prevertebral, retropharyngeal, carotid, and lateral neck spaces. The parapharyngeal and pterygoid spaces are entered by retracting the submandibular gland anteriorly while dissecting superior and medial to the posterior belly of the digastric muscle along the medial surface of the mandibular ramus. The prevertebral and retropharyngeal spaces are entered by first identifying the prevertebral fascia by retracting the strap muscles medially and the carotid sheath laterally at a level inferior to the carotid bifurcation. The space can then be bluntly dissected superiorly in the midline to the level of the abscess. The midline horizontal neck incision can be made to access the region of the strap muscles, thyroid, and trachea. A horizontal incision in the lower left neck with dissection to the prevertebral fascia medial to the carotid sheath provides a drainage conduit for the esophagus and upper mediastinum. A horizontal submental incision provides a direct route to the bilateral submandibular spaces and floor of mouth.

After securing the airway by an awake fiberoptic intubation or tracheotomy, the proposed incision site is marked on the neck, injected with 1% lidocaine with 1:100,000 epinephrine, and sterilely prepped and draped. In most cases, the patient should not be paralyzed during the procedure in order to allow monitoring of adjacent cranial nerves. The guiding principle of surgery for deep neck infection is obtaining adequate access and drainage of the infected space while minimizing risk to normal structures. Following incision through the superficial cervical fascia, blunt dissection with a small curved hemostat and Kitner sponge can help separate normal structures while creating a pathway to the infected compartment. Finger dissection of neck tissues should be avoided in patients with a history of transcervical IV drug abuse because broken needles may be left in the neck soft tissue. Access to the deep neck often requires excision of enlarged lymph nodes that block access to the infected space; however, care should be exercised not to overdissect because this may increase the risk to normal nerves and vessels that may be displaced or obscured by inflammation. Once the deep neck space is entered, any fluid or pus should be cultured, followed by irrigation with copious amounts of isothermic normal saline. External drainage is maintained by placement of a ½ to 1-inch Penrose drain, which is brought out through the incision and secured to the neck skin with a suture. The remainder of the incision can be closed loosely with 4.0 nylon sutures.

Selected Complications of Deep Neck Infections

Vascular Complications

Lemierre's Syndrome

Lemierre's syndrome is a rare thrombophlebitis of the internal jugular vein most often caused by the anaerobic, gram-negative bacillus *Fusobacterium necrophorum*.[26] Although this syndrome is rare, awareness is important given the characteristic presentation and potentially fatal outcome if not recognized and treated. The syndrome typically follows a period of pharyngitis before progressing to fever, lethargy, lateral neck tenderness and edema, occasional trismus, and septic emboli most commonly seen as bilateral, nodular infiltrates on chest radiograph or septic arthritis. The bacterium is thought to spread via the tonsillar veins to the internal jugular system where the bacterial endotoxin induces platelet aggregation and septic thrombus formation. Diagnosis is confirmed by neck CT with IV contrast demonstrating a filling defect in the internal jugular system. First-line therapy includes intravenous beta-lactamase–resistant antibiotics with or without heparin anticoagulation. Surgery to excise the jugular vein may be indicated in patients with a worsening clinical course despite appropriate medical therapy or in the event of neck abscess formation.

Cavernous Sinus Thrombosis

Cavernous sinus thrombosis is a life-threatening infection with a mortality rate of 30% to 40% caused by retrograde spread of infection from the upper dentition or paranasal sinuses via the valveless ophthalmic venous system to the cavernous sinus.[27] Symptoms include fever, lethargy, orbital pain, proptosis, reduced extraocular mobility, and dilated pupil with sluggish pupillary light reflex. The diagnosis is best confirmed by magnetic resonance study of the brain with contrast to demonstrate dural enhancement in the region of the cavernous sinus. Treatment includes critical care life support, broad-spectrum intravenous antibiotics, and anticoagulation therapy.

Carotid Artery Pseudoaneurysm or Rupture

Rare cases of carotid artery pseudoaneurysms or rupture have been reported after spread of infection from the retropharyngeal or parapharyngeal spaces to the carotid space.[28] Hallmarks of this complication include a pulsatile neck mass, Horner's syndrome, palsies of cranial nerves IX through XII, expanding hematoma or neck ecchymosis, or bright red blood from the nose or mouth in the setting of a deep neck infection. The complication requires immediate surgical ligation of the carotid artery.

Mediastinitis

Mediastinitis is a relatively rare complication of deep neck infection with a mortality rate of 30% to 40% caused by spread of infection along the retropharyngeal and prevertebral planes of the neck into the upper mediastinum.[29,30] Presentation includes diffuse neck edema, dyspnea, pleuritic pain with deep breathing, tachycardia, hypoxia, and

pleural effusion or mediastinal widening on chest radiograph. Thoracic CT scan with intravenous contrast often reveals the presence of fluid collection, air-fluid levels, or stranding or infiltration of the mediastinal fat. Broad-spectrum intravenous antibiotics are necessary due to a high frequency of multiple pathogens including gram-positive, gram-negative, aerobic, and anaerobic species. If limited to the anterior-superior mediastinum, transcervical drainage via a bilateral cervicotomy with blunt dissection along the prevertebral plane often provides sufficient access for drainage, irrigation, and placement of soft rubber drains. Thoracotomy should be strongly considered in cases that extend beyond the upper mediastinum or that involve more than one mediastinal compartment. In a meta-analysis of 69 patients with mediastinitis from cervical abscess, the mortality rate was 19% among patients who underwent both cervical and thoracic drainage, and 47% among those who underwent cervical drainage alone.[31]

Necrotizing Fasciitis

Necrotizing fasciitis is a severe form of deep neck infection that occurs more often in older age groups (age older than 60 years) and immunocompromised patients, especially patients with poorly controlled diabetes.[32] The origin of the infection is commonly odontogenic and involves mixed aerobic and anaerobic flora. Clinical presentation may consist of a rapidly progressive cellulitis with pitting neck edema and orange-peel appearance from obstructed dermal lymphatics with or without subcutaneous crepitus. Neck CT with intravenous contrast reveals tissue gas in more than 50% of cases, and widespread, nonloculated hypodense areas without peripheral enhancement consistent with liquefaction necrosis. Treatment requires critical care support, management of immunocompromising conditions, broad-spectrum intravenous antibiotics, and surgical exploration. Findings at surgery consistent with necrotizing fasciitis include foul odor, brown, watery fluid collections, and liquefied and grayish fat and muscle that pull apart with minimal finger pressure. Debridement of dead tissue until a bleeding, viable edge or vital nerves or vessels are reached is recommended. The wound is thoroughly irrigated, packed with moist gauze, and left open for a second-look procedure in 48 to 72 hours. Surviving patients may require skin grafting or flap reconstruction once the infection subsides. Adjuvant hyperbaric oxygen therapy can be considered if available.[33] Mortality may be as high as 20% to 30% in treated patients, and is highest in patients with mediastinal extension.[32]

CHAPTER FIFTEEN

Head and Neck Manifestations in the Immunocompromised Host

Theresa B. Kim

Steven D. Pletcher

Andrew N. Goldberg

Key Points

- Immunosuppressed patients are at risk for fungal, bacterial, and viral infections, and have higher rates of certain malignancies, often with a more aggressive clinical course than that seen in immunocompetent individuals.
- Most immune deficiencies are acquired and affect the adaptive immune system, resulting in T and B cell dysfunction.
- Highly active antiretroviral therapy (HAART) has had a profound impact on the disease course of HIV and has led to a decrease in many of the complications associated with the disease.
- There is a striking similarity in the pattern of increased rates of cancer in HIV-positive patients and transplant recipients, suggesting that immune deficiency plays a role in the pathogenesis of cancer.
- Human herpesvirus 8 infection coupled with the host's state of immunosuppression plays a causal role in the development of Kaposi's sarcoma.
- Immunosuppressed organ transplant recipients are at highest risk for nonmelanoma skin cancer and squamous cell carcinoma is twice as likely to develop as basal cell carcinoma.
- Most lymphomas occurring in immunosuppressed patients are non-Hodgkin's lymphoma of the B-cell type, the majority of which are associated with Epstein-Barr virus infection.
- Salivary gland dysfunction marked by decreased salivary flow rates and xerostomia is common in immunosuppressed patients.
- Many patients with HIV develop parotid lesions, the most common of which are benign lymphoepithelial cysts that are effectively treated with HAART in most cases.
- Invasive *Aspergillus* infections such as invasive fungal sinusitis and malignant otitis externa are life-threatening conditions occurring in immunosuppressed patients that require prompt recognition and treatment with surgical debridement and systemic antifungal agents.
- Hearing loss is common in immunosuppressed patients and may result from infectious causes in HIV-positive patients or immunosuppressive drugs in organ transplant recipients.
- Oral candidiasis is the most common oral lesion in HIV-positive patients but must be distinguished from other infectious and neoplastic lesions.

Spectrum of Immunosuppression

Immunosuppression occurs in the setting of genetic, infectious, and other acquired disorders. The cells of the immune system derive from hematopoietic stem cells in the bone marrow, circulate in the blood and lymph, and are present in nearly every tissue.[1] Protection of the host occurs by two mechanisms: innate and adaptive. The innate immune system is widely conserved among many vertebrate species and is the first line of defense. The primary cells involved are neutrophils, eosinophils, basophils, macrophages/monocytes, dendritic cells, and natural killer cells. Adaptive immunity protects the host against pathogens that escape innate immune responses and is a characteristic of higher vertebrates. The cellular components involved in adaptive immunity are T cells and B lymphocytes. Immunodeficiencies can affect any of the components of the innate and adaptive immune systems.

Congenital immunodeficiencies, which are less common than acquired, rarely affect the innate immune system. Severe combined immunodeficiency (SCID) affects both the T and B cells of the adaptive immune system, and children born with this disorder often die of infections in early childhood. Other genetic immunodeficiencies that affect T and B cells include DiGeorge's syndrome, X-linked agammaglobulinemia, Wiskott-Aldrich syndrome, common variable immunodeficiency, and selective immunoglobulin deficiencies in which serum concentrations of one or more immunoglobulin subclasses are reduced. Clinical characteristics of T-cell dysfunction include onset of symptoms in early infancy (4 to 5 months) with recurrent fungal, viral, and mycobacterial organisms and infections with opportunistic infections such as *Pneumocystis*.[2] B-cell deficiencies are marked by recurrent infections with encapsulated organisms such as sinopulmonary infections, otitis

Table 15-1

Causes of Immunosuppression

Genetic

Common variable immunodeficiency (CVID)
DiGeorge's syndrome
Selective immunoglobulin deficiencies
Severe combined immunodeficiency (SCID)
Wiskott-Aldrich syndrome
X-linked agammaglobulinemia (XLA)

Acquired

Human immunodeficiency virus (HIV)
Hematologic malignancies
Myeloproliferative disorders
Diabetes mellitus
Iatrogenic drug-induced immunosuppression
Chemotherapeutic agents
Corticosteroids
Immunosuppressive agents after solid organ and bone marrow transplantation

media and sepsis, and increased incidence of atopy, but no increased susceptibility to fungal or viral infections.[2]

Acquired immunodeficiencies are much more common than genetic immunodeficiencies. Acquired immunodeficiency may result from infection with the human immunodeficiency virus (HIV); hematologic malignancies and myeloproliferative disorders such as multiple myeloma or leukemia; diabetes mellitus; or iatrogenic drug-induced immunosuppression from chemotherapeutic agents, corticosteroids, and other immunosuppressive agents after solid organ and bone marrow transplantation (Table 15-1). Patients with immunosuppression are at higher risk than their immunocompetent counterparts for developing fungal, bacterial, and viral infections, and have higher rates of certain malignancies. Much of this pathology may manifest in the head and neck and thus otolaryngologists should be familiar with the spectrum of disease affecting immunocompromised patients.

Human Immunodeficiency Virus/Acquired Immunodeficiency Syndrome

Biology and Immunology

HIV infects and debilitates lymphocytes and macrophages leading to progressive immune compromise. Progressive decline in immune function in later stages of infection culminates in the acquired immunodeficiency syndrome (AIDS). Anecdotal reports[3] of unusual infections and idiopathic immune deficiency, primarily in homosexual men, began in the early 1980s and rapidly grew into the HIV/AIDS epidemic that has affected the world population. Every day, more than 6800 people become infected with HIV and 5700 people die of AIDS.[4] Worldwide, approximately 33.2 million people are living with HIV infection, with sub-Saharan Africa being the most severely affected region, where AIDS is the leading cause of death. After many years of increase, the global prevalence of HIV has stabilized and in some countries has even decreased.[4] With wider availability of effective treatment, rates of death have also recently begun to decline.

Transmission of HIV occurs through body fluids and tissues. Virus from an infected patient may inoculate the bloodstream of another individual through a breach in skin or mucosa, or via intravenous infusion. Modes of transmission include sexual intercourse, the sharing of needles by intravenous drug users, vertical transmission from mother to child, and, rarely, transfusion of contaminated blood products or accidental exposure in health care workers. More than 50% of new HIV infections in the United States occur in men who have sex with men; infection after heterosexual intercourse and injection drug use lead to 32% and 18% of new infections, respectively.[4]

HIV is a retrovirus in the Lentivirus subfamily, named for the slow progression of disease in affected individuals. These viruses establish chronic infections with a long incubation time and slow progression of disease. Viruses in the Lentivirus family typically infect cells involved in immune modulation; in the case of HIV, that is primarily CD4 T cells and macrophages, resulting in defects in both humoral and cell-mediated immunity. The virus life cycle begins when the virus binds to the CD4 receptor, a surface protein on the helper T subset of T lymphocytes, which is also expressed on macrophages. Fusion of the viral and cell membranes allows entry of the viral core into the cell. The reverse transcriptase enzyme, a protein carried by the virus, allows transcription of RNA into DNA (a reversal of normal transcription), then mediates transcription of the viral RNA genome into viral DNA. Viral integrase, another viral protein, then facilitates incorporation of the viral DNA into the host genome. The viral DNA is transcribed into multiple RNA copies by the host cell. This newly created RNA may be spliced and translated into viral proteins or it may remain intact as a future viral genome. Translation of some viral RNA sequences results in protein precursors or multiple proteins bound together. These precursors undergo proteolytic processing by a viral protease that liberates the functional viral proteins. These proteases are required for viral infectivity. Following replication of the viral genome and proteins, the new viruses bud from the infected cell and proceed to infect new cells. The viral DNA polymerase is error-prone, incorporating one mismatched nucleotide per genome per round of transcription. This, combined with the amount of replication that occurs, establishes a vast pool of genetic diversity.[5,6] The development of vast genetic diversity also gives the virus an advantage in the development of drug resistance and provides a critical barrier to vaccine development.

Diagnosis and Classification

HIV infection is diagnosed when anti-HIV antibodies are detected in the serum by screening enzyme-linked immunosorbent assay (ELISA) and is confirmed with specific antibody detection with Western blot. Persistent antibodies against HIV typically occur within 3 months of infection. The CDC classification system for HIV, last updated in 1993, is based on the clinical manifestations of disease and the patient's CD4 count (Table 15-2).[7] These classifications assist in assessing the level of immune compromise and the corresponding risk for development of opportunistic infection or neoplasm. Three clinical categories have been identified: (A) asymptomatic HIV infection, persistent generalized lymphadenopathy, or acute HIV infection (a mononucleosis-type syndrome); (B) symptomatic conditions such as oral thrush, oral hairy leukoplakia, and fungal sinusitis that are attributed to HIV infection but do not fall into category A or C; (C) AIDS-defining conditions (Table 15-3). Patients may be further stratified according to their CD4 counts: (1) >500 cells/μL; (2) 200 to 499 cells/μL; (3) <200 cells/μL. The lowest accurate CD4 count, not the most recent, is used for classification purposes. AIDS is diagnosed for any patient who develops an AIDS-defining illness (category C) or CD4 less than 200 cells/μL (category 3). The World Health Organization (WHO) classification for HIV infection includes four clinical stages[8]:

1. Asymptomatic HIV infection or persistent generalized lymphadenopathy

2. Moderate unexplained weight loss (<10% of body weight), recurrent respiratory tract infections, herpes zoster, angular cheilitis, recurrent oral ulceration, papular pruritic eruptions, seborrheic dermatitis, or fungal nail infections

3. Unexplained severe weight loss (>10% of body weight), chronic diarrhea or persistent fever for more than 1 month, oral manifestations such as persistent oral candidiasis, oral hairy leukoplakia, or necrotizing gingivitis, pulmonary tuberculosis (current), severe bacterial infections, unexplained anemia, neutropenia, or chronic thrombocytopenia

Table 15-2

Classification System for HIV Infection

CD4 Categories	Clinical Categories (A) Asymptomatic, Acute or Persistent Generalized Lymphadenopathy	(B) Symptomatic	(C) AIDS-Defining Illness
(1) >500 cells/μL	HIV	HIV	AIDS
(2) 200 to 499 cells/μL	HIV	HIV	AIDS
(3) <200 cells/μL	AIDS	AIDS	AIDS

Table 15-3

AIDS-Defining Illnesses

Burkitt's lymphoma, immunoblastic or primary brain
Candidiasis, bronchopulmonary or esophageal
Cervical cancer, invasive
Coccidioidomycosis, disseminated or extrapulmonary
Cryptococcosis, extrapulmonary
Cryptosporidiosis, chronic intestinal (>1 month)
Cytomegalovirus disease (liver, spleen, and lymph nodes excluded)
Encephalopathy, HIV-related
Herpes simplex, chronic ulcers (>1 month), bronchopulmonary or esophageal
Histoplasmosis, disseminated or extrapulmonary
Isosporiasis, chronic intestinal (>1 month)
Kaposi's sarcoma
Mycobacterium avium complex, *Mycobacterium kansasii,* or other species, disseminated or extrapulmonary
Mycobacterium tuberculosis, any site
Non-Hodgkin's lymphoma
Pneumocystis jiroveci pneumonia (formerly *Pneumocystis carinii*)
Pneumonia, recurrent
Progressive multifocal leukoencephalopathy
Salmonella septicemia, recurrent
Toxoplasmosis of brain
Wasting syndrome caused by HIV

Adapted from CDC 1993 revised classification system for HIV infection and expanded surveillance case definition for AIDS among adolescents and adults. *MMWR Morb Mortal Wkly Rep.* 1993;41(RR-17):1.

4. HIV wasting syndrome, *Pneumocystis* pneumonia, recurrent severe bacterial pneumonia, chronic herpes simplex infection for more than 1 month, esophageal candidiasis, extrapulmonary tuberculosis, Kaposi's sarcoma (KS), cytomegalovirus infection, central nervous system (CNS) toxoplasmosis, HIV encephalopathy, extrapulmonary cryptococcosis, chronic cryptosporidiosis or isosporiasis, disseminated mycosis, lymphoma or other solid HIV-associated tumors, invasive cervical carcinoma, or symptomatic HIV-associated nephropathy or cardiomyopathy

Highly Active Antiretroviral Therapy

When left untreated, HIV infection causes gradual debilitation of the immune system over a period of years, resulting in profound immunocompromise and AIDS. Advances in understanding of HIV biology have allowed for the development of medications targeting the reverse transcriptase and protease enzymes critical to the viral life cycle. Current drugs do not eradicate the virus, thus the major goals of treatment are the complete inhibition of HIV replication, reduction in HIV-related morbidity, and prevention of vertical transmission.[9-11] Antiretroviral agents from five classes of drugs are currently available to treat HIV infection. These include nucleoside/nucleotide reverse transcriptase inhibitors (NRTIs), non-nucleoside reverse transcriptase inhibitors (NNRTIs), protease inhibitors (PIs), entry inhibitors (EIs), and integrase inhibitors.[11] Combinations of three or more of these agents allow for such effective suppression of viral replication that the emergence of drug-resistant variants is delayed, forming the basis of highly active antiretroviral therapy (HAART).[10] The use of HAART is credited for a 45% decline in mortality rates during the late 1990s, although in more recent years, the decline in mortality has been more modest, only 8% between 2000 and 2004.[12]

The U.S. Department of Health and Human Services recommends initiation of HAART for patients with history of an AIDS-defining illness or with CD4 less than 350 cells/μL.[11] The timing of HAART initiation in asymptomatic patients with CD4 greater than 350 cells/μL is not well defined and the decision should be guided by the potential benefits and risks associated with therapy, patient comorbidities, and willingness to adhere to long-term treatment. Drug resistance testing is recommended for all patients with diagnosed HIV, regardless of whether treatment will be initiated. Two types of combination regimens are generally used: NNRTI-based (one NNRTI with two NRTI) and PI-based (one or two PI with two NRTI). The choice of regimen is determined by patient comorbidities (e.g., tuberculosis infection, liver disease, and cardiovascular disease), dosing convenience, potential drug interactions, and results of genotypic drug resistance testing.

Immune Restoration Disease

Recently, infections with opportunistic organisms occurring in HIV-positive patients who initiate antiretroviral therapy have been recognized and are known as immune reconstitution syndrome or immune restoration disease (IRD).[13,14] Diagnostic criteria for IRD include a previous diagnosis of AIDS, concurrent antiretroviral therapy with increasing CD4 cell count, and an exacerbation or atypical presentation of opportunistic infections.[15] The most common pathogens associated with this condition are *Mycobacterium* (tuberculous and nontuberculous), *Cryptococcus*, herpesviruses, and hepatitis B and C viruses.[13] Symptoms may occur as soon as a few days following HAART initiation, although most patients develop symptoms 2 to 8 weeks after beginning HAART.[15] IRD may occur in 10% to 50% of patients initiating HAART, but opportunistic infections are rare, occurring in 5% of patients.[16] It is also seen in 5% of transplant recipients after dose reduction in immunosuppressive medications.[17] IRD is thought to be caused by overly exuberant pathogen-specific immune responses as

patients recover immune function.[13-15,17] IRD-associated mycobacterial infections generally present with fever, lymphadenopathy, and worsening respiratory function.[18] HIV-positive patients not already receiving HAART who present with mycobacterial infections should not be started on HAART until after the infection is controlled.[15] Trials examining the role of steroidal and nonsteroidal anti-inflammatory agents in the treatment of IRD are ongoing.[18]

Occupational Exposure to Human Immunodeficiency Virus Infection

With more than 1.3 million HIV-positive children and adults in the United States[4] and with the high prevalence of otolaryngologic complaints among these patients, most otolaryngologists will treat HIV-positive patients. An understanding of the risks of occupational transmission as well as precautions that may minimize such transmission is essential. There have been 57 documented cases of HIV seroconversion among U.S. health care personnel following occupational exposure, the most recent occurring in 2000.[19] Because of the voluntary nature of the reporting system, there may be underreporting of cases. Exposures that carry a risk for HIV transmission are percutaneous injuries (e.g., needlestick or cut with a sharp object) or contact of mucous membrane or nonintact skin with blood, tissue, or body fluids that are potentially infectious. The risk of transmission from fluid other than blood or transmission through nonintact skin is too low to be estimated in prospective studies. Even though cerebrospinal fluid carries a risk of transmission, nasal secretions, saliva, sputum, sweat, tears, urine, and vomitus are not considered infectious unless they are visibly bloody.[20] Pooled prospective data suggest an average risk of HIV transmission of 0.3% for needlesticks and 0.09% following mucous membrane exposure.[21] Whereas injury from suture needles has been suggested as a possible source of occupational exposure to HIV, such an injury has not been implicated as a source of transmission in prospective studies. Although a lower viral load (<1500 RNA copies/mL) or one that is below the limits of detection probably indicates a lower titer exposure, it does not rule out the possibility of transmission.

Prevention of blood exposure through the use of safe practices, barrier precautions, safe needle devices, and other innovations is the best way to prevent infection with HIV and other blood-borne pathogens.[22] Simple strategies such as using double gloves, eye protection, impermeable gowns, and special techniques for passing sharp objects have all been suggested to minimize exposure risk. Despite such precautions, needlesticks and mucosal exposures will continue. After exposure to blood or other infectious fluids, the following actions should be taken immediately[22]: Wash needlestick areas and cuts with soap and water; flush nose, mouth, or skin with water; irrigate eyes with clean water, saline, or sterile irrigants. To minimize the risk of disease transmission, postexposure prophylaxis (PEP) should be initiated within hours of exposure and should continue for 4 weeks.[20] The number of agents used depends on the type of exposure and risk profile of the source patient (Table 15-4). Treatment may be discontinued if the source patient subsequently tests negative for HIV infection and does not demonstrate any evidence of acute HIV infection. Exposed individuals should be tested for HIV at the time of exposure with follow-up testing at 6 weeks, 12 weeks, and 6 months after exposure.[20] Prevention of HIV transmission following PEP is not complete. There have been at least 20 cases of seroconversion despite the use of PEP,[21] with some of the patients having received multiple drug regimens. Thus careful adherence to universal precautions with avoidance of exposure remains the most prudent way to prevent infection.

Table 15-4

Postexposure Prophylaxis (PEP) Recommendations

	Infection Status of Source		
Exposure Type	**HIV-Positive, Class 1[a]**	**HIV-Positive, Class 2[b]**	**HIV Status Unknown[c]**
Less severe[d]	Basic 2-drug PEP	Expanded ≥ 3 drug PEP	Generally no PEP warranted; consider basic 2-drug PEP for source with HIV risk factors[e]
More severe[f]	Expanded 3-drug PEP		

[a]Asymptomatic HIV infection or known low viral load (<1500 copies/mL).
[b]Symptomatic HIV infection, AIDS, or known high viral load.
[c]For example, deceased source person with no samples available for HIV testing.
[d]For example, solid needle or superficial injury.
[e]If PEP is administered and the source is later determined to be HIV-negative, PEP should be discontinued.
[f]For example, large-bore hollow needle, deep puncture, visible blood on device.

Immunosuppression and Malignancy

Patients with immune deficiency are at increased risk for developing malignancy (Table 15-5). The mechanism of oncogenesis is unknown, but the striking similarity between increased malignancies in immunosuppressed transplant recipients and patients with HIV suggests that immune function plays a vital role. In HIV, three types of cancer occur at markedly increased rates during later stages of the disease and are thus considered AIDS-defining malignancies. These include KS, non-Hodgkin's lymphoma (NHL), and invasive cervical cancer. A meta-analysis comparing the incidence of cancer in patients with HIV/AIDS and immunosuppressed transplant recipients demonstrated a striking similarity in the pattern of increased rates of most types of cancer. Both groups had increased rates of AIDS-defining malignancies, Hodgkin's lymphoma, squamous cell carcinoma of the lip, and nonmelanoma skin cancer.[23] Non–AIDS-defining malignancies in patients with HIV also occur later in the disease course, often after the diagnosis of AIDS.[24,25] These findings suggest that immune deficiency plays a role in the pathogenesis of cancer, although the mechanism of oncogenesis is unknown. There is no clear evidence linking immune depression with other types of head and neck cancer.

Kaposi's Sarcoma

Epidemiology and Pathogenesis

KS is an angioproliferative disorder that causes lesions marked by spindle cell proliferation, neoangiogenesis, inflammation, and edema.[26,27] There are four clinical variants with identical histologic features but with distinct epidemiologic patterns: classic KS, endemic KS, immunosuppression—or transplant-related KS, and HIV-associated KS (AIDS-KS).[28-30] The classic form of KS was first described in older men of Eastern European or Mediterranean descent, with lesions typically occurring on the upper and lower extremities.[29] An endemic variety of KS was also recognized in black adults and children in Africa, where it was and continues to be very common.[31] In 1981, Friedman-Kien published a report of KS occurring in otherwise healthy young homosexual men[32] and eventually the association between HIV infection and the development of KS became well established. By 1989, HIV-KS was reported in 15% of all US patients with AIDS.[33] The overall risk of KS in AIDS patients was estimated to be 20,000 times that of the general population and more than 300 times that of other immunosuppressed patients. Since the introduction of effective antiretroviral therapy, there has been a marked decrease in the incidence of AIDS-KS,[34,35] with estimated incidence now being approximately 5%.[36] As solid organ and hematopoietic transplantation became more common, transplant recipients were also found to be at increased risk for developing KS.[37-39] Prevalence reports vary depending on geographic location, ranging from 0.5% in the United States to 5.3% in Saudi Arabia.[40] The risk

Table 15-5

Head and Neck Malignancies Associated with Immunosuppression

Malignancy	Immunosuppressive State	Site(s) of Presentation	Notes
Kaposi's sarcoma*	HIV infection Transplant recipients	Skin, oral mucosa, and lymph nodes HIV—70% occur in head and neck Transplant recipients—lower extremities	More aggressive course compared to immunocompetent Associated with HHV8 Marked decrease since HAART
Lymphoma Non-Hodgkin's lymphoma (NHL)*	HIV infection	⅔ have head and neck involvement	More likely to have advanced disease
Hodgkin's lymphoma (HL)	HIV infection	Nearly universal cervical lymph node involvement	
Posttransplantation lymphoproliferative disorder	Transplant recipients	40% have head and neck involvement	Most are B-cell NHL but HL also occurs
Noncutaneous squamous cell carcinoma (SCC)	HIV infection Transplant recipients	Larynx, lip, oral cavity, oropharynx	Evidence supporting increased incidence is equivocal except for lip SCC (which may be considered cutaneous)
Nonmelanoma skin cancer	HIV infection Transplant recipients	Any site	Much higher risk in OTR, especially for SCC Same risk factors as general population More aggressive course compared to immunocompetent

*AIDS-defining malignancy.
HAART, highly active antiretroviral therapy; HHV8, human herpesvirus 8; OTR, organ transplant recipients.

for KS in organ transplant recipients is highest within the first 2 years after transplant and is increased with HLA mismatches.[41]

During the early AIDS-KS epidemic, a striking relationship was seen between the mode of HIV infection and the risk of developing KS. The risk for acquiring AIDS-KS was reported to be as low as 1% for patients who acquired HIV via blood transfusion, whereas in the population of men who have sex with men (MSM), the risk was 21%.[33] KS was seen in only 2% of AIDS cases in women, with most of them reporting sexual contact with MSM.[31] These epidemiologic disparities led to speculation that an infectious component, possibly sexually transmitted, played a role in AIDS-KS.[33] In 1994, Chang and colleagues identified Kaposi's sarcoma–associated herpesvirus (KSHV), a new herpesvirus, within KS lesions.[42] KSHV is formally designated as human herpesvirus 8 (HHV8) and, along with Epstein-Barr virus (EBV), is a member of the gammaherpesvirus subfamily of herpesviruses.[43,44] HHV8 has been identified in more than 95% of all KS lesions regardless of the epidemiologic subtype.[29,30] The varying prevalence of HHV8 infection worldwide may explain the wide range of KS prevalence in different countries.[45] The mechanism of oncogenesis has not been fully elucidated, in that KSHV is present in both immunosuppressed and immunocompetent individuals.[46] It is believed that HHV8 infection coupled with the host's state of immunosuppression plays a causal role.[29,47,48]

HHV8 infection itself appears to be a worldwide epidemic whose onset may have predated the HIV epidemic.[47,49-51] Despite its widespread prevalence, the modes of transmission of HHV8 are incompletely understood. Some studies suggest that sex between men is an important route of transmission.[49,52,53] In populations with high rates of endemic KS, familial clustering of HHV8 seropositivity was seen.[54] Data suggesting vertical transmission from mother to child have also been reported,[55,56] but do not explain the increased prevalence of HHV8 infection in prepubescent children. Some researchers have concluded there may be a role for child-to-child nonsexual transmission, perhaps via saliva.[56-58]

Presentation and Diagnosis

Compared with the classic and endemic forms of KS, immunosuppression-related KS and AIDS-KS are more aggressive. The clinical course of AIDS-KS ranges from an indolent, slowly progressive disease to a rapidly progressive and fatal course.[28] AIDS-KS is associated with a shortened life expectancy, although most patients die of opportunistic infection or lymphoma and not KS per se.[59] Multiple lesions develop in many patients, who more commonly have lymph node or visceral organ involvement. Frequently involved sites include the skin, oral mucosa, and lymph nodes. AIDS-KS occurs in the head and neck in as many as 70% of cases,[60,61] whereas immunosuppression-related KS tends to occur in the lower extremities.[30] Oral KS occurs in roughly one third of AIDS-KS,[62] whereas in immunosuppression-related KS cutaneous lesions are most common.[63] Cutaneous disease presents as multicentric macular and papular lesions that are nontender and nonblanching. These frequently coalesce and progress to violaceous, nodular lesions (Fig. 15-1). They are usually asymptomatic but may become pruritic and aesthetically displeasing. Mucosal KS commonly occurs in the oral cavity, and oral KS, which is associated with lower CD4 counts than cutaneous disease,[66] may be a first sign of HIV infection.[64,65] Oral KS may resemble cyclosporine-associated gingival hyperplasia in organ transplant recipients but cyclosporine usually causes generalized fibrotic gingival hyperplasia whereas oral KS produces a more localized red-purple enlargement.[67] The most frequently affected sites in oral KS are the hard palate, gingiva, and tongue.[64] Mucosal KS is more likely to be symptomatic than cutaneous disease. Lesions may cause loose teeth and are associated with pain, ulceration, and bleeding.

Depending on its location, visceral KS may be asymptomatic or rapidly fatal. Postmortem studies suggest that more than 25% of AIDS-KS patients have visceral lesions.[30] These most commonly involve the gastrointestinal (GI) tract, liver, spleen, and lungs. GI disease is often asymptomatic, whereas median survival in pulmonary KS without treatment is only a few months.[68] The most common presenting symptoms of pulmonary KS are dyspnea and cough, usually without fever unless concomitant infection is present. It may be difficult to distinguish pulmonary KS from other neoplastic and infectious diseases clinically, thus radiologic studies play an important role in its diagnosis. Computed tomography (CT) of the chest is often sufficient to diagnose pulmonary KS[69] and may identify lymphatic or extrapulmonary involvement.[68]

Otolaryngologists may encounter patients with KS of the larynx associated with symptoms ranging from chronic cough or hoarseness to acute upper airway obstruction.[70-73] If diagnosis and treatment proceed appropriately, acute airway obstruction may be avoided. Local treatment in isolated disease or systemic treatment in multicentric disease is recommended to avoid progression to airway compromise.[71]

Once the diagnosis of KS is suspected, biopsy may be performed for pathologic confirmation. The histopathology of KS is characterized by abnormal proliferation of lymphatics. Lesions may occur in three forms: patch, plaque, and nodule.[74] Nodular lesions are more common in immunosuppression-related and AIDS-KS, and are marked by proliferation of slitlike vascular channels, extravasated erythrocytes, and spindle-cell proliferation (Fig. 15-2). KS lesions may be mimicked by bacillary angiomatosis, which also causes vascular proliferative lesions. The presence of pleomorphic bacilli on Warthin-Starry silver stain helps distinguish bacillary angiomatosis.[75,76] The identification of HHV8 DNA may help distinguish KS from other vascular lesions.[77] If KS is identified in a patient without a known history of HIV infection, an HIV test is warranted.

At the initial evaluation of a KS patient, a complete skin examination and oral cavity examination should be performed. A normal examination in these areas does not ensure the absence of KS because clinically significant visceral lesions may present in the absence of mucocutaneous disease. If unexplained GI or pulmonary symptoms are present, radiologic imaging of the chest and abdomen and GI endoscopy should be performed. The classic appearance of small, submucosal vascular nodules establishes the diagnosis of visceral KS. Endobronchial biopsy may result in significant hemorrhage and is discouraged. The constitutional symptoms of fevers, night sweats, and weight loss should be recorded as well as the immunologic status, including CD4 count and viral load.

Figure 15-1. Nodular Kaposi's sarcoma of the gingiva and palate. Given the ulcerated and fungating appearance, the differential diagnosis includes non-Hodgkin's lymphoma and squamous cell carcinoma. *(Courtesy of Dr. Russel Corio.)*

Treatment

Despite multiple therapeutic options, treatment is palliative and there is no cure. The disease course is variable; many patients achieve remission of KS but succumb to other causes of death. The course is complicated by increased susceptibility for developing opportunistic infections related to immunosuppression. Treatment of KS is determined by the extent and location of disease, as well as the severity of symptoms. Specific indications for treatment of KS include cosmetically disfiguring lesions, symptomatic oral lesions, symptomatic visceral lesions, or pain or edema associated with lymphadenopathy or extensive cutaneous disease. Local therapies may be useful in localized lesions or for cosmesis, but they do not prevent new lesions from developing in untreated areas[78] and recurrence rates are high.[30] Local treatments include alitretinoin topical gel (the only FDA-approved topical treatment for KS), local radiation, intralesional chemotherapy injection, cryotherapy, laser therapy, and surgical excision.

Restoration of immune function when possible should be a primary goal, because lesions often regress with the reversal of immunosuppression. Withdrawal of immunosuppressive agents in transplant recipients may, however, lead to transplant failure in up to half of patients.[29] Some data suggest that using sirolimus instead of

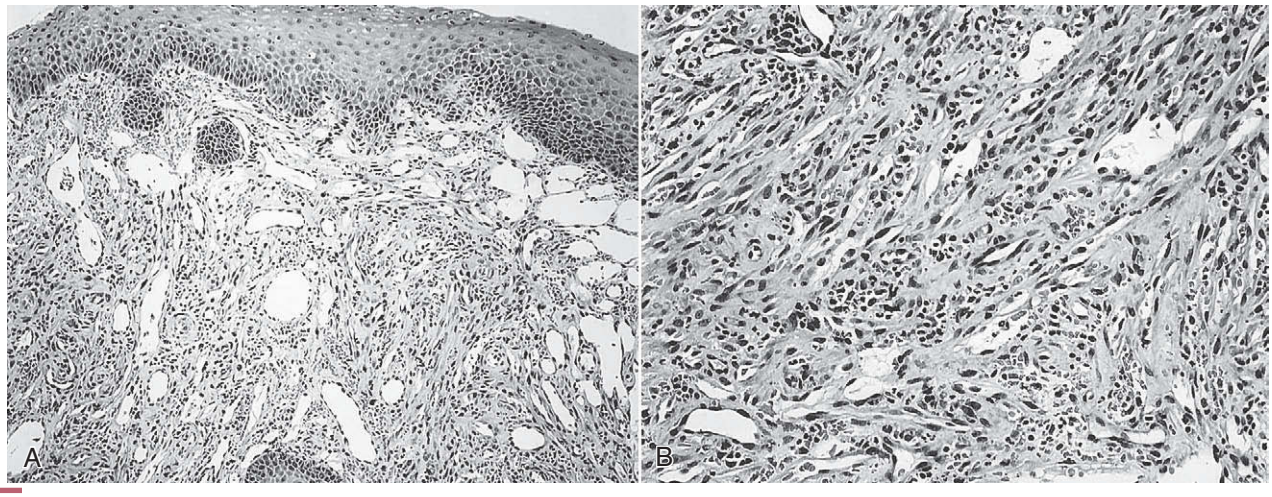

Figure 15-2. Mucosal Kaposi's sarcoma. **A,** Photomicrograph of submucosal Kaposi's sarcoma showing slit-like vascular channels and scattered extravasation of erythrocytes (×100). **B,** Higher-power photomicrograph of the same lesion showing characteristic spindle cell proliferation (×200).

cyclosporine-based immunosuppression regimens may result in regression of immunosuppression-related KS lesions, but further investigation is needed to substantiate these results.[63,79] HAART is now recognized to be a cornerstone of AIDS-KS treatment of all stages.[34,78,80] Antiretrovirals have been shown to decrease KS tumor growth, and active investigation in the use of protease inhibitors for non-AIDS patients with KS is ongoing.[81,82] The AIDS Clinical Trial Group (ACTG) staging system for KS originally took into account tumor burden, immune status as reflected by CD4 count, and the presence of systemic illness to predict likelihood of survival.[83] More recent data have demonstrated that only high tumor burden and systemic illness portend an unfavorable prognosis.[84]

Four agents are currently FDA-approved for systemic treatment of KS. These include liposomal anthracyclines (doxorubicin and daunorubicin), paclitaxel, and interferon-alpha. Other commonly used agents include vinca alkaloids (vincristine and vinblastine) and bleomycin.[34,85] Caution must be exercised when using paclitaxel because serious drug interactions with various components of HAART may occur. Multidrug chemotherapy is associated with increased toxicity, including myelosuppression, and results have been disappointing in widespread disease.[85] HIV-positive patients on chemotherapy are also at increased risk of developing opportunistic infections.[86] As the molecular basis of KS pathogenesis becomes more clearly defined, therapies targeting specific pathways are being developed. These experimental treatments have mostly focused on angiogenesis, HHV8 replication and life cycle, and cytokine regulation.[87] There are ongoing clinical trials investigating antiangiogenic compounds such as imatinib mesylate,[88] matrix metalloproteinase inhibitors,[89] and interleukin-12.[90]

Cutaneous Neoplasms

Immunosuppressed organ transplant recipients and HIV-positive patients have a higher risk of developing skin cancer compared to immunocompetent individuals. Risk factors for the development of skin cancer in immunosuppressed patients are the same as those in the general population, with fair skin, sun exposure, and family history of skin cancer being the principal factors.[91-94] Even though the rate of nonmelanoma skin cancer (NMSC) is increased in both groups, organ transplant recipients have a markedly higher risk than people with HIV/AIDS.[23] The incidence of NMSC in OTR can be as high as 34%.[95,96] In the general population, basal cell carcinoma (BCC) is more common than cutaneous squamous cell carcinoma (SCC), whereas organ transplant recipients develop SCC twice as frequently as BCC.[97] The risk of developing NMSC increases dramatically with longer posttransplant times.[97,98] At 10 years after transplantation, the prevalence of NMSC is 32%.[99] Within the HIV-positive population, BCC is second behind KS as the most common cutaneous malignancy, with a prevalence of 1.8%.[93] CD4 count does not correlate with the incidence or severity of NMSC.[100,101] Both groups have increased rates of lip SCC.[23,24] The evidence linking immunosuppression to increased risk of melanoma is less clear than for NMSC, in that increased rates of detection may reflect greater surveillance in immunosuppressed patients.[92,101]

Compared to NMSC in the general population, NMSC in these patients, particularly SCC, is more often invasive and aggressive, with higher rates of metastasis and recurrence.[92,100-102] Melanoma also has more aggressive features in the setting of immune depression, and shorter disease-free intervals and overall survival have been demonstrated in HIV-positive patients.[103]

Treatment outcomes vary with the type of skin cancer. Although more aggressive types of BCC in HIV-positive patients have been reported,[104-106] standard excisional techniques result in cure rates similar to those in the general population.[100,101] In contrast, cutaneous SCC is associated with higher mortality in immunosuppressed patients, with mortality around 3% in organ transplant recipients[107] and up to 50% in HIV patients who have metastatic SCC.[108] As in the management of Kaposi's sarcoma, reduction of immunosuppression in organ transplant recipients is associated with reduced incidence and improved outcomes for skin cancer.[102] There are no clear guidelines for the management of cutaneous SCC or melanoma in HIV patients, but local excision with early consideration for systemic therapy is generally recommended.[101] Because of the aggressive nature of skin cancers in immunosuppressed patients, early detection with a low threshold for biopsy of suspicious lesions is recommended.

Squamous Cell Carcinoma

Data regarding the incidence of noncutaneous SCC in immunosuppressed patients are controversial. Several studies have reported increased incidence of noncutaneous SCC in organ transplant recipients, with one large series reporting a 0.5% incidence, which was a 20-fold increase over the control population.[109,110] In particular, patients undergoing liver transplantation had an even greater risk.[111,112] There have also been reports of increased head and neck SCC in HIV-positive patients.[24,113] Confounding factors of pretransplantation tobacco and alcohol use, however, may contribute to the increased incidence seen in both groups.[109,112-114] High levels of immunosuppression in organ transplant recipients[109] and lower CD4 count in HIV-positive patients[115] may confer an increased risk. Immunosuppressed patients, however, do appear to experience a more virulent clinical course than the general population. Organ transplant recipients and HIV-positive patients tend to present at an earlier age and with more advanced disease than their immunocompetent counterparts.[109,110,115] As in immunocompetent individuals, the larynx is the most common site of involvement, followed by the oral cavity and oropharynx.[114,116] Tobacco cessation and alcohol abuse counseling, as well as early detection through biopsies of suspicious lesions, are warranted.

Higher susceptibility to infection with HPV in organ transplant recipients and HIV-positive patients may play an important role in the development of noncutaneous head and neck SCC.[24,116] HPV infection has been associated with head and neck SCC, particularly of the tonsil.[117] Organ transplant recipients and patients with HIV/AIDS also have increased incidence of other HPV-related cancers, such as cervical and anogenital cancer.[23] It is thought that immune compromise could lead to increased infection rates and failure to resolve the infections.[118] As more insight is gained into the pathophysiology and clinical behavior of HPV-related cancers, management strategies and the role of prophylactic HPV vaccination in immunosuppressed patients may be better defined.

Treatment of organ transplant recipients and HIV-positive patients with head and neck SCC should follow established guidelines. Even though surgical intervention remains an important option, patients often require combined therapy for advanced disease. The use of chemotherapy in these patients may put them at significant risk for opportunistic infection. Little data exist regarding the tolerance and efficacy of radiation therapy; however, patients with HIV have been shown to tolerate radiation therapy to the head and neck.[119]

Lymphoma

HIV-positive patients and organ transplant recipients are at higher risk for developing non-Hodgkin's lymphoma (NHL) and Hodgkin's lymphoma (HL) than immunocompetent individuals. EBV-associated NHL is the most common type of lymphoma to develop in both groups. NHL comprises a heterogeneous group of tumors, but the overwhelming majority (>95%) are B-cell derived.[78] Lymphomas occurring in immunosuppressed organ transplant recipients are categorized within a disease entity known as posttransplantation lymphoproliferative disorder (PTLD). The WHO classification system divides PTLD into four categories[120,121]:

1. Early lesions (reactive plasmacytic hyperplasia and infectious mononucleosis-like PTLD
2. Polymorphic PTLD (polyclonal and monoclonal)
3. Monomorphic PTLD (B-cell and T-cell lymphomas)
4. HL and HL-like lymphomas

The WHO classification for AIDS-related NHL includes three groups[122]:

1. Lymphomas occurring in immunocompetent patients (Burkitt's, diffuse large B-cell, immunoblastic, and anaplastic)

2. Lymphomas occurring specifically in HIV-positive patients (primary effusion lymphoma and plasmablastic lymphoma)

3. Lymphomas that also occur in other immunodeficiency states (PTLD-like B-cell lymphoma associated with HIV infection)

Most AIDS-related NHL are EBV-associated B-cell lymphomas such as Burkitt's lymphoma, diffuse large B-cell lymphoma, and plasmablastic lymphoma (PBL).[78,85,123,124]

EBV, along with HHV8, is a member of the gammaherpesvirus family. It is estimated that more than 90% of the world adult population is infected.[125] It is found in up to 50% of AIDS-related NHL[126] and nearly 90% of PTLD.[127] EBV alters tumor suppressor p53 gene expression and protein regulation, which is thought to play a role in oncogenesis,[44,85] but given the nearly ubiquitous presence of EBV infection, it may be that the intensity of immune suppression determines the risk of developing NHL.[126] However, immunosuppressed patients have not been found to have increased rates of EBV-associated nasopharyngeal cancer,[128] and a large proportion of AIDS-related NHL have not demonstrated EBV. Thus the role of EBV in NHL oncogenesis remains unclear and is an area of ongoing investigation.

AIDS-Related Non-Hodgkin's Lymphoma

Epidemiology and Presentation

AIDS-related NHL occurs in up to 19% of HIV-positive patients[85] and is the second most common malignancy to develop in HIV-positive patients.[129] Patients are much more likely than their immunocompetent counterparts to present with advanced disease, B symptoms (fever, chills, night sweats, and weight loss), and extranodal disease, including bone marrow involvement.[78,85,129] Seventy percent to 80% of AIDS-related NHL is diagnosed with initial stage III or IV disease, in stark contrast to only 10% to 15% of high-grade NHL in the HIV-negative population.[130-133] Whereas most NHLs develop in the setting of advanced immune suppression, NHL may occur in the setting of relative immune competence and thus cannot be ruled out based on a high CD4 count or low viral load. Burkitt's lymphoma, in particular, has been noted to occur in patients with a relatively high CD4 count.[134,135] Even though the incidence of Kaposi's sarcoma has clearly declined since the advent of HAART, the effect of HAART on AIDS-related NHL has been less significant. Although some studies suggest a trend toward declining incidence, others have found an increased incidence of NHL in the HAART era.[78,136]

As with immunocompetent patients with NHL, AIDS-related NHL most commonly presents in the head and neck, with nearly two thirds of patients with head and neck manifestations.[129] Extranodal disease is twice as common in AIDS-related NHL compared to non-HIV associated NHL.[129,137,138] Extranodal head and neck sites include the oral cavity, sinonasal region, pharynx, nasopharynx, orbit, parotid gland, larynx, mandible, and CNS.[139-145] Other sites of extranodal disease include the GI tract, bone marrow, and liver. Nodal disease predominates in the neck with frequent involvement of the submandibular, jugulodigastric, and supraclavicular regions.[146]

NHL of the head and neck often presents as a growing mass. Constitutional symptoms are frequently present with fever, night sweats, and unintentional weight loss (greater than 10% of body mass) present in 82% of patients.[147] Initial symptoms are dependent upon the location of disease. Sinonasal lymphoma usually presents with nasal obstruction or other nonspecific symptoms consistent with chronic rhinosinusitis.[148] NHL of the oral cavity most commonly affects the gingiva and palate and may manifest as a persistent sore, an enlarging mass, or loose teeth. Hoarseness, respiratory symptoms, and dysphagia may indicate laryngeal or pharyngeal disease. Nasopharyngeal lymphoma may present with nasal obstruction and serous otitis media. Because of the close association with HIV, patients newly diagnosed with NHL should be screened for HIV infection.

PBL is a unique type of diffuse large B-cell lymphoma that typically involves the oral cavity and mandible but has been reported in other regions including the paranasal sinuses, skin, and lymph nodes.[78,149] Although first described as an AIDS-related NHL, there are reports of PBL occurring in HIV-negative patients and OTR.[150-152] The gingiva and hard palate mucosa are most commonly involved and tumors have a propensity for adjacent bone invasion.[153] These lesions must be distinguished from benign gingival enlargements like pyogenic granuloma and peripheral giant cell granuloma.[149] Unlike other NHLs, PBLs are generally HHV8 and EBV-negative,[150] although some series report positivity.[152,154]

Diagnosis

The diagnosis of lymphoma in HIV-positive patients begins with a high index of suspicion. Multiple common manifestations of HIV disease such as peripheral generalized lymphadenopathy and benign oral ulcerations may mimic the findings for patients with lymphoma. The combination of a rapidly enlarging lesion and constitutional symptoms is particularly concerning for NHL. The diagnosis of lymphoma may be made with fine needle aspiration (FNA) biopsy. Even though histologic type may be determined from a cell block following aspiration, this test may not be performed and some pathologists prefer larger tissue specimens for diagnosis and determination of histologic type. Thus open biopsies may be considered. The prognosis and management depend upon the presence of extranodal disease; therefore a thorough investigation of the CNS, mediastinum, and abdomen should be performed with magnetic resonance imaging (MRI), or CT if MRI is not available. Leptomeningeal disease is the most common manifestation of CNS involvement, occurring in up to 10% of patients,[155] and is best evaluated with MRI.[156] A bone scan and bone marrow biopsy may also be useful in the staging process.

Prognosis and Treatment

The International Prognostic Index (IPI), developed in 1993, is a clinical tool used to predict survival in NHL.[157] Factors associated with poor prognosis include age older than 60 years, advanced tumor stage, elevated serum lactate dehydrogenase, poor performance status and more than one extranodal site of disease. It has been validated in patients with AIDS-related lymphoma, in that high-risk IPI scores have been shown to predict poor survival.[130,158,159] One large study demonstrated 3-year survival rates for low, low-intermediate, high-intermediate, and high-risk groups to be 66%, 42%, 35%, and 8% respectively in the HAART era.[160] Recent data suggest that, in the HAART era, the relationship between CD4 count and survival in NHL may be less significant than was previously thought.[158,161] However, other reports show that CD4 count continues to be a predictor of survival.[136,162,163] Before advent of HAART, overall survival in NHL was only 10%.[78] Numerous studies have demonstrated improved survival when combining HAART with standard combination chemotherapy. Up to 92% of patients achieve complete remission[136] and nearly 50% achieve 3-year survival even with high-intermediate risk IPI scores.[130,164]

AIDS-related NHL is typically treated with multiagent chemotherapy in combination with HAART.[165] The therapy must balance the need to eradicate the neoplasm with the risk of further immune suppression. Systemic treatment of NHL may be complicated by marrow suppression, immunosuppression, mucositis, and opportunistic infections, resulting in a high rate of morbidity and mortality.[85] Rituximab, an anti-CD20 antibody, has shown promising results in the treatment of NHL in HIV-negative patients, and clinical trials are ongoing to investigate its use in AIDS-related NHL. Radiotherapy has a role for patients with localized disease or for palliation of symptomatic lesions. NHL confined to the cervical nodes has an improved response to therapy with longer associated survival than extranodal disease involving the paranasal sinuses, mandible, and other extranodal sites.[145] Primary CNS lymphoma has perhaps the poorest prognosis with its tendency to recur and association with profound immune suppression.[133,166] Outcomes for relapsed, aggressive NHL are extremely poor and no effective treatments are available. Whereas the treatment of choice for relapsed NHL in immunocompetent patients is autologous

stem cell transplantation (ASCT), opportunistic infections and toxicity have limited its use in AIDS-related NHL.[165]

Posttransplantation Lymphoproliferative Disorder

PTLD is a complication of solid organ and hematopoietic transplantation marked by EBV-driven abnormal lymphoproliferation. The overall incidence in adults is approximately 2% to 3%,[127] while in children the incidence is close to 8%.[167] It is the second most common malignancy to develop in organ transplant recipients, after cutaneous malignancy.[114] Nearly 40% of patients with PTLD present with findings in the head and neck, especially in Waldeyer's ring and cervical lymph nodes.[168] PTLD involving the head and neck usually presents with mononucleosis-like symptoms and adenotonsillar hypertrophy, and may be associated with upper airway obstruction.[114,168,169] There are also reports of PTLD involving the nasal cavity and paranasal sinuses,[170,171] as well as facial cutaneous manifestations.[140]

Most PTLDs are NHLs of the B-cell type.[114] Incidence varies significantly with the type of organ transplanted, with the highest rates in multiorgan or intestinal transplants and lowest rates in renal transplants.[127] PTLD develops in the setting of severe immunosuppression, which impairs the formation of a cytotoxic T lymphocyte immune response to EBV. The risk of developing PTLD is highest in EBV-naive patients, which may account for the higher incidence in children. It occurs in a bimodal temporal distribution, with most cases occurring within the first 2 years after transplantation and a smaller peak occurring later than 2 years after transplantation.[127]

Treatment should be directed first toward decreasing immunosuppression regimens to allow an adequate T-cell response. Up to 50% of patients respond to immunosuppression reduction.[172,173] Patients who fail to respond to immunosuppression reduction may require systemic therapy such as combination chemotherapy, cytokine therapy, or anti-CD20 therapy (rituximab).[114,127] Surgery is reserved for management of local symptoms, and acute upper airway obstruction caused by tonsillar hypertrophy may require tonsillectomy.[174]

Hodgkin's Lymphoma

Hodgkin's lymphoma can be seen in transplant recipients and patients with HIV. In transplant patients, it is a much less common manifestation of PTLD than NHL, comprising only 1.8% to 3.5% of all PTLDs,[175] but its incidence is still 15-fold greater than that in the general population.[176] Risk factors for the development of HL in transplant recipients include bone marrow transplantation and a history of graft-versus-host disease (GVHD).[175,177] HL-like PTLD is clinically similar to classic HL occurring in the posttransplant setting but is distinguished by its pathologic features such as cell markers and background proliferation.[175,177] HL occurring in the setting of PTLD has a better prognosis than other PTLD lymphomas[176] and should be managed like other PTLD lymphomas with a focus on reduction of immunosuppression and appropriate chemotherapy.[175]

Hodgkin's Lymphoma in Human Immunodeficiency Virus

Although not considered an AIDS-defining malignancy, HL is the most common non–AIDS-defining tumor occurring in patients with HIV.[123,178] The incidence of HL is increased nearly 5- to 15-fold in patients with HIV (HIV-HL) compared to that in HIV-negative patients.[175,179] Data suggest that HIV-HL is more common in homosexual and intravenous drug–using men than in other HIV risk groups.[85,180] Several features distinguish HIV-HL from HL occurring in HIV-negative patients. HIV-HL is more likely to present with advanced disease, extranodal involvement including bone marrow in up to 50%, and B symptoms in 40% (compared to 27% in HIV-negative patients).[178,180,181] In both groups, cervical lymphatic involvement is common; one series demonstrated cervical node involvement in all cases of HIV-HL.[180] Notably, EBV is present in more than 90% of HIV-HL patients compared to less than 50% of non-HIV patients.[123,181] The histology of HIV-HL is also distinct from that of the general population. HIV-positive patients more frequently develop the aggressive mixed cellularity and lymphocyte-depleted subtypes in comparison to the predominance of nodular lymphocytic subtypes in the general population.[179] The most surprising finding in HIV-HL is that its incidence has unexpectedly increased in the HAART era. Patients with moderate immunosuppression (CD4 between 225 and 249 cells/μL) are more than twice as likely to develop HIV-HL than patients with severe immunosuppression (CD4 < 25 cells/μL).[179] It is believed that increased CD4 counts allow for improved survival of Reed Sternberg cells, which are the characteristic pathologic cells seen in HL.[182] Upon diagnosis of HIV-HL, staging evaluation should include CT imaging of the brain, chest, and abdomen, as well as a bone marrow biopsy.[123] Evaluation of the patient's immune status should also be performed with CD4 count and viral load testing.

There have been no randomized controlled trials for treatment of HIV-HL,[183] but the accepted standard of treatment consists of combination chemotherapy and antiretroviral therapy. Patients treated with HAART in combination with chemotherapy have shown improvement in response to therapy, longer disease-free survival, and longer overall survival when compared with patients treated with combination chemotherapy alone.[181,184] Estimated 2-year survival improved from 45% in patients treated with chemotherapy alone to 62% in those treated with combined HAART and chemotherapy.[185] Complete response to therapy and overall survival are much worse than in HIV-negative patients, however. Overall survival rates in HIV-HL patients compared with HIV-negative patients were 68% vs. 92% at 1 year and 41% vs. 77% at 5 years.[181]

Salivary Gland Disease

Parotid Lesions in Human Immunodeficiency Virus

Parotid lesions are common in HIV-positive patients, especially children in whom up to 18% may present with parotid masses.[186-188] These lesions may result from AIDS-related malignancies such as NHL[143,144] or KS[189,190] or from diffuse infiltrative lymphocytosis syndrome (DILS), but the majority of parotid enlargement in HIV-positive patients is the result of a benign process known as benign lymphoepithelial cyst (BLEC). BLEC of the parotid produces persistent, nontender parotid enlargement associated with cervical lymphadenopathy in up to 90% of patients.[191] Inspissated secretions can lead to duct obstruction with resulting sialadenitis and pain.[192] These lesions have varying proportions of cystic and solid components,[193] and even though only unilateral clinical disease may be evident, radiologic evaluation nearly always reveals bilateral changes.[194,195] Histologically, BLEC has cyst walls lined by hyperplastic and metaplastic squamous epithelium, and contains aggregates of lymphoid proliferation.[191] The differential diagnosis of cystic parotid lesions includes Sjögren's syndrome, cystic Warthin's tumor, and branchial cleft cysts. Bilateral cystic Warthin's tumors may be differentiated radiologically from BLEC based on the presence of focal nodularity in Warthin's tumors and the associated lymphadenopathy of BLEC.[195]

Evaluation of HIV-positive patients who present with a parotid mass should begin with thorough history focusing on the time of onset and rate of growth of the mass as well as any symptoms associated with the mass such as pain. Constitutional symptoms such as weight loss, fever, and night sweats should be investigated and if present should alert the physician to the possibility of lymphoma or tuberculosis. Physical examination should focus on the common features of BLEC—the contralateral parotid should be examined for bilateral masses and the neck should be examined for lymphadenopathy. The examiner should look for evidence of malignancy such as induration, pain, fixation, and facial nerve dysfunction.

FNA can be useful in the diagnosis of parotid masses. Unilateral masses, or masses suspicious for malignancy, should undergo FNA. A study of 99 parotid FNAs in HIV-positive patients found 75% to be consistent with BLEC, 14% were infectious/inflammatory, and 6% were neoplastic. Of the neoplastic lesions, all were malignant, with three NHLs, one multiple myeloma, one metastatic adenocarcinoma from the lung, and one direct extension from a cutaneous BCC. In 6% of patients, the FNA was nondiagnostic.[196] FNA of BLEC reveals a heterogeneous lymphoid population, scattered foamy macrophages, and anucleated squamous cells in a proteinaceous background.[191] Germinal centers, myoepithelial islands representing metaplasia of ductal epithelium, and cystic ductal dilatation (Fig. 15-3) differentiate BLEC

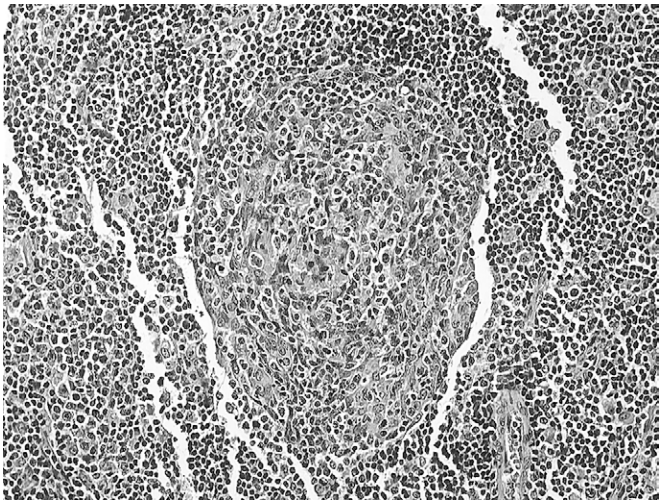

Figure 15-3. Benign lymphoepithelial cyst. Photomicrograph demonstrating squamous metaplasia of the ductal epithelium in human immunodeficiency virus–related cystic lymphoepithelial disease of the parotid gland (×200).

from lymphoma.[197] Aspiration may also be useful for the relief of symptoms in larger cysts, although the lesions may recur. Initial aspirates should be sent for cytologic and microbiologic evaluation.

A variety of treatment options exist for patients with BLEC. Patients not already receiving HAART should be referred for treatment initiation because these lesions may regress with antiviral therapy.[198,199] For minimally symptomatic patients without significant cosmetic deformity, observation alone represents the best option. Low-dose radiation treatment results in a greater than 50% reduction in the size of the lesion. This improvement, however, typically lasts less than 10 months.[200] Some patients are treated with repeated needle aspirations although the repetitive nature of this treatment is suboptimal. Needle aspiration combined with doxycycline or tetracycline sclerotherapy may result in significant size decrease.[201-203] A 1 mg/mL doxycycline solution has been used, injecting 1 to 2 mL through an intravenous catheter following cyst aspiration. Most patients are left with smaller residual fibrotic masses but long-term results of this treatment are unknown.[201,202]

HIV-associated BLEC typically does not require parotidectomy. Parotidectomy may be considered in those rare cases of BLEC that undergo rapid size change, are disfiguring, or have significant pressure symptoms. Other indications for parotidectomy include FNA cytology suggestive of neoplasm or unilateral masses with a significant solid component or features worrisome for malignancy. There have been no reports of malignant transformation of BLEC.[191]

Diffuse Infiltrative Lymphocytosis Syndrome

Parotid gland enlargement associated with sicca symptoms was recognized in HIV-positive patients in the 1980s, and Itescu and colleagues first categorized DILS as a discrete entity in 1990.[204] DILS occurs in the setting of HIV and is marked by salivary gland enlargement with circulating and visceral CD8 lymphocytosis. It is often associated with cervical lymphadenopathy, and up to 60% of patients also report sicca symptoms such as xerostomia and xerophthalmia.[192,205,206] In the pre-HAART era, DILS occurred in approximately 3% to 4% of HIV-positive patients, but in the HAART era its incidence has dropped significantly to less than 1%.[205] It occurs twice as frequently in black patients as in whites.[207,208] Diagnosis is confirmed with minor salivary gland biopsy demonstrating lymphocytic infiltration or with positive gallium Ga67 scintigraphy when biopsy is not possible.[192]

DILS is phenotypically similar to Sjögren's syndrome in terms of salivary gland enlargement, sicca symptoms, and salivary gland histology. However, whereas parotid swelling is universal in DILS, it occurs in less than one third of patients with Sjögren's syndrome.[192] In addition, DILS is characterized by more frequent occurrence of extraglandular lymphocytic infiltration, predominance of CD8 cells in lymphoid aggregates (as opposed to CD4 in Sjögren's syndrome), and the infrequent presence of serum autoantibodies.[192,205] Extraglandular disease in DILS may include lymphocytic interstitial pneumonitis in up to half of patients,[209] but this complication is becoming less common in the HAART era.[205]

Xerostomia in Human Immunodeficiency Virus and Transplant Recipients

HIV-positive patients as well as patients who suffer from chronic graft-versus-host disease (GVHD) are significantly affected by xerostomia. The prevalence of xerostomia is reported to be 2% to 10% in HIV-positive patients.[210] Chronic GVHD may develop in up to 40% to 70% of patients receiving transplants from matched, unrelated donors,[211] and 80% of patients with extensive GVHD complain of xerostomia.[212] In the setting of HIV, some cases are iatrogenically induced by the use of HAART, antidepressants, and other drugs, whereas other cases are caused by chronic mouth breathing secondary to sinonasal disease or adenoidal hypertrophy. Still others are related to DILS as noted earlier. Salivary flow rates are diminished in the setting of HIV infection or GVHD,[210,213,214] which leads to increased incidence of dental caries and impaired deglutition. Salivary substitutes, frequent saline rinses, and sialogogues help alleviate these problems. Dental caries can be prevented with fluoride.

Cervical Lymphadenopathy in Immunosuppressed Patients

The otolaryngologist is often consulted to evaluate cervical adenopathy in immunosuppressed patients. The diagnostic workup of cervical lymphadenopathy starts with a thorough history and physical examination. The clinician should question the patient about risk factors for infectious causes of cervical adenopathy, including contact with cats and dogs and exposure to tuberculosis, and risk factors for head and neck malignancy, including tobacco and alcohol use. An enlarged lymph node is more likely to be pathologic when certain local and constitutional features are found on history and physical examination.

Although constitutional symptoms by themselves are not a specific indicator of infection or malignancy, the presence of such symptoms without a known cause warrants further investigation. Cervical lymphadenopathy caused by lymphoma in immunosuppressed patients is associated with B symptoms in nearly 50% of patients.[78,178,180,215] The distribution, size, and mobility of neck nodes may suggest infectious or malignant etiology. Cervical lymphadenopathy that is greater than 2 cm, unilateral, painful, deep, or asymmetric is suspicious for a pathologic cause, specifically granulomatous disease or lymphoma.[216] Tender adenopathy is more likely to be secondary to bacterial infections, including tuberculosis, whereas nontender, enlarging neck nodes may result from malignancy.[217] A thorough head and neck examination should search for potential primary sites of infection or malignancy.

FNA should be the initial method of pathologic sampling for suspicious nodes. The diagnostic yield of FNA is increased with multiple passes of the needle while suction is applied to the plunger. The presence of a cytopathologist or a technician is beneficial for two reasons: (1) Preparation of the specimen for cytology can be properly and judiciously carried out, and (2) the adequacy of the aspirate for diagnosis can be determined and FNA repeated if necessary. Ultrasound guidance increases the diagnostic yield in lymph nodes that are difficult to palpate. The overall sensitivity and specificity of FNA in HIV-positive cervical adenopathy has not been clearly defined and is likely operator dependent. Sampling errors, improper preparation of cytopathology slides, and misinterpretation of the cytologic features can cause false-negative results. Because lymphoma is always a concern, a cell block should be obtained from the FNA specimen. This allows for further diagnostic evaluation such as flow cytometry to clearly differentiate reactive tissue from lymphoma and determine the class of lymphoma, which may have treatment implications. In patients with lymphoma diagnosed on FNA but without adequate specimen for histologic typing, an open biopsy should be considered. Fresh biopsy

Table 15-6

Differential Diagnosis of Lymphadenopathy in Immunosuppressed Patients

Diffuse infiltrative lymphocytosis syndrome (HIV-positive patients)
Idiopathic
Infectious
Bacterial lymphadenitis or abscess secondary to oropharyngeal infection
Cat-scratch disease
Mycobacterial lymphadenitis: tuberculous and atypical organisms
Pneumocystis lymphadenitis or thyroiditis
Toxoplasma lymphadenitis
Viral lymphadenitis: cytomegalovirus, Epstein-Barr virus
Lymphoepithelial cysts of the parotid gland (HIV-positive patients)
Neoplastic
Lymphoma (includes posttransplantation lymphoproliferative disorder)
Non-Hodgkin's lymphoma
Hodgkin's disease
Metastatic carcinoma
Metastatic Kaposi's sarcoma
Metastatic melanoma
Salivary gland tumors
Thyroid tumors

specimens should be sent directly to the pathologist, who should be informed of the possibility of lymphoma.

Organ transplant recipients are at higher risk for development of cervical involvement, which is seen in 6% of patients, and extrapulmonary tuberculosis, which is seen in 10% to 20%.[218] Head and neck sites of tuberculosis infection in organ transplant recipients include the cervical lymph nodes,[219] larynx,[220,221] and middle ear.[222] Nontuberculous mycobacterial infections also occur in immunocompromised patients and frequently cause pulmonary infections, cervical lymphadenitis, and ulcerative skin lesions, but has also been reported to involve the temporal bone.[223]

Cervical Adenopathy in Human Immunodeficiency Virus

Data regarding the incidence of cervical adenopathy are sparse, but one series demonstrated that of all HIV-positive patients presenting for FNA of an enlarged lymph node, 54% had cervical involvement.[224] Approximately 40% of HIV-positive patients with adenopathy have benign reactive lymphadenopathy.[225-227] and 20% to 30% have tubercular etiology.[226] In this background of hyperplastic adenopathy, however, cases of infectious and neoplastic etiology exist, including *Mycobacterium* tuberculosis, fungal infection, *Pneumocystis jiroveci* (formerly *Pneumocystis carinii*), lymphoma, KS, and other processes that also occur in the general population (Table 15-6).[224,225,227] Malignancy may be present in up to 10% of cases. Differentiating among these processes remains challenging, yet critical to the appropriate management of lymphadenopathy in the setting of immunosuppression. The tendencies for multiple pathologic processes to coexist in this population and the poor sensitivity of many clinical findings and tests often make it necessary to perform microbiologic and histologic evaluations of lymph node tissue.

Extrapulmonary tuberculosis is the second most common cause of cervical lymphadenopathy in HIV-positive patients.[224,225,227] Tuberculosis is the leading cause of death in HIV-positive patients and effective treatments are available, thus prompt diagnosis and initiation of therapy are essential. The most common site of extrapulmonary tuberculosis involvement in HIV-positive patients is the lymph nodes,[224] but other head and neck sites that may be involved include the larynx,[220,228,229] oral cavity and lip,[230,231] or the parotid gland.[232]

The patient's immune status, as indicated by the history of opportunistic infection, CD4 count, and viral load, may help narrow the differential diagnosis of cervical adenopathy. Whereas NHL and mycobacterial infection are more likely to be present in the setting of advanced immunosuppression, the CD4 count alone is not sufficient to exclude malignancy or infection.[134,135,179] The purified protein derivative (PPD) or tuberculin skin test may facilitate the diagnosis of mycobacterial lymphadenitis. In the setting of advanced HIV infection and immune compromise, however, the patient may become anergic, resulting in a low sensitivity of the PPD test. The criterion for a positive result in an HIV-infected patient is a skin reaction greater than 5 mm in diameter rather than 10 mm as in the general population.

FNA biopsy should be the initial method of tissue sampling in most cases of suspicious cervical lymphadenopathy in the HIV-infected patient. If possible, a cell block should be created from the sample and the sample should be sent for cytology, flow cytometry, and culture and stains for aerobic and anaerobic bacteria, mycobacteria, and fungi. In the largest series among HIV-positive patients, FNA provided a definitive diagnosis in more than half of patients and directed further clinical investigation in another 30%, while 20% of the initial samples were inadequate for pathologic evaluation.[227] A subsequent study in children corroborated these results, with only 8% of samples being inadequate for diagnosis.[225]

An FNA diagnosis of follicular hyperplasia should be correlated with the clinical picture and should not, by itself, absolve the clinician's suspicion of lymphoma. The decision to perform a diagnostic open biopsy should be driven by a suspicion of malignancy or infection in the setting of a negative or inconclusive FNA.[217,233] Conditions that would favor proceeding with an open biopsy in the setting of an inconclusive finding include nodes greater than 2 cm and growing; onset associated with a low CD4 count; asymmetric, unilateral, or localized lymphadenopathy; constitutional symptoms of unknown origin; mediastinal adenopathy; or hepatosplenomegaly. Open biopsy of suspected metastatic carcinoma should be avoided and, if possible, the diagnosis should made by FNA. When metastatic carcinoma is diagnosed, a thorough examination of the upper aerodigestive tract should be performed under general anesthesia in search of a primary tumor.

Sinonasal Infection

Presentation and Pathogenesis

As in the general population, sinonasal complaints are common a mong immunosuppressed patients. Reports of prevalence among HIV-positive patients range from 10% to 68%, depending on the criteria used.[234-237] Nearly 50% of patients undergoing allogeneic stem cell transplantation (STC) complain of rhinosinusitis, and 12% of solid organ transplant recipients develop acute sinusitis.[238,239] Chronic graft-versus-host disease is a risk factor for sinusitis in hematopoietic transplant recipients.[238,240] The maxillary and ethmoid sinuses are most frequently involved,[234,241,242] and symptoms of acute or chronic sinusitis are similar to those of the general population. These include fever, facial pain or pressure, nasal congestion, and mucopurulent nasal discharge and postnasal drainage. Patients with chronic sinusitis are often relatively asymptomatic, reporting only congestion and nasal discharge. Some patients present initially with pulmonary complaints such as bronchospasm or infection, resulting from postnasal drainage.

Several pathogenic mechanisms have been proposed to account for the high incidence of sinusitis in immunocompromised patients. First, impaired systemic and local immunity due to HIV infection or immunosuppressive therapy leaves the host susceptible to infection.[237] Second, decreased mucociliary clearance times in patients with HIV infection[243,244] and ciliary abnormalities in the nasal mucosa of bone marrow transplant recipients[245] have been noted. Impaired mucociliary function may result in stasis of secretions and increased susceptibility to sinonasal infection, or may reflect damage to the nasal microenvironment from repeated infection resulting in reduced mucociliary clearance. Finally, some data suggest that polyclonal B-cell activation with increased production of immunoglobulin E leads to increased atopy in

HIV-positive patients, manifesting as new or increased allergic symptoms (allergic rhinitis, drug allergies, and asthma).[246] However, attempts to directly correlate sinusitis with atopic disease in HIV-positive patients have been unsuccessful,[235] and a recent study in HIV-positive children did not find increased prevalence of atopy.[247]

The spectrum of bacteria implicated in immunosuppression-associated sinusitis is similar to that seen in the general population. The most common pathogens include *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Moraxella catarrhalis* in acute sinusitis and *Staphylococcus*, *Pseudomonas*, and anaerobes in chronic sinusitis.[248,249] Other unusual nonfungal pathogens cultured from immunocompromised patients include *Legionella pneumophila*,[250] *Acanthamoeba*,[251-253] *Mycobacterium kansasii*, *Pasteurella multocida*,[254] and cytomegalovirus.[255]

The clinical and radiologic characteristics of sinusitis are closely linked to the degree of immunosuppression. Patients with relatively normal immune function (CD4 ≥ 200 cells/μL) should be treated with standard regimens for acute and chronic sinusitis.[248,256] As immune function deteriorates, patients are more susceptible to extensive disease and chronic sinusitis is more likely to develop,[257] thus antibiotic coverage should include *Staphylococcus*, *Pseudomonas*, and anaerobes.[248] One report found that patients with a diagnosis of AIDS had significantly worse CT findings by the Lund Mackay classification system[258] than did patients with HIV.[234] Patients in more advanced stages of immunosuppression as reflected by CD4 less than 200 cells/μL or absolute neutrophil count (ANC) less than 600 cells/μL are at risk for infection with more aggressive disease such as pseudomonal or invasive fungal sinusitis.[259,260]

Fungi such as *Aspergillus* and the Mucorales order (especially *Rhizopus* and *Mucor*) are particularly important pathogens in immunosuppression-related sinusitis because these organisms have the potential to cause invasive and oftentimes fatal disease.

The incidence of invasive fungal sinusitis (IFS) is 1.7% after hematopoietic transplantation,[238] with the highest risk occurring in the immediate posttransplant period.[261,262] It is much more common in hematologic malignancy such as acute myelogenous leukemia (14% incidence) or acute lymphoblastic leukemia (4% incidence) than in HIV/AIDS or solid organ transplantation.[263,264] This difference in susceptibility may be explained by the fact that neutrophils are essential in the immune response to fungal infections.[265,266] Solid organ transplant recipients and patients with HIV/AIDS generally retain neutrophil function, but patients in the later stages of HIV can become neutropenic and typically are at risk for IFS when CD4 counts fall below 50 cells/μL.[267] Regardless of the cause of immunosuppression, the major determinant of risk is the presence and duration of neutropenia (ANC < 600 cells/μL).[263,265] Prophylactic antifungal therapy in patients with hematologic malignancies and hematopoietic and solid organ transplant recipients has not been shown to be effective for the prevention of IFS.[262] *Aspergillus fumigatus* is the most common fungal pathogen in invasive and noninvasive sinusitis for both immunosuppressed and immunocompromised patients.[260] Other fungi that have been isolated include *Candida albicans*,[268] *Rhizopus arrhizus*,[269] *Cryptococcus neoformans*,[270] *Exserohilum*,[271] and *Valsa sordida*,[272] among others.[263]

Invasive fungal sinusitis is a life-threatening condition and early diagnosis and treatment are paramount. Histopathology combined with culture and stains is the most effective diagnostic approach for fungal sinusitis. Unilateral symptoms (facial paresthesias, swelling, pain, or rhinorrhea) with or without fever in a patient with ANC less than 600 cells/μL or CD4 less than 50 cells/μL should alert the clinician to the possibility of IFS. Proptosis along with cranial nerve findings, such as decreased extraocular motions or vision, suggests orbital involvement. Meningismus and mental status changes are late-stage symptoms suggestive of intracranial spread.

Diagnosis

The initial evaluation of an immunosuppressed patient with symptoms of sinusitis should include a thorough head and neck examination as well as nasal endoscopy in order to identify any mucosal or structural abnormalities. Endoscopy-guided cultures should be obtained if discharge from the middle meatus or sphenoethmoid recess is identified. The diagnosis of IFS can pose a challenge, because physical examination findings may be very subtle. The endoscopic findings range from pale, ischemic mucosa to well-circumscribed necrotic plaques. Perforations of the nasal septum and hard palate may be present. Fungal infection may be accompanied by suppuration, causing confusion with bacterial sinusitis.[260]

Radiologic studies often play a key role in diagnosis. Unilateral edema of the sinonasal mucosa with or without bony erosion on seen CT scan (Fig. 15-4) should lead to suspicion of fungal sinusitis or a neoplasm. But even though CT imaging is the study of choice to identify bony erosion, MRI is superior in delineating the intracranial or orbital extent of disease.[261] Changes seen on T1 images are isointense

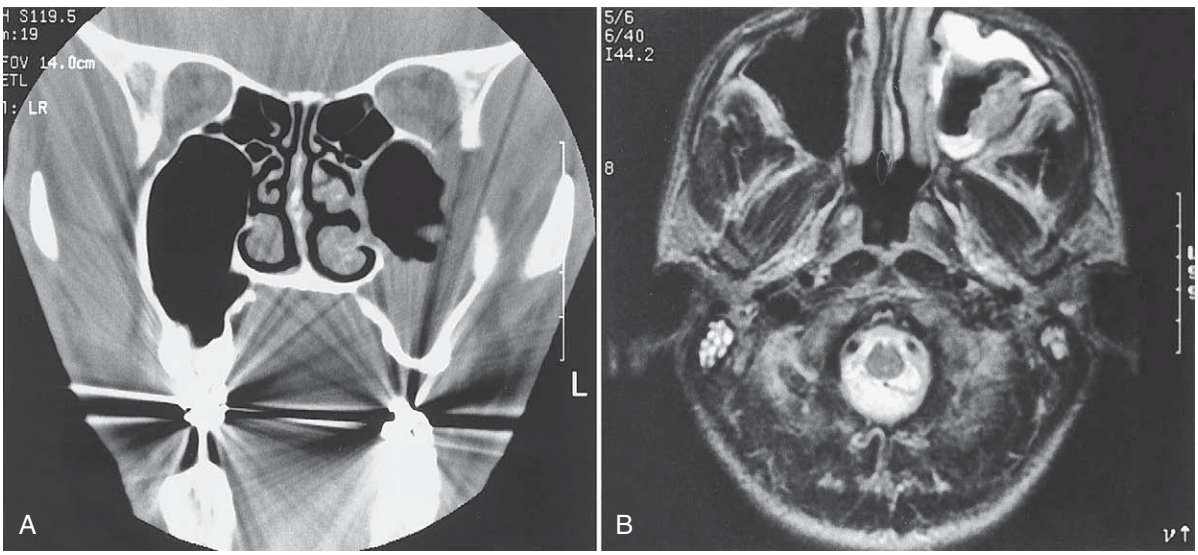

Figure 15-4. Computed tomography and magnetic resonance imaging of *Aspergillus* sinusitis. **A,** Coronal computed tomography of the paranasal sinuses shows left maxillary sinusitis with erosion of the superior lateral bony wall. **B,** T2-weighted axial magnetic resonance imaging of the same case shows thickened left maxillary sinus mucosa with a hyperintense signal consistent with inflammation and a transmural process of the lateral wall with a hypointense signal corresponding to the region of bone destruction in **A**. Differential diagnosis includes invasive fungal disease, lymphoma, and squamous cell carcinoma.

in bacterial and fungal infections, but the T2 images demonstrate low signal intensity for fungal disease and high intensity for bacterial disease. A low threshold for imaging patients with low neutrophil or CD4 counts is advised.

Invasive fungal sinusitis represents a diagnostic and therapeutic emergency and any suspicion should be addressed as soon as possible. Consideration may be made for inferior and/or middle turbinate biopsy[263,273] or diagnostic antral lavage[226] with biopsy and histologic examination. Frozen section of biopsy specimen is often used to accelerate initiation of treatment with antifungal agents. Drainage from the middle meatus and biopsy tissue should be collected and sent for bacterial and fungal culture. There are as yet no uniform guidelines for the diagnosis of IFS, although any suspicious lesions should undergo biopsy with silver staining, histopathology, and culture.

Fungal sinusitis can extend via thrombophlebitic or hematologic spread and thus may enter into the orbit or intracranially without histologic evidence of mucosal invasion.[274] The angiocentric invasion pattern of *Aspergillus* may allow extension of disease into the orbit or intracranially without evidence of bony destruction on imaging study. Thus, in the clinical scenario consistent with fungal sinusitis and fungal elements identified on silver stain or culture, treatment of fungal sinusitis should begin regardless of the histologic confirmation of invasion.

Treatment

The goals of management of sinusitis in immunocompromised patients include swift treatment of bacterial sinusitis and early identification of fungal sinusitis or neoplasm. Initial medical management of acute bacterial sinusitis consists of broad-spectrum antibiotics, decongestants, and saline irrigation. Antibiotics should have good coverage of *Streptococcus*, *Staphylococcus*, and *H. influenzae*; amoxicillin/clavulanate or cefuroxime represent good first-line choices. Antibiotic coverage should also include *Pseudomonas* and anaerobes in patients with moderate immunosuppression or those who do not respond to initial antibiotic treatment.[248] Topical decongestants may enhance sinus drainage and provide symptomatic improvement.[275] Patients should be followed closely, and if fever or local symptoms persist after 10 days of therapy, surgical drainage should be considered. Patients with a rapidly progressive course or toxic presentation should undergo early imaging and aggressive treatment, including parenteral antibiotics and possible surgical intervention. As culture and biopsy results become available, the antibiotic coverage may be narrowed. A total of 4 to 6 weeks of antibiotics should be administered.[256]

Fungal sinusitis should be suspected when fever or other symptoms persist despite aggressive medical treatment. Histopathology combined with culture and stains is the most effective diagnostic approach for fungal sinusitis. Sinusotomy and debridement should be pursued to establish drainage and obtain mucosa and sinus contents for histopathologic and microbiologic evaluation. Surgical intervention is particularly important for patients with a low neutrophil or CD4 count. Endoscopic or external approaches may be used depending on the surgeon's preference. Fresh frozen section should be performed on suspicious mucosal lesions to allow rapid diagnosis and timely intervention.

Invasive fungal sinusitis requires immediate, aggressive treatment. Without treatment, mortality is reported to be 50% to 80% due to intracranial and orbital involvement.[261] Ideal treatment involves three components: systemic antifungal therapy, surgical debridement of infected tissue, and restoration of immune function. In particular, immunosuppression should be reversed because restoration of neutrophil count is required to prolong survival.[263,264] Granulocyte colony-stimulating factor has not been substantiated to be helpful in the treatment of invasive fungal sinusitis. Initiation of HAART should be considered in an attempt to improve the underlying immune status of HIV-positive patients. High-dose, broad-spectrum antifungal medication such as amphotericin B should be administered intravenously in all cases with a clinical picture compatible with IFS, regardless of whether invasion has been demonstrated histologically. Liposomal amphotericin B,[261,276] echinocandins such as caspofungin[277,278] or micafungin,[279] and broad-spectrum triazoles such as posaconazole[280] are alternative medical therapies for patients with poor renal function.

Surgical debridement of involved tissue is important to minimize fungal load, in that medical therapy alone is typically insufficient. The severity of infection and level of immune impairment should be considered when planning surgical intervention. Sinusotomy alone is insufficient; as much as possible, involved tissue should be debrided to bleeding margins.[261] Intraoperative frozen sections may assist in defining the extent of resection by determining the boundaries of invasion.[281] Transfacial approaches may be required in the setting of extensive disease, which may require maxillectomy, orbital exenteration, or craniofacial resection for optimal disease control; however, the chances of survival with intracranial extension are dismal.[282] Aggressive surgery must be considered in the context of the patient's overall condition and prognosis. Postoperative management should continue intravenous antifungals with consideration for antifungal-containing saline irrigation.[280] Careful follow-up and a low threshold for repeated surgical exploration is required. Patients in whom fungal disease appears clinically to have resolved may develop persistent chronic bacterial sinusitis, thus continued follow-up is necessary.[283]

Although more commonly involving the paranasal sinuses, invasive fungal infections of the pharynx and larynx have been described in HIV-positive[284-286] and other immunosuppressed patients.[287-290] Diagnosis and treatment of these invasive infections requires a high degree of suspicion and prompt initiation of medical therapy. In one case, a total laryngectomy was required for disease control.[291]

Immunosuppressed patients with chronic sinusitis are also candidates for surgical intervention. Friedman and colleagues found that endoscopic sinus surgery in HIV-positive patients with chronic sinusitis resulted in symptomatic improvement in 75% of patients, comparable to their results in the general population. This effect was found to be independent of CD4 count and has led the authors to suggest the same treatment algorithm for chronic sinusitis in patients regardless of HIV status.[292] These findings were bolstered by Murphy and colleagues who showed a significant decrease in the symptoms of sinusitis and increased quality of life in HIV-positive patients with chronic sinusitis following endoscopic sinus surgery.[293] Follow-up time in these studies was limited. Because of the devastating nature of invasive fungal sinusitis and the susceptibility of posttransplant patients to opportunistic infections, some authors advocate pretransplant endoscopic sinus surgery in patients who demonstrate evidence of sinusitis.[239,294]

Otologic and Neurotologic Manifestations of Immunosuppression

External and Middle Ear

Malignant Otitis Externa

Although most commonly occurring in older diabetic patients, malignant otitis externa (MOE) also occurs in immunocompromised patients,[295] often in younger and nondiabetic patients with hematologic malignancy or HIV.[296] The susceptibility of the immunocompromised patient to MOE is attributed to a combination of impaired chemotaxis and neutrophil function, and depressed humoral immunity.[297] The pathogenesis of MOE is further facilitated by the breakdown of the local cutaneous barrier in the external auditory canal (EAC) secondary to dermatologic lesions (e.g., eczema, seborrhea) and self-induced trauma caused by pruritus. Otitis externa (OE) may progress to malignant OE if not managed aggressively and in a timely fashion. Spread to the skull base with resulting temporal bone osteomyelitis occurs via the fissures of Santorini and the tympanomastoid suture.[297] Temporal bone osteomyelitis should be suspected when otalgia, swelling, and otorrhea persist despite therapy or when there is onset of facial nerve paralysis or other cranial nerve dysfunction. Unlike in diabetic patients, fungal MOE accounts for a significant portion of infections in patients with immunocompromise secondary to HIV or hematologic malignancy.[298,299] *Aspergillus* species are most common in fungal infections. As in the general population, *Pseudomonas aeruginosa* is the primary etiologic agent in bacterial MOE.

Early diagnosis and management of MOE is essential in that this is a life-threatening condition, especially in patients with low CD4

counts and neutropenia.[297] Otoscopy may reveal granulation tissue at the bony cartilaginous junction of the EAC, although fungal MOE has a propensity to involve the middle ear and mastoid without EAC involvement early in the disease course.[299] EAC debris should be cultured and stained for bacteria, fungi, acid-fast bacilli (AFB), and *Pneumocystis*, although culture results may be negative due to previously administered topical or oral antibiotics. CT may show erosion of the EAC bone or suggest skull base involvement, whereas MRI is more useful for detecting soft tissue changes. Technetium-99 scintigraphy is a very sensitive but relatively nonspecific test for detecting increased osteoblastic activity. In contrast, gallium-67 citrate scintigraphy is more specific for osteomyelitis and some suggest its use to monitor response to therapy.[295,297] Others, however, have noted persistently positive scans in the setting of recurrent disease.[296]

Oral fluoroquinolones have become the treatment of choice in bacterial MOE with cure rates near 90%.[296] However, recent data demonstrate nearly 35% resistance of *P. aeruginosa* to ciprofloxacin, thus ciprofloxacin in combination with the third-generation cephalosporin ceftazidime has been recommended.[295] Management of fungal MOE consists of long-term intravenous antifungals with adequate coverage against *Aspergillus*. Serial gallium-67 bone scans may help monitor the response to therapy.

Middle Ear

Eustachian tube obstruction caused by adenoidal hypertrophy or sinonasal disease is common in HIV-infected children and adults. It is therefore not surprising that otitis media (OM) commonly occurs in the HIV-infected population. Although there is no clear link between immunosuppression and increased incidence of OM,[226] limited data suggest that HIV-positive patients may be more prone to systemic complications related to acute otitis media (AOM).[300,301] Serous otitis media (SOM) and conductive hearing loss (CHL) are more prevalent in adults and older children, whereas AOM more frequently occurs in young children.[300-302] The bacteriology of AOM parallels that in HIV-negative patients, with *S. pneumoniae*, *H. influenzae*, group A *Streptococcus*, and *M. catarrhalis* predominating.[301,303] Therefore initial therapy for acute OM is the same as that for the HIV-negative patient. In the severely immunocompromised child, antibiotic coverage should be expanded to include *S. aureus*, because there may be an increased incidence of this pathogenic organism in HIV-positive children.[304] If OM persists, tympanocentesis should be considered to guide therapy by culture and sensitivity results.

The role of tympanostomy tube placement and adenoidectomy in the management of recurrent OM and persistent SOM is poorly established in HIV-infected patients. As with immunocompetent patients, placement of tympanostomy tubes may result in chronic otorrhea or persistent tympanic membrane perforation. It has not been established that these adverse scenarios are seen more frequently in HIV-positive patients. The severity of hearing loss and morbidity associated with OM should be taken into account when deciding whether to place tympanostomy tubes.

HIV-positive patients who progress to develop chronic otitis media, cholesteatoma, or persistent tympanic membrane perforations should be evaluated for surgical intervention. Advances in the treatment of HIV infection have resulted in HIV-positive patients living longer with relatively less immune compromise. The improved overall prognosis of HIV-positive patients may lead to an increase in chronic ear disease, and HIV patients undergoing elective otologic surgery have not been shown to have adverse events related to their immunosuppression.[305]

Systemic complications of AOM are uncommon in immunocompetent children, and some data suggest that these complications are more likely to occur in the setting of advanced immunocompromise.[301,306] Patients with suppurative OM refractory to antibiotics should undergo early tympanocentesis for culture and special stains, and granulation tissue, polyps, and other masses should be carefully biopsied to rule out neoplasms and atypical infections.

Special Considerations

P. jiroveci (formerly *P. carinii)* and *A. fumigatus* represent organisms that may cause otomastoiditis in immunocompromised patients. Extrapulmonary manifestations of *P. jiroveci* have become more common with the routine use of pentamidine for *P. jiroveci* pneumonia,[307] and otomastoiditis and caused by *P. jiroveci* often occurs in the absence of pulmonary disease.[307-311] The route of transmission of *P. jiroveci* to the temporal bone is not clear, but retrograde spread from the nasopharynx through the eustachian tube and hematogenous spread have been proposed. Patients with *Pneumocystis* otomastoiditis commonly present with unilateral otalgia, otorrhea, hearing loss, and a polypoid mass on otoscopy. CT of the temporal bones reveals bony sclerosis without erosions and opacification of the middle ear and mastoid air spaces. A persistent aural polyp accompanied by signs and symptoms of OM despite otic drops and systemic antibiotics should undergo biopsy for histopathology and special stains. Silver stains should be requested and may reveal *P. jiroveci* organisms surrounded by a foamy granular exudate. *P. jiroveci* otitis externa is resolved with recovery of hearing using oral trimethoprim-sulfamethoxazole.[307,308]

A. fumigatus infection of the ear may present as a chronic OE in relatively immunocompetent patients, but can also cause a rapidly fatal invasive otomastoiditis or malignant OE in patients with poor immune function. Risk factors for invasive aspergillosis of the temporal bone include a low CD4 count, AIDS diagnosis, neutropenia, corticosteroid therapy, antineoplastic therapy, and prolonged antibiotic therapy. Otomastoiditis caused by *A. fumigatus* may start in the middle ear space or extend from the EAC.[299] Invasive disease results in destruction of ossicles, erosion of the facial canal with nerve invasion, and destruction of dural plates with possible extension to the dural sinuses and other intracranial structures.[312] Vertigo indicates labyrinthine invasion by *Aspergillus*, whereas meningismus and mental status changes indicate intracranial extension. Facial nerve weakness indicates bone invasion, which can often be confirmed by the presence of bony erosion on temporal bone CT.

Invasive OE caused by *A. fumigatus* presents with otalgia, otorrhea, and hearing loss. Otoscopy usually reveals white debris or granulation tissue in the EAC, which may be mistaken for cholesteatoma. There should be a high index of suspicion for the presence of invasive *Aspergillus* of the temporal bone in immunocompromised patients with persistent OE or OM and new cranial nerve findings. Otorrhea should be routinely cultured and stained for bacterial and fungal organisms and for *Pneumocystis*. If the tympanic membrane is intact, tympanocentesis should be performed when antibiotic therapy is ineffective. If *Aspergillus* is identified on stain or culture, invasive disease can be implied by the presence of bone erosion on CT. The presence of fungal invasion in a mucosal biopsy from the middle ear is diagnostic for *Aspergillus* otomastoiditis. MRI of the skull base should be performed if extensive mastoid disease or dural plate erosion is present on CT with special attention given to lateral sinus blood flow and other clues of intracranial extension.

OE and OM caused by invasive *A. fumigatus* require prompt surgical and drug therapy.[313] High-dose amphotericin B should be started immediately. As much *Aspergillus*-infected tissue as possible should be removed to slow down extension of disease to vital structures and to facilitate the ameliorating effects of drug therapy and host immunity. In the case of OE caused by invasive *Aspergillus*, infected soft tissue and bone of the EAC should be debrided. Limited disease may be addressed by a transcanal approach, but a transmastoid approach with removal of the canal wall will provide more complete debridement and less risk to the facial nerve. Otomastoiditis should be managed with a radical mastoidectomy if middle ear contents and mastoid air cells are to be removed. The management of the facial nerve in these cases is controversial because invasion of the nerve by *Aspergillus* is not easily proven without biopsy. When the facial nerve is paralyzed and gross evidence of invasion and necrosis is present, the nerve should be resected and grafted when appropriate.

The absence of tissue invasion on histopathology and the absence of bone erosion on CT do not rule out the diagnosis of invasive *Aspergillus* of the temporal bone. The clinician should maintain a high index of suspicion for invasive aspergillosis in severely immunocompromised patients despite the absence of these findings. Therefore the patient with early *Aspergillus* infection may first be treated with topical clotrimazole and frequent cleaning of EAC debris. If symptoms persist or

cranial nerve deficits occur, surgery and amphotericin B should be considered after biopsy specimens are taken and CT studies repeated.

Neuropathies in Human Immunodeficiency Virus

Neurologic disorders are a common manifestation of HIV infection resulting from the neurotropic and immunosuppressive properties of the virus and susceptibility to CNS infections such as CMV, toxoplasmosis, or cryptococcal meningitis. In the pre-HAART era, 30% to 50% of patients in later stages of immunodeficiency developed the AIDS dementia complex, also known as HIV-associated dementia (HAD).[314,315] The prevalence of neurologic complications of AIDS has decreased by nearly half in the HAART era, but 10% to 15% of patients still develop HAD.[316] HAD is a subcortical dementia marked by memory loss, apathy, and difficulty with reading and comprehension in the early stages. Patients gradually progress over months to develop global dementia and often have concomitant motor and sensory neuropathies.[316] It is thought to be caused either by repeated exposure to infected monocytes that cross the blood-brain barrier or by autonomous viral production in the brain, which serves as a reservoir for the virus.[314]

The incidence of peripheral neuropathy, now the most common neurologic manifestation of AIDS, has also decreased dramatically in the HAART era. Symptomatic peripheral neuropathy is present in approximately 30% of patients.[317,318] Cranial nerve involvement is rare, with 2% to 3% incidence cited in older studies wherein the most commonly affected nerves were the facial, trigeminal, optic, and cochleovestibular nerves.[319,320] Peripheral neuropathy associated with HIV infection may affect motor nerves, causing spastic paraparesis, but more commonly affects sensory nerves in a phenomenon known as distal sensory polyneuropathy (DSP).[316] DSP is characterized by symmetric polyneuropathy and axonal degeneration. A similar pattern of neuropathy can selectively affect cranial nerves in the form of a mononeuritis multiplex, resulting in a transient mononeuropathy or progressive sensorimotor polyneuropathy.[321] Although previously noted to occur in patients with lower CD4 counts, in the HAART era, CD4 count does not seem to correlate with rates or severity of symptomatic DSP.[317,318] The pathogenic mechanisms of DSP are not fully understood, but direct neural invasion by HIV is not likely to play an important role.[317] Rather, its pathogenesis is likely multifactorial. One important factor may be the HIV envelope glycoprotein gp120, which is thought to bind to chemokine receptors and induce neuronal injury in the dorsal root ganglion.[316,317] Direct mitochondrial toxicity from antiretroviral NRTI is also thought to contribute to neuropathy in HIV patients.[316-318,322] Finally, necrotizing vasculitis associated with CMV or varicella zoster virus infection may also play a role in axonal degeneration.[322]

HAD must be differentiated from other causes of CNS dysfunction such as CMV encephalitis, progressive multifocal leukoencephalopathy (PML), meningitis, primary CNS lymphoma, and depression.[316] PML is a demyelinating disease of the CNS associated with papovavirus infection. In PML, there is progressive deterioration of mentation and other neurologic functions, including cranial nerve weakness. *Toxoplasma gondii* infection of the brain produces large areas of coagulation necrosis. The resulting mass lesion causes altered levels of consciousness and focal deficits, including cranial nerve dysfunction. Toxoplasmosis is definitively diagnosed by brain biopsy but is usually diagnosed presumptively by the presence of an enhancing lesion on MRI or CT, and a clinical and radiographic response to empiric management with pyrimethamine and either sulfadiazine or clindamycin.

Cranial nerve deficits may result from primary or secondary CNS lymphoma, with the trigeminal and facial nerves most commonly being involved.[323-325] Aseptic meningitis is also associated with cranial neuropathies secondary to increased intracranial pressure and perineural inflammation.[326] Idiopathic facial nerve paralysis has previously been reported to occur at much higher frequencies in HIV-positive patients.[327] However, given the extremely rare occurrence of idiopathic facial nerve paralysis even among HIV-positive patients, these findings have not been substantiated over time. The diagnosis of cranial neuropathies may be complicated by the presence of multiple concurrent pathologic processes of the CNS and peripheral nervous system.

Hearing Loss

Early in the HIV epidemic, several small studies suggested higher levels of idiopathic sensorineural hearing loss (SNHL), primarily affecting the high frequencies in patients with HIV. However, more recent data have not demonstrated an increased incidence of idiopathic hearing loss in the HIV-positive population.[226,328] Antiretroviral treatment does not appear to cause increased rates of hearing loss.[329] Although patients with HIV may not have clinical evidence of auditory dysfunction, many studies have demonstrated delayed wave latencies on auditory brainstem evoked response (ABR) testing.[330-333] These ABR abnormalities occur in patients with symptomatic or asymptomatic HIV infection. The central auditory pathway in the upper brainstem is dysfunctional in earlier stages of HIV infection as indicated by prolonged I-V and III-V intervals, whereas the lower brainstem is affected in advanced HIV infection as indicated by a prolonged I-III interval.[334] These findings were attributed to the central nervous effects of HIV infection.

The labyrinth is not as common a site of HIV-related pathology as is the central auditory system. Few abnormal findings are present on temporal bone histopathology, even on specimens from which viruses have been cultured.[335] However, a recent study demonstrated that patients with HIV had abnormal posturography results compared to normal individuals and that vestibular dysfunction worsens with advanced immunosuppresssion.[336] These findings may reflect the CNS effects of HIV infection.

Opportunistic diseases including CNS toxoplasmosis, tuberculosis meningitis, cryptococcal meningitis, and NHL may also cause SNHL in the AIDS patient. Sudden deafness and vestibular hypofunction in association with acute HIV infection and aseptic meningitis has been demonstrated, possibly as a result of a viral labyrinthitis or cochleovestibular neuropathy.[337]

Cryptococcal Meningitis

Cryptococcal meningitis is an opportunistic infection by the fungus *C. neoformans* and is the AIDS-defining illness in 40% to 60% of patients who are diagnosed with AIDS.[338,339] Since the introduction of HAART, the incidence of opportunistic infections with *C. neoformans* in patients with HIV has decreased dramatically from up to 66 cases per 1000 persons in 1992 to 2 to 7 cases per 1000 persons in 2000. Meningitis is the most common manifestation, occurring in nearly 75% of cases.[338,340] Cryptococcal meningitis is associated with severe immunocompromise and rarely occurs when the CD4 count is greater than 100 cells/μL. Bilateral SNHL occurs in 18% to 30% of patients with cryptococcal meningitis.[341,342] Hearing loss demonstrates sudden onset with slow progression, and is usually reversible with treatment of the underlying disorder.[342] Cryptococcal meningitis in patients with AIDS differs from that occurring in immunocompetent individuals in that AIDS patients develop fewer mass lesions, have higher fungal burdens, and have a poor cerebrospinal fluid (CSF) inflammatory response.[326,343] Cryptococcal meningitis may present with cranial nerve palsies affecting the facial or vestibular nerves due to elevated intracranial pressure.[343,344] Temporal bone histopathology in patients with cryptococcal meningitis demonstrates extensive invasion and destruction of the fibers and spiral ganglion of the cochlear nerve. Relative sparing of cochlear structures and vestibular nerves occurs in most cases, except in fulminant infections.[345-348]

The diagnosis of cryptococcal meningitis may be delayed because of its sometimes indolent course. The most common presentation is headache, fever, malaise and altered mental status over several weeks,[343] but patients with cryptococcal meningitis may only complain of sudden hearing loss.[348] Hearing loss is the most common cranial nerve manifestation followed by abnormal papillary reflexes, extraocular muscle paralysis, facial nerve paralysis, and blurred vision. Intracranial hypertension is thought to be the primary cause of visual and extraocular abnormalities associated with cryptococcal meningitis.[343]

If SNHL resulting from cryptococcal meningitis is misdiagnosed as idiopathic sudden hearing loss or autoimmune inner ear disease, management with corticosteroids places the patient at risk of develop-

ing fulminant life-threatening cryptococcal infection. Sudden and rapidly progressive hearing loss in an immunocompromised HIV-infected patient should therefore include serum cryptococcal antigen and a lumbar puncture before corticosteroid therapy is considered. Elevated CSF cell count is seen in immunocompetent patients, but is often low in patients with HIV.[343] The diagnosis is made by the detection of cryptococcal antigen and by the identification of *C. neoformans* on culture. Visualization of the encapsulated budding yeast using India ink is a quick and easy but less sensitive test. The current standard therapy is at least 2 weeks of amphotericin B (0.7 to 1 mg/kg/day), or liposomal amphotericin B for patients with renal dysfunction.[343] The addition of 5-fluorocytosine has been shown to have additive benefit.[349,350] Patients are treated with fluconazole (200 mg/day) for 6 to 12 months, with consideration for discontinuation after CD4 count is above 100 to 200 cells/μL for at least 6 to 12 months.[343] Persistent intracranial hypertension may require serial lumbar punctures, acetazolamide, or ventricular-peritoneal shunt placement.[351]

As with mycobacteria, *Cryptococcus* infections in HIV-positive patients may be associated with IRD. Cryptococcal infections in IRD may present with lymphadenitis, CNS lesions, or skin or soft tissue lesions, but aseptic meningitis is most commonly reported.[17,18] These infections usually represent reactivation from previously treated infections.[18] Differentiating IRD-related cryptococcal infections from true opportunistic infections is difficult but important, because management differs in these patients. There are no universally accepted guidelines, but tapered doses of prednisone have been proposed.[17] Moreover, HAART-naive patients who present with opportunistic infections may benefit from deferral of HAART initiation until after the initial treatment phase has succeeded.[15,18]

Otosyphilis

Otosyphilis should be suspected in any HIV-infected patient who presents with cochleovestibular complaints. In turn, HIV infection should be suspected in all patients diagnosed with syphilis. An alarming trend of increased rates of syphilis has emerged with the HIV epidemic. After steady declines in the incidence of infection until 2000, the incidence in the United States by 2005 was up to 3 cases per 100,000 people.[352] The primary demographic group affected has been men who have sex with men who account for 65% of cases.[352,353] The reasons for the change include a decrease in safer sex practices and increased illicit drug use.[352] Patients with HIV differ from HIV-negative patients with syphilis in that HIV infection is associated with a higher risk of developing neurosyphilis.[352] The interval between primary infection and otosyphilis appears to be shortened to 2 to 5 years in HIV infection compared to 15 to 30 years in the general population.[354] Even in patients clinically cured of syphilis, viable treponemes have been isolated from perilymph and temporal bone tissue.[355,356] Thus it has been suggested that residual treponemes, which remain dormant in the temporal bone, are reactivated as cell-mediated immunity deteriorates in the setting of HIV. Neurosyphilis can occur at any stage of syphilis infection, thus otosyphilis should be suspected in an HIV-infected patient with cochleovestibular abnormalities and a previous history of treated syphilis because labyrinthine disease may result from reactivation, reinfection, or persistent treponemal infection.

The incidence of hearing loss has been reported to be nearly 20% in patients with latent syphilis and 54% of patients with neurosyphilis.[357] Hearing loss resulting from syphilis is usually bilateral, may be progressive or fluctuate, or may have a sudden onset.[357,358] Tinnitus, aural fullness, and dysequilibrium occasionally occur. The audiometric curve often shows a low-frequency hearing loss in association with diminished speech discrimination scores. Fortunately, the majority of patients either recover hearing or have stable hearing after appropriate treatment.[357,359]

The diagnosis of otosyphilis is based upon history and serologic testing in patients with no other apparent cause for cochleovestibular dysfunction. Traditionally, nontreponemal tests such as Venereal Disease Research Laboratory (VDRL) and rapid plasma reagin (RPR) tests have been used for initial screening. In recent years, however, nontreponemal testing using an enzyme immunosorbent assay (EIA) has become the screening test of choice.[360] If positive, confirmatory testing with treponemal-specific tests such as fluorescent treponemal antibody absorption (FTA-ABS) or microhemagglutinin-treponema pallidum (MHA-TP) should be performed. CSF of any patient suspected of neurosyphilis should be examined.[361] Treponemal-specific tests remain positive for life, even after successful eradication of infection. Nontreponemal EIA testing is not helpful in cases of reinfection, and VDRL may be negative in tertiary syphilis. Patients with reactive treponemal tests but nonreactive nontreponemal tests who have clinical findings consistent with otosyphilis should be presumptively treated. Temporal bone CT findings in otosyphilis may be normal, but irregular lucencies in the otic capsule or ossicular chain with a characteristic "moth-eaten" appearance can help confirm the diagnosis.[362]

Treatment of syphilis is the same in HIV-positive and HIV-negative patients. The current CDC recommendation for treatment for otosyphilis is aqueous crystalline penicillin G (18 to 24 million U per day) for 10 to 14 days, followed by benzathine penicillin G (2.4 million U intramuscularly weekly) for up to 3 weeks.[361] Corticosteroids are also often used in otosyphilis, but in HIV-infected patients may be associated with a risk of further immunocompromise, leading to infectious complications. Corticosteroid therapy should be of short duration and be given in close consultation with the patient's primary care provider.

Approach to Sensorineural Hearing Loss in Human Immunodeficiency Virus–Positive Patients

The first priority in the evaluation of SNHL in a patient with HIV infection is to rule out potentially life-threatening disease. A thorough history should include a description of the rate of progression of hearing loss and the presence of dysequilibrium, other neurologic symptoms, headache, fever or neck stiffness. A complete list of all medications with attention to HAART should be obtained and ototoxic drugs discontinued if medically feasible. A complete head and neck and neurologic examination should be performed. An audiometric evaluation should include a pure tone audiogram, stapedial reflex testing, and speech discrimination scores. Electronystagmography is useful in the evaluation of dysequilibrium to assess peripheral function. Laboratory studies, including VDRL, FTA-ABS, serum cryptococcus antigen, antinuclear antibodies, erythrocyte sedimentation rate, and rheumatoid factor titers should be routine in the evaluation of patients with SNHL. If SNHL is accompanied by headache, fever, meningeal signs, or other neurologic abnormalities, head CT or MRI should be followed by lumbar puncture. Patients with advanced immunocompromise and progressive or sudden SNHL should also undergo brain imaging followed by CSF examination. Cryptococcal antigen and fungal, mycobacterial, and bacterial cultures should be performed. CSF should also be examined for cytology, VDRL and cell count, protein, and glucose. MRI of the cerebellopontine angle (CPA) with gadolinium should be considered in patients with asymmetric hearing loss and an otherwise negative workup to rule out acoustic neuromas or other lesions of this region. Auditory brainstem response abnormalities are common in the HIV-infected population, rendering this test insensitive for the detection of cochlear nerve pathology caused by mass lesions in the CPA and internal auditory canal.

Management of hearing loss in the HIV-infected population should focus on the underlying cause (Table 15-7). As mentioned earlier, indiscriminate administration of corticosteroids in the setting of HIV infection is risky. There may be multiple causes of hearing loss during the course of HIV infection. As a result, the clinician should be prepared to repeat the evaluation in search of new causes of SNHL in cases of sudden and rapid deterioration of residual hearing. Finally, auditory rehabilitation with hearing aids has an important role in maintaining the quality of life in an otherwise disabling and isolating disease. Initial experience with cochlear implantation in patients with HIV has demonstrated successful results with no increase in postoperative complications.[363,364]

Hearing Loss in Transplant Recipients

Patients with chronic renal failure are known to have higher rates of sensorineural hearing loss, as demonstrated by both pure tone audiometry and ABR testing.[365,366] Whereas treatment with dialysis has not been shown to improve hearing function, one small study

demonstrated improvement in ABR findings after renal transplantation.[366] In contrast, patients who undergo liver transplantation have increased rates of SNHL. Nearly 15% of children undergoing liver transplantation were found to have SNHL by audiologic testing.[367,368] Studies in adults suggest that immunosuppression with tacrolimus may be an important factor in the development of posttransplantation hearing loss.[369,370]

Oral Cavity

Oral lesions occur in many patients during the course of HIV infection. The most common oral manifestation is candidiasis, followed by oral hairy leukoplakia.[371] Other common findings include KS, periodontal and gingival infections, aphthous ulcers, herpes simplex stomatitis, and xerostomia (Table 15-8). The risk for developing an HIV-related oral lesion correlates with lower CD4 counts, although some data suggest that this relationship weakens with longer durations of HIV infection (>10 years).[371] The use of HAART has caused a 10% to 50% decrease in HIV-associated oral disease, particularly for oral candidiasis,[372] although in children this beneficial effect is not as significant.[373] Overall, oral complications develop in approximately 20% of HIV-positive patients on HAART.[374] KS and NHL are the most prevalent malignancies occurring in the oral cavity and pharynx. However, as the longevity of AIDS patients increases, so does their risk of developing other malignancies. The clinician should be prepared to handle this increasing challenge (1) by being familiar with the oral lesions that commonly occur in this patient population, (2) by performing biopsies of all lesions that are suspicious or that do not respond to a short course of empiric therapy, and (3) by not assuming that multiple concurrent lesions have the same pathogenesis.

Oral Candidiasis

Candidal infection is the most common oral manifestation of HIV infection. In the era of HAART, the incidence of oral candidiasis has decreased by nearly 50%.[375] Reports of prevalence of oral candidiasis are 10% to 24% for patients not on HAART, and 2% to 10% for those on HAART.[376,377] With CD4 counts less than 200 cells/μL, the prevalence increases to 39% for patients not receiving HAART.[376] It also occurs in up to 20% of organ transplant recipients.[378,379] The most common organism responsible is *Candida albicans*, and up to 80% of all HIV-positive patients have oral colonization with *C. albicans*.[380] Oral candidiasis is strongly related to lower CD4 counts and higher viral loads, and possibly with smoking.[381,382] The development of OC in patients on HAART is predictive for immune and virologic failure.[374,383]

Candidal infection of the oral mucosa can take four forms[384]:

1. Pseudomembranous candidiasis (thrush) presents as a smooth white or cottage cheese–like plaque that can occur on any mucosal surface. It is distinguished from other white lesions of the oropharynx in that the white plaques can be rubbed off; when the plaque is wiped off, an erythematous and bleeding base remains.

2. Erythematous candidiasis is marked by mild or moderately erythematous patches.

3. Angular cheilitis presents as tender and erythematous fissures and ulcers at the oral commissure (Fig. 15-5).

4. Hyperplastic candidiasis, the rarest type, most commonly involves the buccal mucosa to produce raised white plaques that cannot be scraped off.

The differential diagnosis of this lesion includes leukoplakia, carcinoma in situ, and oral hairy leukoplakia. Candidal infection can be diagnosed based on the resolution of these lesions with empiric anticandidal therapy. More definitive diagnosis can be made by a potassium hydroxide preparation or Gram stain of a scraping or by periodic acid–Schiff stain of a biopsy specimen. Candida species have also been reported to cause necrotizing lesions of the epiglottis in immunocompromised patients.[385,386]

Oral candidiasis in patients with CD4 greater than 200 cells/μL is successfully managed with topical antifungals—nystatin suspension 5 mL four times per day, or clotrimazole troches 10 mg five times per day.[387] For patients with CD4 counts less than 200 cells/μL, oral fluconazole or itraconazole is recommended, with ketoconazole as an alternative.[388] Posaconazole has been demonstrated to be effective for oral candidiasis refractory to azoles.[389,390] The use of fluconazole prophylaxis for the prevention of oral candidiasis is not recommended due to the risk of side effects and lack of survival benefit.[391]

Oral Hairy Leukoplakia

Oral hairy leukoplakia is a white lesion with a corrugated and shaggy surface; it most frequently occurs on the lateral surface of the tongue. Oral hairy leukoplakia affects 3% to 10% of HIV-positive patients,[392,393] and may also occur in immunosuppressed transplant recipients.[378,394] It is rare in children, occurring in only 3% to 4% of HIV-positive children.[186] Oral hairy leukoplakia is caused by EBV,[387] and its presence in an otherwise asymptomatic patient is a strong indicator of a diagnosis of HIV infection with moderate to severe immunosuppression. Risk factors for the development of oral hairy leukoplakia include low CD4 count, high viral load, and the presence of oral candidiasis.[393,395,396] The

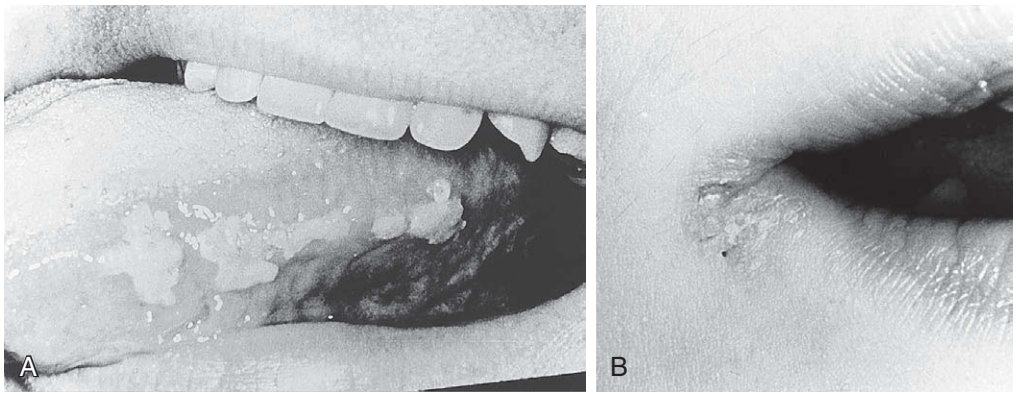

Figure 15-5. Pseudomembranous candidiasis and angular cheilitis. **A,** Pseudomembranous candidiasis of the lateral surface of the tongue. These smooth white plaques are easily scraped from the mucosa, leaving an erythematous and bleeding base. **B,** Angular cheilitis characterized by tender ulcers and fissures of the oral commissure as a result of candidal infection. *(Courtesy of Dr. Steven Ashman.)*

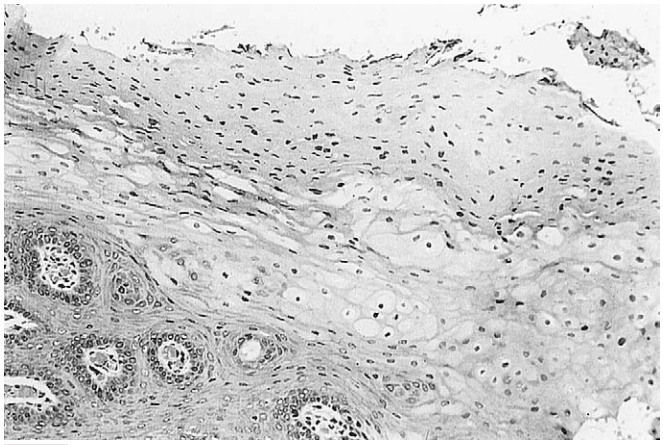

Figure 15-6. Oral hairy leukoplakia. Characteristic hyperparakeratosis is present, as is a layer of "balloon cells" in the upper spinous cell layer. *(Courtesy of Dr. Russel Corio.)*

presence of oral hairy leukoplakia is not as strongly predictive for immune and virologic failure as oral candidiasis.[383]

When an oral lesion persists despite a short course of anticandidal therapy, a biopsy is indicated to rule out a malignant or premalignant lesion. The differential diagnosis of oral hairy leukoplakia includes leukoplakia, carcinoma in situ, hypertrophic candidiasis, and lichen planus. Oral hairy leukoplakia is diagnosed on biopsy by the presence of hyperkeratosis, acanthosis, clear or "balloon" cells in the upper spinous cell layer with minimal inflammation, and the presence of EBV in the basal epithelial cells (Fig. 15-6).[384] Once the diagnosis is made, further management is rarely needed because OHL is often asymptomatic and does not undergo malignant transformation. There are insufficient data to support evidence-based recommendations for treatment. Topical treatments such as podophyllin or retinoin have been investigated, but recurrence is common. One small study found that the addition of acyclovir with podophyllin cream resulted in complete remission at 12 months.[397] The use of systemic antivirals (desciclovir, valacyclovir, acyclovir, ganciclovir, foscarnet, and famciclovir) has been reported, but the body of evidence is too small to determine their efficacy.[387]

Herpes Simplex Virus

Infections of the oral cavity by herpes simplex virus increase in all stages of HIV infection. Seropositivity for HSV approaches 95% in the HIV-positive community, compared to 80% in the general population.[398] The prevalence of HSV lesions has decreased in the HAART era, and recent prevalence is reported at 2% to 3%.[186,399] Herpetic lesions are particularly persistent when the CD4 count is less than 100 cells/μL. Herpes labialis is the most common manifestation of herpes simplex infection of the oral cavity. When this manifestation occurs in the HIV-infected patient, these "fever blisters" are generally larger, more numerous, persist longer, and recur more frequently than in the general population. Intraoral infection by herpes simplex usually affects the keratinized and attached mucosa of the hard palate and gingiva and the dorsum of the tongue. The characteristic appearance is that of small round ulcers without an erythematous halo. Multiple ulcers can produce significant discomfort with mastication and swallowing, threatening nutrition. Herpes simplex virus (HSV) infection in the HIV-infected patient is likely to be prolonged and less localized than in the general population.

Herpes simplex infection is usually diagnosed empirically by the characteristic appearance of lesions and is treated with oral famciclovir, valacyclovir, or acyclovir for 7 days, although severe lesions may require intravenous acyclovir.[398] For lesions that persist after adequate treatment, cell scrapings from the base of the lesion should be cultured for sensitivity testing. The treatment of choice for acyclovir-resistant HSV is intravenous foscarnet. Daily suppressive therapy with oral acyclovir, famciclovir, or valacyclovir should be considered for patients who have frequent or severe recurrences.

Oral Histoplasmosis

Histoplasmosis is a granulomatous fungal disease caused by *Histoplasma capsulatum* and is an AIDS-defining illness.[400] *H. capsulatum* is endemic in areas of North, Central, and South America, Asia, and Africa, but it can be found throughout the world.[401] Nearly 50% to 80% of adults in endemic areas may be infected, with most being asymptomatic.[402] Although immunocompetent patients can develop oral lesions, oral histoplasmosis is strongly associated with HIV infection. In endemic areas, the prevalence of oral histoplasmosis is 3% in HIV-infected patients and less than 0.1% in non–HIV-infected patients,[400,403] thus any patient who presents with oral histoplasmosis should undergo HIV testing. Symptomatic histoplasmosis infection presents as acute pulmonary, chronic pulmonary, or disseminated disease.[403] Mucocutaneous involvement most often occurs in the setting of disseminated histoplasmosis but can occur in isolation.[400] Histoplasmosis affecting the nasal cavity[404] and parotid gland[405] of HIV-positive patients has been reported, and oral histoplasmosis may also occur in immunosuppressed organ transplant recipients.[406] The presence of oral histoplasmosis is associated with CD4 counts less than 50 cells/μL and higher mortality at 6 months than for patients with disseminated histoplasmosis without oral involvement.[407,408]

Patients with oral histoplasmosis present with painful, erythematous patches that progress to raised, granulomatous lesions that may be covered with an adherent pseudomembrane.[400] Associated cervical adenopathy may be present.[409] Diagnosis is established by antigen

testing in body fluids and by biopsy of lesions with histology and culture for *H. capsulatum*.[402] For oral histoplasmosis occurring in the setting of disseminated disease, treatment depends upon the severity of disease.[401] For moderately severe or severe disease, systemic amphotericin B (3 mg/kg/day) for 1 to 2 weeks followed by oral itraconazole (200 mg three times daily for 3 days then 200 mg twice daily for 12 months) is recommended. For mild to moderate disease, oral itraconazole alone may be sufficient. Patients with CD4 counts less than 150 cells/μL or other immunosuppressed patients with recurrent disease should be placed on daily itraconazole prophylaxis.

Gingivitis and Periodontal Disease

Periodontal disease associated with HIV infection is classified into three categories[410]:

1. Linear gingival erythema presents with distinct linear erythema that does not respond to conventional periodontal therapy and is closely related to the presence of oral candidiasis.

2. Necrotizing periodontal disease, which can occur in immunocompetent patients, presents with ulceration of the interdental papilla associated with gingival bleeding and pain (necrotizing ulcerative gingivitis) that may invade the alveolar bone (necrotizing ulcerative periodontitis). Both are also strongly associated with oral candidiasis. Case reports have described extension of this necrotizing process into the maxillary or mandibular bone and is known as necrotizing ulcerative stomatitis.

3. Progression of chronic periodontal disease is enhanced.

With the use of HAART, the prevalence of periodontal disease has dropped from less than 10% to as low as less than 1% in one study.[410] The presence of necrotizing periodontal disease in a patient not known to have HIV infection should prompt serologic testing, because this disease is strongly associated with HIV. Patients with CD4 less than 200 cells/μL are much more likely to develop necrotizing periodontal disease than those with CD4 greater than 200 cells/μL.

The differential diagnosis of a destructive process that involves the soft tissue and bone of the alveolar crests includes lymphoma, SCC, KS, bacillary angiomatosis, fungal infection, and mycobacterial infection. The presence of bone destruction out of proportion with the soft tissue changes is more likely to be caused by bacillary angiomatosis than necrotizing ulcerative periodontitis.[76] Tissue should be sent for histopathologic and microbiologic testing. Periodontal consultation should be requested for appropriate and expeditious management of periodontal disease.

The mainstay of therapy for HIV-related gingivitis and periodontitis includes dental plaque removal and oral rinses with 10% povidone-iodine, with 0.1% to 0.2% chlorhexidine gluconate.[384] Because periodontal disease in HIV-positive patients is closely associated with candidiasis, topical or systemic antifungal treatment should also be employed.[410] If present, necrotic tissue should be debrided and the teeth scaled. If patients fail to respond to initial management, parenteral antibiotic therapy with clindamycin or metronidazole should be instituted.

Aphthous Ulcers

Aphthous ulcers are of three types, all of which affect unattached oral mucosa. Herpetiform ulcers are smaller than 0.2 mm in diameter and are self-limited. Minor aphthous ulcers are well-circumscribed, painful ulcers less than 6 mm in diameter with an erythematous halo. In the HIV-infected patient, ulcers frequently coalesce to form larger lesions lasting about 2 weeks. Major aphthous ulcers (Sutton's disease) are larger than 6 mm in diameter (Fig. 15-7). They are painful, persist for weeks, and threaten nutritional intake. They are difficult to grossly differentiate from malignancy. In the HAART era, the incidence of aphthous ulcers ranges from 1% to 8% in HIV-positive patients.[375,399,411]

Management should focus on ruling out malignancy, providing symptomatic relief, and monitoring nutritional status. The edge of the ulcer should be biopsied and submitted for histopathologic study to rule out lymphoma and SCC. The size, chronicity, and exquisite tenderness of major aphthous ulcers mandate close monitoring of body weight and the provision of liquid nutritional supplements. Initial treatment for minor ulcers with over-the-counter topical protective and analgesic medications is recommended.[412] For major or nonhealing minor lesions, thalidomide (200 mg/day) has been shown to be effective for treatment, but ineffective for prevention of recurrence.[387] Intralesional or systemic steroids have also been found to be effective.[412]

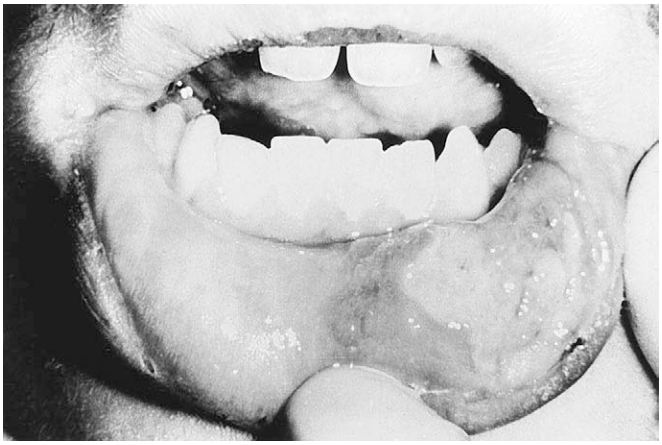

Figure 15-7. Major aphthous ulcer (Sutton's disease) of the lower lip. This lesion is indistinguishable from lymphoma or squamous cell carcinoma and should undergo biopsy. *(Courtesy of Dr. Steven Ashman.)*

Human Papillomavirus

Human papillomavirus (HPV) may cause oral or genital warts, which, like other HIV-associated oral lesions, occur with lower CD4 counts.[413] The incidence of oral warts in HIV-positive patients is 1.6%, and interestingly, the incidence of oral warts increases with lower viral loads.[414] Whether this phenomenon is explained by a mechanism similar to immune reconstitution syndrome is unclear. Oral HPV infection rates have not decreased in the HAART era, and in fact may have increased in white men infected with HIV.[387] Few studies have investigated optimal management of these lesions in the HIV population, but surgery is the most common therapy for symptomatic lesions. Alternative therapies include cidofovir, bleomycin, cimetidine, podophyllin, or intralesional interferon.

Miscellaneous

Although more commonly involving the paranasal sinuses, invasive fungal infections of the pharynx and larynx have been described in HIV-positive[284-286] and other immunosuppressed patients.[287-290] Diagnosis and treatment of these invasive infections requires a high degree of suspicion and prompt initiation of medical therapy. In one case, a total laryngectomy was required for disease control.[291]

Human Immunodeficiency Virus–Associated Facial Lipoatrophy

First described in 1998,[415] lipodystrophy is a term used to refer collectively to the changes in fat distribution that occur in HIV-positive patients. These changes include peripheral lipoatrophy affecting the face and extremities; lipohypertrophy, which may manifest as increased fat deposition in dorsocervical fat pads ("buffalo hump"), increased breast size and abdominal girth, and visceral adipose tissue; and metabolic disturbances such as hypertriglyceridemia, hypercholesterolemia, insulin resistance, type 2 diabetes mellitus, and elevated hepatic transaminases.[416-418] There is not yet consensus regarding the definition and classification of the manifestations of lipodystrophy, which hinders interpretation of the literature.[418] Reports of prevalence vary widely due this lack of standardized case definitions and differences in methodology,[419] but a review of recent literature found that the prevalence of

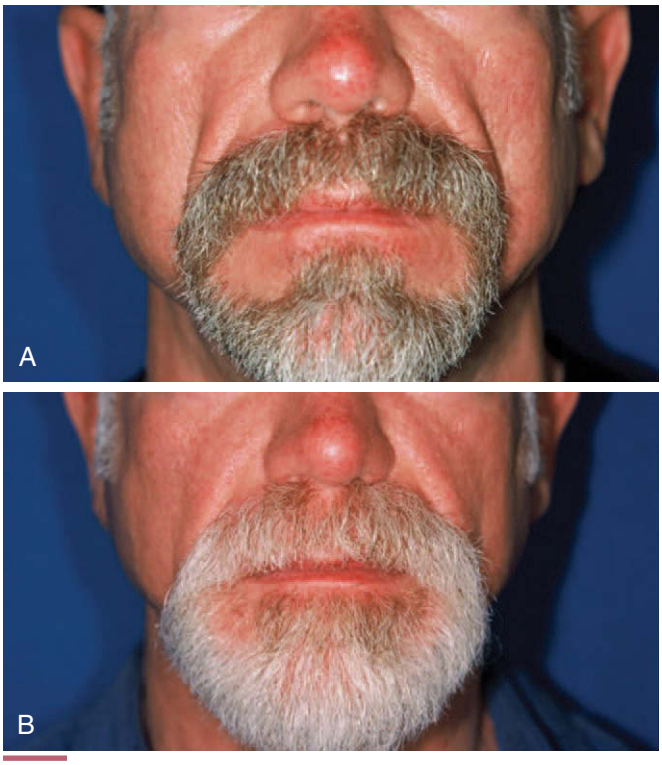

Figure 15-8. Moderately severe facial lipoatrophy, before **(A)** and after **(B)** treatment. *(Courtesy of Dr. Michael Echavez.)*

peripheral lipoatrophy in HIV-positive men and women was 22% to 38%.[420] The cause and mechanism of lipoatrophy remain unknown. Many reports have demonstrated that the use of antiretroviral therapy including NRTIs and protease inhibitors, but not NNRTIs,[418,419,421] is associated with lipoatrophy. These findings have led some to conclude that inhibition of lipid and adipocyte regulatory proteins by antiretrovirals or mitochondrial toxicity from NRTIs is responsible.[418] However, other studies have shown a strong correlation with AIDS diagnosis, CD4 count, and viral load, and not with HAART, suggesting a role for HIV infection itself.[418,422] This discrepancy may be due to different methodologies used in the studies, and it is possible that these various factors may have an impact on some but not others of the different manifestations of lipodystrophy.[416]

Facial lipoatrophy is characterized by fat atrophy in the malar, buccal, melolabial, and temporal regions (Fig. 15-8).[423,424] Patients affected by peripheral lipoatrophy may feel embarrassed or stigmatized by their aesthetic appearance, and studies have shown that these negative effects may lead to decreased adherence to HAART.[418] Objective assessment of the severity of lipoatrophy is difficult, because CT and MRI are both costly and not practical for routine use. Ultrasound has been shown in some studies to be useful,[425,426] but other data suggest that changes detected with ultrasound do not correlate with changes seen on CT.[427] This controversy may reflect difference in methodology used.

Many different treatment strategies have been proposed for facial lipoatrophy, but unfortunately no medical therapies have been shown to be effective. Surgical options include autologous fat grafting,[424,428] hyaluronic acid injection,[429,430] poly-L-lactic acid injection,[431-433] calcium hydroxylapatite injection,[434,435] malar or submalar synthetic implant placement,[436] and other injectable fillers.[437-439] Current FDA-approved treatments for facial lipoatrophy include calcium hydroxylapatite and poly-L-lactic acid. Few comparative studies have been performed and have found no difference in successful outcomes between implant placement and injection with fat or synthetic substances.[440-442] The decision to treat facial lipoatrophy and the method used to correct the cosmetic deformity should be guided by patient and surgeon preference.

Summary

With advances in the treatment of HIV infection and increased success of organ transplantation, patients with immunosuppression live longer, healthier lives. The recognition and management of disease entities occurring in this unique population are important in further reducing morbidity and mortality from head and neck diseases. Even though managing these patients is a challenge for the otolaryngologist, a clear understanding of the basic pathophysiology of conditions affecting the head and neck in immunocompromised patients will allow the otolaryngologist to more effectively evaluate and treat these diseases.

CHAPTER SIXTEEN

Special Considerations in Managing Geriatric Patients

Meena Seshamani

Matthew L. Kashima

Key Points

- The population is aging, as people are living longer.
- The geriatric population is made up of a significant proportion of otolaryngologic practice.
- Presentation in older adults may be different than in the younger population, and the spectrum of disease may be different.
- Diagnosis, prognosis, and goal of therapy need to be discussed with patient and family.
- Sensory disorders affecting hearing, speech, taste, smell, and balance are common and may significantly affect the quality of life of the geriatric patient.
- Awareness of how otolaryngologic processes affect the geriatric population will allow for better satisfaction for the patients, their families, and the otolaryngologists involved in caring for this population.

The social and economic significance of the graying of America has received a great deal of attention. Numerous articles and editorials document the projected rate of growth of the geriatric population and how it will affect the practice of medicine. Together, geriatricians and other specialists in geriatric medicine and surgery are developing a system of care that keeps older adults healthier, more functional, and more independent at older ages than was previously possible. Otolaryngologists have taken up the challenge of describing and treating problems involving the senescent ear, nose, and throat. Otolaryngologists play a role as communication specialists and are a key resource for helping older adults avoid isolation. The American Society of Geriatric Otolaryngology was formed in 2007 to help the specialty present a unified position in treating geriatric patients with otolaryngologic conditions.

Magnitude

The term *geriatrics* was coined by I. L. Nascher in 1909.[1] Since then, industrialized countries have experienced an exponential increase in life expectancy, from 50 years in 1900 to 78 years in 2005, with a prediction of 85 years by 2050.[2] Coupled with this increased longevity is a historic bump in birth rate during the 2 decades after World War II (i.e., the "baby boom") and a current decline in fertility, leading to an increasing proportion of the population in the older age groups. In 1980, 11.3% of the U.S. population was 65 years of age or older, compared with 12.4% in 2005[3] and a projected 19.6% in 2030.[4] Within the geriatric population, persons 85 years of age and older make up the fastest growing segment, more than doubling from 2 million (1.0% of the population) in 1980 to 5 million (1.7% of the population) in 2005.[3]

The aging of the population in turn affects systems of social support, in that the number of people who work and generate income declines relative to those who do not work. This concept underlies the "old age dependency ratio," which is the number of people aged 65 and older per 100 working people (between 15 and 64 years of age). Currently there are just more than five supporting individuals for every elderly person. By 2050, this number is expected to drop to two.[5]

Disability and disease are more prevalent in older populations. One study of the National Health and Nutritional Examination Survey found that 74.6% of women and 67.4% of men aged 65 and older suffer from chronic diseases such as arthritis, diabetes, coronary artery disease, cerebrovascular accidents, or chronic lower respiratory tract disease.[6] Moreover, older adults are more likely to experience limitations in activities of daily living, with 53% of people aged 85 years and older reporting functional limitations.[7] In turn, chronic disease and functional limitations translate to increased health care utilization and cost. Nearly half of lifetime-per-capita health expenditures occur after age 64 years.[8] From 1980 to 2005, nursing home and home health care expenditures increased 8-fold from $21 billion to $169 billion.[9] The expected growth of the geriatric population therefore portends a significant impact on society's social, economic, medical, and ethical needs and obligations.

Basic Principles of Geriatric Medicine

Irvine defined six basic principles that are useful in the care of older patients.[10] Clinical decisions in this patient group tend to be complex. The fundamentals are:

1. Coexistence of multiple diseases: The unitary disease hypothesis usually does not apply. As people age, they accumulate medical diagnoses, both major and minor. These comorbidities can have an impact on the presentation and response to therapy in older adults. Signs and symptoms are more likely to be the result of several medical problems.

2. Unique spectrum of illness: In addition to many of the diseases seen in their younger counterparts, older adults tend to suffer certain

diseases that occur only in old age. This includes a wide range of degenerative disorders and certain cancers.

3. Unusual presentation of illness: Typical symptoms, such as fever and pain, are often absent, and nonspecific symptoms, such as anorexia or falling, may herald a serious underlying disorder.

4. Proper role of the aging process: Differentiating treatable disease from the natural aging process may be difficult, particularly in the area of degenerative diseases. Most geriatric specialists believe that patients and families have a tendency to overrate the role of aging. As a result, they experience unnecessary suffering and dysfunction. Specific disease processes should be sought and treated whenever possible.

5. Underreporting of health problems: Patients and families often fail to report symptoms commonly relegated to old age.

6. Function-based treatment goals: Improving a patient's quality of life may shift therapeutic goals toward maximizing function and independence, possibly at the expense of potential for cure.

Medical care provided to older adults serves several purposes. Treatment can be directed at specific acute disease processes, and the goal of this therapy can be curative or palliative. Health care can also be directed toward chronic conditions related to the aging process, such as presbycusis. Here treatment can be directed toward reversing these conditions, preventing further disability, or educating patients about their condition. Prevention is also an important function for health care, and otolaryngologists should take advantage of opportunities to educate patients about lifestyle implications on future health.

Access to Medical Care

Consideration of barriers to medical care in older adults can help physicians play a central and effective role in the advocacy of their older patients. For example, a decreased level of strength and confidence may limit the ability of the older adult to visit a physician's office or the hospital, especially in the absence of strong family or community support. Social support systems often function better for acute and more serious problems, leading to the potential neglect of wellness and prevention initiatives. The high cost of modern health care may also create a barrier; the typical older couple has to save $300,000 to pay for health care costs not covered by traditional Medicare plans.[11]

An additional barrier to care is difficulty in obtaining accurate data from this population. Older adults have a relatively high incidence of memory impairment and cognitive dysfunction, which can significantly affect the ability of the practitioner to obtain an accurate history.[12] Even the presence of involved caregivers (e.g., adult children) may not be enough to provide complete historical data.

Diagnostic Testing

Because of the general principles mentioned previously, diagnosis may be the most challenging aspect of medical care in older patients; the focus should be on identifying treatable diseases and symptoms. A good deal of judgment is required to separate specific illness from the adverse (but natural) effects of aging, and it is usually not appropriate to attribute symptoms to aging unless other causes have been ruled out first.

Invasive diagnostic procedures are relatively contraindicated when functional reserve is poor. Fortunately, modern diagnostic techniques, especially in imaging, have limited the need for invasive procedures.

Treatment

Medical Therapy

The proper use of medications is particularly important in the older patient. Indeed, one study showed that the adverse effects of medication were the most common cause of symptoms mistaken for senile dementia.[13] According to Avon and Gurwitz, any symptom in an older patient may be a drug side effect until proven otherwise.[14] It is well known that sensitivity to drugs increases with advancing age, but the reasons for this are not completely clear. There is some evidence that drug metabolism by the liver and clearance by the kidney both decline as one ages, but this does not explain the entire phenomenon. Drug receptors at the cellular level also seem to increase in sensitivity. Drug interactions can be prevented by carefully evaluating existing drug therapy before starting any new medicines; this is especially important in the geriatric population, because most older patients are taking several drugs (both over-the-counter and prescription) at any given time.

Finally, the use of some medications by older adults should be completely avoided because of the known high incidence of side effects. A good example is sympathomimetic decongestants in older men, which frequently cause urinary retention.

Surgical Therapy

The decision to operate is never made lightly, and this is particularly true for older patients. Given the higher rate of chronic disease, preoperative cardiac, renal, and pulmonary clearance is important. Moreover, the physiologic changes that occur with aging affect the body's ability to respond to insults. Aging is associated with globally decreased functional reserve, which may be well-compensated under normal conditions, but not during times of physiologic stress. For example, reduced fibroplasia and decreased ability to remodel collagen can lead wounds in the older adult to heal slower. Up to 60% of older patients hospitalized for major surgical procedures suffer acute delirium or confusion.[7] Data from the Department of Veterans Affairs demonstrates a 6% 30-day mortality for patients aged 70 years and older, and 20% are likely to have at least one complication during their hospital stay. The 30-day mortality rate increases by 10% for every year after age 70. Complications and mortality are also associated with preoperative American Society of Anesthesiologists status, and may be more common after emergency procedures.[15]

End-of-Life Care

An important consideration with the treatment of older patients is the goal of therapy. Whether palliative or curative, the goal must be explicitly discussed with patients and their families to ensure that everyone is in agreement regarding the patient's global state of health.[7] Difficulties can arise when there is a difference in goals between a patient and his or her adult children, or when the patient's or family's expectations are unrealistic.

Issues of end-of-life care are particularly relevant in the current environment of rising health care costs. Even though costs are concentrated in the older age groups, studies have shown that they are particularly concentrated at the end of life, with costs in the last year skyrocketing six times higher than costs in prior years.[16] Indeed, economic studies have shown that inpatient expenditures are related more with proximity to death than with age, whereas long-term care expenditures are more closely related to patient age.[17] As the population ages, decisions on end-of-life care can have far-reaching socioeconomic ramifications.

The Aging Ear

The normal process of aging affects all parts of the ear, but the greatest clinical impact is on cochlear and vestibular function. Presbycusis, which is the loss of hearing that is associated with aging, is the most common type of auditory dysfunction and is thought to be due to a series of insults over time, including age-related degeneration, noise exposure, and diseases of the ear. It is greatly affected by genetic background, diet, and systemic disease. Vestibular symptoms are present in more than half of older adults. Because balance depends on input from the ears, eyes, and peripheral sensory systems, all of which degenerate over time, impaired function in any of these systems contributes to vestibular complaints.

The pinna is commonly involved in actinic disorders, especially basal and squamous cell carcinoma. Sun protection and frequent inspection are important. The external auditory canal suffers a decrease in cerumen production due to degeneration of cerumen glands and a reduction in the total number of glands. This may lead to a drier cerumen that is less protective of the underlying skin and may result

in a higher incidence of impaction and infection. Ceruminosis can be exacerbated by an increase in hair at the external auditory meatus. The skin also undergoes atrophy, which results in itching, fragility, and subsequent self-induced lacerations. The use of topical emollients has been recommended for difficult cases.

Presbycusis

Presbycusis, which is the auditory dysfunction associated with the aging process, is a generic term used to include several forms of hearing degeneration. It has been estimated that of the 27 million Americans with hearing loss (13% of the population), only 10% to 20% are due to noise exposure and most of the remainder is age-related.[18] Presbycusis may have a devastating effect on older individuals by reducing their ability to communicate, thereby jeopardizing autonomy and limiting opportunities of being an active member of society. An impaired ability to communicate can also have wide-ranging health effects, because ineffective communication between a patient and his or her health care provider can lead to missed diagnoses.[7] With the growth of the aged population, presbycusis has become a great challenge to the otologist.

Gacek and Schuknecht initially defined four histopathologic types of presbycusis: (1) sensory, which is characterized by hair cell loss; (2) neural, which is associated with the loss of spiral ganglion cells and axons; (3) metabolic, which is characterized by strial atrophy; and (4) mechanical or conductive.[19] Subsequently, two more categories were added: mixed and indeterminate. The indeterminate category alone may account for 25% of cases.[20] Recent studies indicate that a mixture of pathologic changes may be present most of the time.[21]

Sensory Presbycusis

The audiometric findings in this type of presbycusis include an abrupt, steep, and high-frequency sensorineural loss with slow, symmetric bilateral progression, usually beginning during middle age. Pathologic lesions are limited to the first few millimeters of the basal turn of the cochlea. There is flattening and atrophy of the organ of Corti due to the loss of hair cells and supporting cells. There is also an accumulation of lipofuscin, which is the aging pigment.

Neural Presbycusis

Audiometric findings include gradual hearing loss with a moderate slope toward the high frequencies; however, there is a disproportionately severe decrease in speech discrimination. This difficulty with speech discrimination makes hearing loss refractory to amplification in many cases. Atrophy of the spiral ganglion and nerves of the osseous spiral lamina occur mainly in the basal turn of the cochlea. The organ of Corti is largely intact, as opposed to what is found in sensory presbycusis.

Strial Presbycusis (Metabolic Presbycusis)

The hearing loss associated with strial presbycusis is flat sensory loss beginning during the third through sixth decades and progressing slowly. Speech discrimination is generally good, and no recruitment is present. This condition is often familial, and patients do well with amplification. The characteristic pathologic findings are that atrophy of the stria vascularis is either patchy in the basal and apical turns or diffuse. The organ of Corti and spiral ganglion cells are usually unaffected.

Inner Ear Conductive Presbycusis

Both inner ear conductive presbycusis and atrophy of the spiral ligament cause bilateral symmetric sensorineural loss, with an upward slope toward the high frequency and preserved speech discrimination. No anatomic correlates with conductive sensorineural hearing loss are known, but it is hypothesized that the functional loss is due to stiffness of the basilar membrane, which correlates with its anatomic shape. The histopathologic pattern of atrophy of the spiral ligament includes different degrees of pathologic changes that are progressive through the patient's life; it is most noticeable in the apical turn and least in the basal turn. Cystic degeneration may cause detachment of the organ of Corti from the lateral cochlear wall, thereby resulting in hearing loss.

Proposed Etiologies

The specific causes of presbycusis are speculative at this time, but they are likely a combination of the effects of years of function, of exposure to harmful environmental factors such as noise and chemicals, and of genetically programmed biologic degeneration.

Morphology

It is clear that morphologic changes in human beings (as well as animal models) regularly demonstrate the age-related loss of inner and outer hair cells and supporting cells, primarily from the basal turns of the cochlea. Outer hair cells decrease more than inner hair cells. Age-related loss of eighth nerve fibers has been reported to be as high as 20% in old rats.[22] Age-related changes may occur as high as the superior olivary complex in the brainstem.

Nixon[23] and previously Glorig and Davis[24] showed high-frequency conductive hearing losses attributed to stiffness and laxity of the joints in the aging middle ear. They also proposed the concept of an inner ear conductive hearing loss due to stiffness of the cochlear partition.

Vascular

Circulatory disorders have long been proposed as the cause of hearing loss in aging persons. In the Framingham cohort, coronary artery disease, stroke, intermittent claudication, and hypertension were linked to hearing loss.[25] However, there is insufficient histopathologic evidence of this etiology for confirmation. The relationship between high-frequency sensorineural hearing loss and the degree of cerebral atherosclerosis has been used to support this theory; unfortunately, both may be independent but age-related. Atherosclerotic disease of renal vessels and inner-ear vessels has also been related to age. In 1959, Johnson and Hawkins demonstrated the progressive involution of the human cochlear vasculature from the fetus and newborn through the aged. They noted that, during the first decade of life, the radiating arterioles and outer spiral vessels in the basal coil attain adult size. Devascularization of capillaries and arterioles was subsequently found in the spiral ligament that is associated with aging.[26] They found a similarity between the degeneration of inner ear vessels with analogous changes in the retina due to microangiopathy, and they demonstrated that the plugging of vascular canals by bony tissue is a generalized phenomenon that is related to aging. They believed that the plugging of vascular canals was one of the major causes of presbycusis.[27]

Metabolic

Much like arteriosclerosis, diabetic angiopathy may contribute to presbycusis. In this disorder, disseminated proliferation and hypertrophy of the intimal endothelium of arterials, capillaries, and venules causes significant narrowing of the lumen; there is also the precipitation of lipids and other substances in the vascular wall. In addition, arteriolosclerosis is more common and more extensive in patients with diabetes. Even though recent epidemiologic studies demonstrate a higher incidence of sensorineural hearing loss among diabetic patients than age-matched controls, this effect is mitigated in populations older than 60 years. Additionally, hemoglobin A1C levels did not correlate with hearing loss.[28,29]

Serum cholesterol may also play a role in presbycusis. In Rosen's studies of Finnish patients on long-term controlled diets,[30] the reduction of saturated fat resulted in a significant lowering of serum cholesterol and an improvement in auditory threshold testing. However, the link between serum lipids and hearing loss is not definitive.[25,31]

Noise

Noise is thought to be a common cause of presbycusis. It is clear that a direct correlation exists between noise-induced inner ear damage and the frequency, intensity, and duration of noise exposure. However, some may effectively argue that noise exposure causes hearing loss at any age and is not true presbycusis. Indeed, recent studies on the interaction of noise-induced hearing loss and age-related hearing loss are contradictory and variable, likely secondary to the underlying influence of other intrinsic and environmental variables on both mechanisms.[32-35]

Noise-induced hearing loss may arise from mechanical damage, metabolic exhaustion, or vascular changes. Mechanical damage is seen

in the cochlea that has been exposed to high-intensity or impulse noise of short duration. There may be detachment of the organ of Corti from the basal membrane. Metabolic exhaustion is characterized by changes of intracellular ultrastructure, thereby indicating the depletion of enzymes and metabolites in overstimulated sensory cells. Noise has clearly been shown to cause ischemic changes of the inner ear. Capillaries below the basilar membrane have been noted histologically to undergo spasmodic changes. In addition, edema of endothelial cells impairs blood flow to the spiral ligament and stria vascularis. Sludging and aggregation of erythrocytes with increased blood viscosity secondary to decreased capillary flow also occurs.

Genetic Considerations

Presbycusis has been found to cluster in families, and in fact approximately half of the variability in presbycusis may be attributed to genes.[36,37] The effect of genes is more pronounced for the strial atrophy pattern of hearing loss (flat audiogram) than the sensory phenotype (high-frequency loss).[25] Genes that may play a role include those that protect against oxidative stress, in that this stress plays a significant role in presbycusis. Proposed genes in recent studies include those that code for glutathione peroxidase and superoxide dismutase, two antioxidant enzymes that are active in the cochlea.[38,39] Genes responsible for monogenic deafness may also play a role.

Hearing and Dementias

Recent studies of the cochlea in temporal bones from patients with confirmed Alzheimer's disease showed a lack of degeneration in the cochlea, which is typical of Alzheimer's patients. This finding is distinguished from findings in the peripheral olfactory and visual systems, which show the typical neurofibrillary tangles and neuritic plaques.[40]

Conversely, a possible relationship between central auditory dysfunction was found in the Framingham follow-up study of 1662 subjects. However, that study is weakened by the absence of objective testing in competing message tests.[40]

Treatment

Amplification remains the mainstay of treatment for presbycusis. The correction of other health factors that may impact age-related hearing loss, such as smoking, hypertension, and cholesterol levels, may play a role. Although dietary measures over the long term may be effective in reducing the progression of hearing loss in certain aging patients, further data are necessary before this treatment modality is clinically accepted.

Cochlear implantation may play a role in treating older adults with severe to profound sensorineural deafness. Such a degree of hearing loss is most often due to an underlying pathologic process such as Meniere's disease or otosclerosis in combination with presbycusis; the latter does not produce this degree of hearing impairment on its own. A recent study of 749 adolescent and adult cochlear implant recipients found that age was a clinically insignificant predictor of audiologic outcome from cochlear implantation, compared with duration of profound deafness and residual speech recognition.[41] Quality-of-life scores between elderly and nonelderly cochlear implant recipients are also similar.[42] As discussed previously, comorbid chronic health conditions seen more commonly in older populations will play a role in surgical planning and perioperative management.

Presbystasis

Presbystasis, which is the dysequilibrium of aging, is a group of disorders that affect the mobility of a large number of older persons. Due to the degeneration of the vestibular, proprioceptive, and visual senses, the ability to walk and drive can be reduced to the point of incapacitation; lessening spatial-orientation abilities contribute to this as well. Loss of balance is the most common manifestation of vestibular dysfunction in older adults.

Although attempts have been made to categorize the dysequilibrium of aging as a single specific entity, a large number of vestibular disorders are seen in older patients. These include vascular disease, Meniere's disease, benign positional vertigo, and adaptation deficits. Input from the vestibular, visual, proprioceptive, and other systems can be thought of as providing input into a common central processor that, in turn, controls posture and eye movement. This adaptive control system alters afferent signals from the various receptors at both visual-vestibular interfaces as well as proprioceptive-vestibular interfaces. Control circuits can be affected by disturbances in the general condition of the patient, the availability of the neurotransmitter, and in pathologic disorders.[43] Other feedback loops help control visual tracking and postural adjustment in response to motion. Cognitive controls also exist and contribute primarily in the areas of spatial orientation, the hallucination of motion, and the development of athletic skills.

Disorders of these sensory organ systems have traditionally been treated by otolaryngologists, neurologists, and ophthalmologists, depending on the organ system causing the most obvious dysfunction. However, development of the unifying discipline of neuro-otology has led to an integrated approach to, evaluation of, and care for older persons with dysequilibrium. Otolaryngologists must be aware of other causes of dysequilibrium or dizziness, because a variety of organ systems may contribute to these difficulties, including vestibular, ocular, proprioceptive, musculoskeletal, central processing, cardiovascular, and neuromotor. For example, side effects of psychotropic medications, abnormalities in blood pressure, leg muscle weakness, neuromotor disorders such as Parkinson's disease, and generalized loss of coordination can contribute to feelings of dysequilibrium and dizziness. The failure of one organ system can be overcome with compensation, but with multisystem failure, increasingly severe deficits occur.[7]

Falls are one of the most common concerns relating to imbalance in older adults. Approximately one-third of adults older than age 65 in the community and one-half of adults older than age 80 in institutionalized settings fall each year. One-third of these falls result in injuries that require medical attention or the restriction of activities for at least 1 day, and 10% to 15% of these falls result in fracture. As a result, the medical costs of fall-related injuries totaled $19 billion in 2000, with nearly $9 billion for hip fractures alone.[44] Moreover, falls lead to functional decline, anxiety, depression, and social withdrawal. In particular, one-half of older adults hospitalized for a hip fracture do not return to prior levels of function.[45]

Vestibular Pathology

Age-related degeneration has been noted in hair cells, neurons, and supporting structures of the peripheral vestibular system, as well as more centrally in the vestibular nuclei and cerebellum. Hair cell loss has been found in the semicircular canals, the utricle, and the saccule. This degeneration is most noted in the central area of the cristae, whereas macular degeneration is more diffuse. Degeneration of the saccule may be greater than that of the macula. A decrease in the total number of peripheral vestibular neurons, as well as a decrease in the size of myelinated nerve fibers, has been described in patients who are older than 65 years old. Degenerative changes also occur in otoconia of the human maculae, deformities of the vestibular end organs, and degeneration of the synaptic structures of afferent dendrites.[46] These degenerative changes are considered to be the vestibular equivalent of presbycusis. Unlike presbycusis, however, asymmetric loss of vestibular function can result in incapacitation.

Diagnostic Methods

The use of objective tests to identify the etiologic basis of presbystasis is essential. Vestibular function studies described elsewhere are applicable in older adults as well. Avoidance of a "trash basket" diagnosis of presbystasis and continuing clinical research into etiologic diagnosis are essential. In particular, studies of electronystagmography, platform posturography, and sinusoidal harmonic acceleration in older adults are ongoing.

In cases of presbystasis arising in the peripheral labyrinth, generalized hypofunction is often found. Symmetric maximum slow-phase velocity responses to warm and cool caloric stimulation of less than 10°C per second per irrigation can be empirically used to identify this condition. In cases of peripheral hypofunction, the use of vestibular nerve suppressants may be contraindicated. Such treatment further reduces the already reduced vestibular input, thereby resulting in further incapacitation.

Treatment

Nonvestibular causes of presbystasis need to be identified and treated specifically. Examples include postural hypotension associated with antihypertensive medications, endocrine imbalances, malnutrition, and cardiovascular insufficiency.

Because of the adaptive control feedback mechanism in the complex vestibular system, treatment modalities have been developed to allow for compensation. Vestibular habituation training involves "exercises" based on feedback control initiated by the habituation effect. Mechanisms of adaptation and compensation are stimulated through repeated elicitation of minor degrees of vertigo.

Other goals of vestibular exercise programs include the improvement of visual tracking when the head is stationary, gaze stability during head movement, and visual-vestibular interactions during head movement and general balance. These exercises are designed to incorporate visual and proprioceptive experiences with vestibular cues.

The twin goals of these exercises are the reestablishment of balance and the reduction of the symptoms of dizziness and disorientation. In many cases, consultation and therapy with a physical or occupational therapist trained in vestibular compensation exercises can be extremely helpful.

Another important consideration that must be stressed to the patient is the prevention of falls. Precautions include the use of night lights (especially en route to the bathroom), the removal of throw rugs, the avoidance of stairs, and the use of ambulatory assistance devices when necessary.

The Aging Nose

Nasal structure and physiology are affected directly by the aging process and by a multitude of indirect factors that are commonly seen in older adults. For example, older adults are more likely to suffer from falls, leading to head and face trauma that can affect nasal function and the sense of smell. They are also more likely to suffer from olfactory dysfunction following a viral upper respiratory tract infection.[47] Some medications used commonly by older adults (e.g., lipid-lowering drugs, anti-inflammatories, and antihypertensives) may desiccate the nose and alter smell and taste.[48] Decongestants and antihistamines make secretions thicker and worsen postnasal drip. Blood thinners can precipitate epistaxis. Age-related deficits in nasal function can adversely affect sleep, eating, and breathing, and significantly alter patient quality of life.

Common Symptoms

The most common nasal complaints in older adults are nasal drainage, postnasal drip, sneezing, coughing, olfactory loss, and gustatory rhinitis. Other symptoms, such as nasal obstruction, epistaxis, and sinus pain, have not been shown to significantly increase with age. It is thought that nasal discharge and postnasal drip among older adults may be explained by the loss of autonomic control. Gustatory rhinitis, which is nasal discharge that is stimulated by eating, similarly may be caused by overactivation of the autonomic control of the mucoserous and Bowman's glands initiated by the sight of food or the act of eating.[49]

There is a general increase in nasal resistance with age, despite the lack of subjective symptoms of nasal obstruction. This may be explained by the fact that many older patients believe that some nasal obstruction is normal and hence not worth mentioning. However, older persons often notice that nasal airflow is subjectively less with exertion.[49]

Mucoepithelial Changes

The effect of age on mucociliary transport is modest. Transport rates are not significantly different between young adults and middle-aged adults, or between middle-aged adults and older adults. However, significant differences exist between younger adults and older adults.[50] The reasons for this are yet unclear. Neither age nor smoking has been definitively related to a reduction in ciliated cells. Other unknown factors may influence change in the viscoelastic properties of the nasal mucus and therefore predispose the older adult to nasal crusting.[51]

Olfactory Changes

Smell and taste typically peak in the third to fourth decades of life and decline in the older ages.[48] Many studies have shown that olfactory thresholds for a wide range of odorants progressively decrease with age.[52-54] The process is probably due to a combination of a loss of receptors and neurons, with alterations in neurotransmitters and central pathways.[55] There is a decrease in olfactory epithelium and reciprocal increase in respiratory epithelium with age, with increased degenerative changes and loss of olfactory bulb fibers.[56-58] One mechanism for the change in the number of olfactory receptor neurons is an increase in apoptosis.[59]

Changes in Nasal Appearance and Intranasal Examination

There is a significant increase in the nasolabial angle and a decrease in the height-to-length ratio of the nose with age. This may be due to the lengthening of the upper lip, resorption of premaxillary fat, resorption of the malar and alveolar ridge, and changes in dentition that are caused by the degenerative process of aging. The decreased height-to-length ratio accentuates the drooping of the nose as it ages. Weakening of the lower lateral cartilage and the caudal septum, along with the loss of elasticity in the enveloping skin, contributes to the descent of the aged nose tip.

On intranasal examination, nasal polyps are more common with advancing years.[60] Abnormalities of the nasopharynx are not common in older subjects.

Treatment

As is the case with younger age groups, medical or surgical treatment of rhinologic problems in older adults requires an accurate diagnosis to select appropriate treatment. Humidification is generally helpful, as is the prudent avoidance of medications that desiccate the nose and aggravate mucosal atrophy, such as topical and systemic decongestants. Underlying osteomeatal blockage due to allergies or infection should be addressed; this may involve treatment in a multidisciplinary setting by the pulmonologist, allergist, otolaryngologist, and other specialists. The treatment of associated medical conditions may be helpful. In patients with vasomotor or gustatory rhinitis, anticholinergics such as ipratropium bromide spray may be effective.

Surgical reconstruction is aimed at reconstituting support for the upper lateral cartilage and elevating the drooping nasal tip.[61] The removal of turbinate mucosa should be avoided, especially when excessive dryness is already a factor. Vidian neurectomy may be indicated in select cases.

The Aging Voice and the Upper Aerodigestive Tract

The phonatory organ is composed of the resonator (larynx), the articulators (supraglottic structures), and the compressors (lungs).[62] Age-related changes in any one or all of these structures can have a direct impact on voice quality and general comfort level (Table 16-1). Furthermore, older people are often exposed to a wide array of environmental and medicinal irritants (indirect factors) that compound the problem, particularly in the case of long-term tobacco smoking (Table 16-2). Older patients may also suffer from a host of medical conditions that can affect vocal quality, such as cancer, vocal fold paralysis, Parkinson's disease, amyotrophic lateral sclerosis, benign essential tremor, diabetes, and other endocrine dysfunctions (see Tables 16-1 and 16-2).[63-67] The frequent occurrence of depression with sensorineural hearing loss can lead to a hyperfunctional voice and muscular tension dysphonia. Therefore treatment of geriatric patients with vocal problems must be directed not only at maximizing the efficiency of the aging phonatory organ through appropriate voice therapy or surgery, but also at treatment of the underlying medical, neurologic, or psychiatric disorder.

Histologic Changes

Laryngeal tissues change a good deal before alterations in the voice are detected. Histologic changes seen within the aging larynx appear to occur with approximately equal frequency in both sexes. Histologic examination suggests that the yellowish discoloration seen clinically represents fat degeneration or keratosis of the mucous membrane. Vocal fold atrophy is thought to represent the laryngeal manifestation

Table 16-1

Common Factors with a Direct Effect on Vocal Quality

Factors	Effect on Vocal Quality
Laryngeal muscle atrophy/fibrosis	Effect on glottic gap and vocal fold thickness, resulting in increased air loss and abnormal acoustics
Cricoarytenoid joint changes	
Mucosal atrophy	Increased chance for injury, pain, and guarding, which affect articulation
Salivary gland atrophy	Decreased lubrication, dry mouth, and secondary dental problems
Alveolar bone resorption	Increased chance for injury, pain, and guarding, which affect articulation
Dental/gingival loss	
Temporomandibular joint disease	
Lower respiratory tract changes	Decreased chest elasticity, abdominal tone, and breath support, which result in decreased vital capacity, vocal fatigue, and decreased volume

Table 16-2

Common Factors with an Indirect Effect on Vocal Quality

Factors	Effect on Vocal Quality
Hearing loss	Vocal misuse
Anxiety/depression	
Dehydrants: alcohol, antihistamines, decongestants, diuretics, megadoses of vitamin C, antidepressants, antihypertensives	Reduced lubrication/ altered secretions
Surgery/disease processes: prior intubation, laryngeal surgery or disease, oral/pharyngeal surgery or disease, nasal/sinus surgery or disease, superior/recurrent laryngeal injury, dental/temporomandibular joint surgery or disease, abdominal/thoracic surgery or disease, limb surgery or disease	Changes in phonation, resonance, and articulation; reduced pulmonary support/ altered posture
Mucosal irritants: allergies, smoking, gastroesophageal reflux, pollution	Direct effect on mucous membranes/ altered secretions
Endocrine dysfunction: hypothyroidism, hormonal therapy	Mucosal/soft tissue alterations, vocal fold edema
Abrupt weight change	Multifactorial

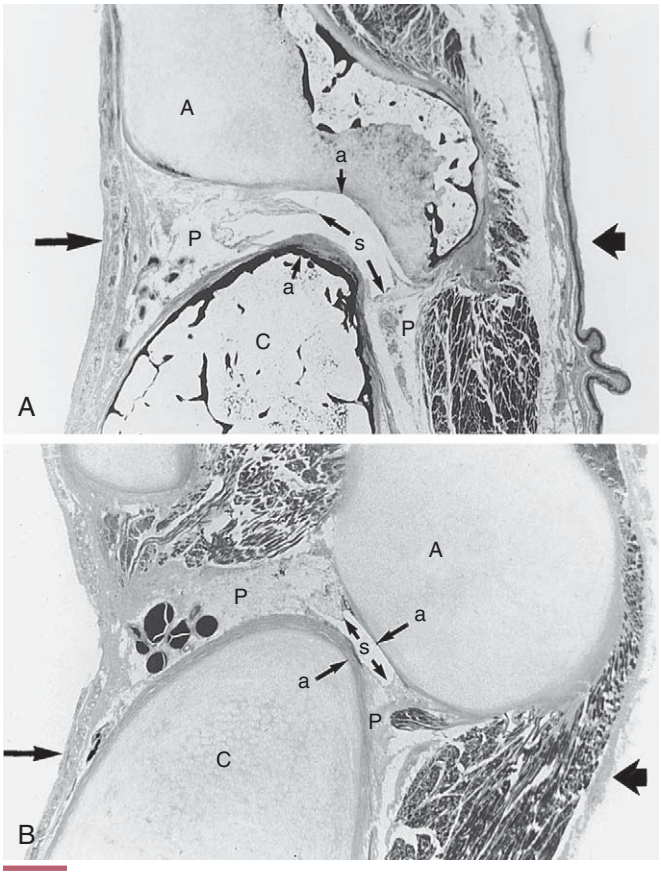

Figure 16-1. **A,** Young cricoarytenoid joint (patient is 29 years old). *A,* Arytenoid; *a,* articular surface; *C,* cricoid; *P,* periarticular soft tissues; *s,* synovium; *fat arrow*, hypopharyngeal epithelium; *thin arrow,* subglottic respiratory epithelium (hematoxylin-eosin; ×3). **B,** Old cricoarytenoid joint (patient is 69 years old). *A,* Arytenoid; *a,* articular surface; *C,* cricoid; *P,* periarticular soft tissues; s, synovium; *fat arrow*, hypopharyngeal epithelium; *thin arrow,* subglottic respiratory epithelium. Note increased calcification and muscle atrophy (hematoxylin-eosin; ×3).

of senescent changes in muscle and mucous membranes. There is general thinning, decreased fiber density, fatty degeneration of the laryngeal muscles, and a decrease in fragmentation of elastic fibers in the submucosa.[68] Studies suggest these changes may be caused by changes in neural input to the muscles.[69] Decreased fiber density is also seen in the laryngeal ligaments and the conus elasticus.

Progressive calcification of the laryngeal cartilages occurs with age.[70] Calcification and ossification begins during the early 20s and is essentially completed by the sixth decade. Small islands of cartilage remain in the central portion of the thyroid cartilage of men; there is preservation of cartilage in the upper portion in women. The cricoid may be almost completely ossified. The arytenoid undergoes ossification of the body and muscular process, with the apex remaining cartilaginous (Fig. 16-1). There seems to be some controversy regarding whether the vocalis process ossifies.[71] This ossification represents the creation of a true haversian system with lamella, osteocytes, and fat marrow. In general, the onset of ossification is later and less extensive in women, and the entire process is quite variable among individuals. Similar age-related changes may occur in the cricoarytenoid joint as well.[72]

Laryngoscopic Appearance

Laryngoscopic characteristics of the aging larynx include a yellowish or dark grayish discoloration of the vocal fold, edema, and vocal fold atrophy. This results in bowing of the vocal fold edges, incomplete glottic closure, and visibility of the ventricle. The prominence of

the contour of the vocal process leads to the typical "arrowhead configuration" of the glottis that is seen so often in the senescent larynx.[73,74]

Acoustic Changes

Dysphonia is present in at least 10% of older adults. Although variable, the senescent voice is typically stereotyped as being tremulous, weak, hoarse, and altered in pitch. Overall, jitter (cycle-to-cycle frequency variation) continues to be significantly greater in the aging population as compared with younger age groups, particularly in men.[75] Aging of the larynx is also associated with a slowing in the opening quotient of the vocal folds, which further adversely affects vocal quality.[76] In men, fundamental frequency levels progressively decrease from 20 to 40 years of age and then increase from 60 through 80 years of age.[77] Vocal fold edema, which is seen in some women, is thought to be due to general endocrine changes that occur after menopause. The latter, along with the lowering of laryngeal position that occurs in women who are more than 60 years old, results in marked lowering of the fundamental frequency and roughness of the voice.[78] The aging woman also tends to read with larger intonation ranges and a greater number of inflections than younger adults.[79] The acoustic characteristics of women's voices show a significant lowering of the frequency of the first formant (f1) with advancing age, which suggests age-related changes in the vocal tract and mentions or positions of speech structures.

Mucosal Changes

The aging process results in significant changes within the mucosa of the oral cavity, salivary glands, teeth, mandible, maxilla, temporomandibular joint, and taste buds. In combination or individually, oral dryness, soft tissue atrophy, decreased mandibular excursion, and temporomandibular joint disease can significantly affect the voice by altering its resonant characteristics.

The epithelium of the mouth becomes atrophic, especially in the prickle cell layer. Parakeratosis and hyperkeratosis may be present, particularly in areas of denture use. Histologically, there is thinning of the tunica propria and blunting of the rete pegs; decreases in capillaries, water content, hyaluronic acid, and collagen content; and an increase in ground substance. In combination with small vessel disease (e.g., arteriosclerosis), these changes make oral tissues more prone to injury, prolonged wound healing, and contribute to the shiny smooth appearance of the senescent oral mucosa.[80] Guarding as a result of oral trauma may adversely affect the voice by modifying the way one articulates and projects speech sounds.

Glandular Changes

Normal physiologic changes that occur in the salivary glands of older adults are the principal cause of dry mouth syndrome, which is one of the most common complaints of this population.[81,82] Secretory rates diminish and salivary viscosity increases in these patients. Submandibular gland parenchymal volume decreases as a result of a reduction in acinar tissue, whereas ducts enlarge. There is also an increase in focal chronic inflammatory changes resulting from hyalinization of the acini and an increase in salivary duct adhesions and obstructions. The end result is a loss of one fourth of the active secretory parenchymal volume and its replacement by connective tissue and fat.[82] Because adequate lubrication is essential for the production of sound in the phonatory apparatus, the presence of dry mouth should be recognized and treated.

Sense of Taste

Many older patients complain of a metallic or salty taste, and decreased levels of sensitivity to sweet, bitter, and sour foods. This loss of taste is multifactorial. Both a reduction in salivation and a reduction in the number of taste buds can occur normally during the aging process.[83] Decreased olfaction, as discussed earlier, as well as systemic medical conditions and various medications can alter patient taste.

Dental/Mandibular Changes

As one ages, there is resorption of mandibular and maxillary alveolar bone and a diminution in regenerative capacity, leading to a loss in the vertical height of the face and a "purse-string" appearance of the mouth. This problem is magnified in edentulous patients, in whom up to 50% of mandibular height may be lost. Histologically, the aging mandible often displays signs of osteoporosis in the form of cortical thinning and loss of its coarse trabeculation patterns. Bone resorption and the diminution of connective tissue around the nerves allow the neurovascular surface to be more easily damaged. Common complaints are paresthesia or pain due to irritation of the mental nerve by ill-fitting dentures, and a burning sensation of the hard palate. As in other areas of the oral cavity, these connective tissue changes contribute to a reduction in the repair capacity after injury.

As far as teeth are concerned, a secondary dentin (calcified dentin) replaces most of the dental pulp. The cementum shows continued deposition and calcification throughout life. Apical migration of gingival tissue leads to a gradual exposure of the tooth root. These processes make individuals prone to periapical infection and periodontal disease.

Any changes in the bony architecture of the maxilla or mandible may adversely affect the voice by affecting the resonance characteristics of speech sounds. The absence of teeth, the use of ill-fitting dentures, oral or dental pain, and paresthesias may further affect certain speech sounds, particularly those involving tongue-to-lip, palate, or teeth apposition. The ability to produce clear plosive (p, t, k, b, d, and g) and fricative (s, z, f, v, sh, ph, and th) sounds may therefore be affected.

The temporomandibular joint may also be affected by the aging process. There is a loss of elasticity and hardening of the articular disc and capsular ligament, a thinning of the articular disc, fibrosis of the articular space, and a flattening of the articular surfaces. Complaints such as joint clicking, dislocation, subluxation, and fracture of the articular head (with subsequent decrease in mouth opening) may indirectly affect the voice, again by altering resonance characteristics and the projection of speech sounds. Speaking with a tight oral aperture narrows resonance of sound within the oral cavity; it may further result in laryngeal elevation, which increases tension in the vocal tract.

Respiratory Changes

The effects of aging on pulmonary function are significant. Age causes changes in the musculature of the lower respiratory tract that affect the function of the chest wall, abdomen, and diaphragm. Pulmonary perfusion, forced expiratory volume, forced vital capacity, elastic recoil, and dynamic pulmonary compliance decrease significantly with age.[84-87] There is a ventilation/perfusion mismatch, an increase in alveolar dead space, an increase in the alveolar-arterial gradient for oxygen delivery, a loss of alveolar surface area, and a change in the pulmonary circulation.[88,89] Body weight commonly increases with age, which increases the demand on the respiratory system. Older men have been found to require more intrasentence breaths, which is thought to be related to decreased vital capacity.[90] All of these changes can result in inadequate breath support and excessively harsh glottal closure to phonate. Over time, this can fatigue the laryngeal apparatus and result in secondary muscular tension dysphonia.

Treatment

For the most part, treatment of presbyphonia is directed at controlling the underlying medical illness and maximizing the efficiency of the phonatory apparatus. This typically involves a multidisciplinary approach involving the expertise of a speech pathologist, otolaryngologist, pulmonologist, neurologist, psychiatrist, oral surgeon, and a generalist. Treatment for gastric acid reflux and attention to proper hydration and other general vocal hygiene measures are important. Maximizing pulmonary efficiency in patients with underlying pulmonary disease is a necessity. General conditioning may be quite helpful in motivated patients. Symptomatic dryness can be addressed with the judicious use of sialogogues, salivary substitutes, and expectorants. Other specific medical illnesses discussed above must be addressed, when present.

Surgery is recommended only after the more conservative measures addressed earlier fail to achieve the results required by the patient. Procedures have been devised in an attempt to adjust vocal pitch as

well as strengthen the voice of patients with flaccid or bowed vocal folds.[91] Isshiki advocates a type 4 thyroplasty for this problem.[92] Others have advocated similar advancement of the anterior commissure to adjust vocal cord tension through an anterior commissure laryngoplasty.[93] Short-term success with these procedures has been achieved, with improvement in loudness and clarity and a decrease in breathiness and air escape. More recently, technologic advancements in injectable fillers hold promise for the treatment of glottic insufficiency; short-term options include hyaluronic acid gels (e.g., Hylaform, Restylane) and collagen-based products (e.g., Cymetra), while calcium hydroxylapatite (e.g., Radiesse) provides more long-term results.[94]

Presbyphagia

Dysphagia is relatively common in older adults, affecting 15% of those in the community and approximately 40% of patients in institutionalized settings.[95] This has contributed to the supposition that swallowing deficits may reflect normal age-related changes. Granieri suggests that the effects of aging on swallowing can be divided into primary, secondary, and tertiary categories.[96]

Primary effects of aging on swallowing include physiologic and structural changes in the oral cavity, pharyngeal, and laryngeal structures. Older adults have a smaller cross-sectional area of masticatory muscles, increased lingual atrophy and fatty infiltration, and diminished strength, mobility, and endurance of these muscles. As a result, swallowing becomes slower with age; the pharyngeal swallow response initiates later, and the swallowing motor response is not as responsive to sensory stimuli.[97-107] Secondary factors include a plethora of general medical and neurologic conditions, such as head and neck cancers and their treatments, neuromotor disorders including stroke and cricopharyngeal spasm, or the general deconditioning associated with illness. Side effects from the use of pharmacologic agents are also more common in older adults. Tertiary aspects involve those changes that can result from social, environmental, and psychologic factors.

Diagnostic Testing

When swallowing disorders are suspected, a complete oropharyngeal and esophageal swallowing evaluation is warranted because of the increased incidence of concomitant problems in both areas. A careful history and physical examination should allow the clinician to distinguish between the two major categories of swallowing impairment: difficulty initiating swallowing and obstruction.[108] Because speech, voice, and swallowing problems are often the first signs of degenerative neurologic or neuromuscular disease, the physical examination should include both head and neck and neurologic evaluations.

Radiographic assessment is considered the gold standard for dysphagia assessment. The modified barium swallow (MBS), which is a videofluoroscopic swallowing study of the head and neck, provides critical physiologic information (i.e., bolus transit from the mouth to the cervical esophagus), swallow transitions, and biomechanics of the swallow that are necessary for treatment. The procedure also provides valuable information about the timing and etiology of aspiration and the effectiveness of rehabilitative strategies. If the study reveals structural or motility disorders of the esophagus, endoscopy and manometric examination are the next diagnostic steps.

Flexible endoscopic evaluation of swallowing is an adjunctive assessment tool to the MBS. Visualization of the pharyngeal-laryngeal mechanism provides symptomatic information about the swallow (i.e., aspiration and pharyngeal residue). This type of endoscopic evaluation is also a valuable biofeedback tool for airway closure maneuvers.

Treatment

Proper treatment of swallowing disorders in older adults requires management by the multidisciplinary team and is contingent on correct diagnosis, considering primary, secondary, and tertiary causes. Treatment may be medical or surgical, but it is more often rehabilitative. Rehabilitative treatment strategies that will improve the safety and efficiency of the swallow are identified during the radiographic procedure and based on the nature of the patient's disorder. Many swallowing rehabilitation techniques require the application of voluntary control to disordered aspects of swallow physiology. These include swallowing therapy strategies, such as the supraglottic swallow or Mendelsohn maneuver, and other oropharyngeal exercises. However, a number of treatment strategies require little patient cognition or cooperation by the older individual, such as postural techniques or changes in diet or food consistency. Recent randomized trials indicate that more research is needed to assess the efficacy of combining these modalities.[109,110] Moreover, little research has looked into sensory-based swallowing therapies such as delivering a sour or cold bolus, given that intraoral stimulation does affect swallowing biomechanics.[111-113] If nonoral feeding is required, reevaluation at regular intervals should be conducted to determine progress in recovery and the optimal time to reinitiate oral intake.

Facial Trauma

Wound healing is affected by aging, in that angiogenesis, epithelialization, and remodeling are all delayed in older patients.[114] Moreover, a decrease in immunologic response can lead to increased susceptibility to wound infection.[115] The facial skeleton undergoes changes with aging; as mentioned above, the most prominent change is resorption of the alveolar bone in the maxilla and mandible. The bone of the facial skeleton becomes brittle, and decreased metabolic activity in the bone makes healing times prolonged. Resorption of bone and its fragility can make placing fixation plates difficult. In particular, the repair of fractures in an edentulous mandible presents a particular challenge, with an atrophic mandible making iatrogenic fractures during repair more likely, and the lack of teeth making the determination of appropriate reduction and occlusion more difficult.[115] Planning for repairing facial fractures in older adults must take these factors into account to ensure the best possible outcome.

Head and Neck Oncology

Etiology

Approximately one fourth of head and neck cancers happen in patients older than age 70.[116] Environmental exposure to carcinogens, most notably tobacco and alcohol, is an important cause of these cancers. The occurrence of cancer in advanced age is probably related to the duration of carcinogen exposure, but also to immune senescence. Immune dysfunction associated with aging is complex and involves several components of the immune system. Wolf suggests that the most important deficit may occur in antigen-specific T-cell cytotoxic function.[117] Autoimmune diseases also are more common with advancing age, and may facilitate tumor progression.

Treatment

Interestingly, although many cancer patients are older than 65 years old, they represent a minority of participants in clinical trials.[118] To encourage the inclusion of older adults in clinical trials, President Clinton in 2000 issued a directive for Medicare to reimburse the costs of routine patient care during clinical trials.[119] However, treatment paradigms are often applied from studies examining younger patients.

As discussed, aging leads to multiorgan functional decline, reduced nutritional status, and psychosocial factors including depression and absence of social support. These factors must be considered with any treatment protocol. In general, older patients tolerate major head and neck cancer surgery well. Morgan and others[120] reviewed 1773 patients undergoing major head and neck operations under general anesthesia. Of the 810 patients between the ages of 65 and 95 years, 3.5% died, and 32% suffered nonlethal complications. By contrast, only 8 of 863 patients between the ages of 35 and 65 years died (0.8%), and the complication rate was 21%. The differences in mortality and complication rates are both significant, but a mortality rate of 3.5% in persons older than 65 years does not seem prohibitive. In a more recent study, McGuirt found that patients who were older than 80 years old had a similar prognosis to that of patients between 65 and 80 years old, but complications were more common with advancing age.[121] Recent studies on reconstructive surgery with free flaps show that the risk of postoperative complications is related to the presence of comorbidities and not age.[122-124] Length of time under anesthesia also correlates with complication rates.[125]

More intensive combination therapies must take into account the presence of comorbidities, age-related frailty, and underlying psychosocial problems. For example, toxic side effects from chemotherapy are more common in older age groups, and older patients—particularly those with poor performance status—may demonstrate reduced compliance and tolerance to radiation therapy.[126]

Thyroid disease is common in the geriatric population, and thyroid cancer behaves more aggressively in older patients. Undifferentiated carcinoma is more common, and recurrence and metastasis occur more frequently in the older adult, even with well-differentiated thyroid cancer. The mainstay of management for well-differentiated thyroid cancer is surgery, but multimodality therapy that includes radioactive iodine is commonly advised in older patients, especially those who have follicular cancer. Bliss and colleagues investigated thyroid surgery in patients who were older than 50 years old. They found no difference in morbidity or mortality when comparing patients 50 to 60 years old with patients 61 to 70 years old and with patients who were older than 70 years old.[127]

Regardless of pathology, before advising a major surgical procedure, careful consideration is given to the patient's motivation as evidenced by his or her current level of function. An active 80-year-old patient with good muscle tone may be a better surgical candidate than a sedentary 65-year-old patient with poor functional residual capacity. A comprehensive preoperative evaluation needs to be completed in all surgical candidates. Current trends in health care are to minimize inpatient care and shorten postoperative admissions. Although this may be feasible for young, healthy adults, the goal of short-stay admissions for older adults may not be realistic; this needs to be taken into account when planning treatments for geriatric patients.[128]

Preoperative teaching is important for all patients and their families, and selected patients may benefit from a 2-week course of nutritional and physical therapy aimed primarily at improving cardiorespiratory function. Patients should understand that they will need to participate in the recovery process, which may last several months; a substantial portion of this time will not be spent in an acute care setting. Patients should understand that recovery may entail a period of rehabilitation at a rehabilitation facility or a subacute care facility; placement in one of these facilities is not to be construed by the patient or his or her family as an adverse event or failure of treatment.

Conclusion

Otolaryngologists and all health care providers are faced with an aging population. Although the spectrum of disease is likely to remain constant for practitioners, the makeup of individual practices may reflect this change in demographics. To prepare for this change, we must continue to expand our knowledge base of the disease processes that affect older adults and our ability to treat this population. Future research will also need to include this group.

CHAPTER SEVENTEEN

Pain Management in the Head and Neck Patient

Edward B. Braun

Jeremy A. Scarlett

Todd J. Schwedt

Robert A. Swarm

Key Points

- Optimizing control of postoperative pain can reduce postoperative morbidity and cost.
- Development of opioid addiction in the context of acute pain treatment is rare.
- Use of patient-controlled analgesia (PCA) postoperatively can improve pain control and patient satisfaction.
- Preemptive analgesia may reduce the magnitude and duration of postoperative pain, thereby reducing use of postprocedural pain medications.
- Perioperative regional anesthetic techniques may allow for superior postoperative pain control compared with the use of systemic opioids and adjuvant pain medications alone.
- Referencing the World Health Organization analgesic ladder can assist in providing pain relief for patients.
- Use of long-term opioid therapy in patients with chronic noncancer pain can be complicated by the development of tolerance, addiction, and hyperalgesia.
- Use of anticonvulsants, antidepressants, nonsteroidal anti-inflammatory drugs (NSAIDs), or interventional therapies is important in the treatment of chronic pain.
- Headaches affect most people at some point in their life, with a 78% lifetime prevalence of tension-type headache and a 16% lifetime prevalence of migraine. Migraine headache is the most common primary headache type leading to physician visits.
- Abnormalities on examination of a patient presenting with headache should be accompanied by consideration of possible secondary causes.
- Therapy for migraine should consist of both acute and prophylactic interventions consisting of headache trigger avoidance, medications, physical therapy, and biobehavioral therapy.
- Initial treatment of trigeminal neuralgia should center around prophylactic medications such as carbamazepine.

Pain Defined

The International Association for the Study of Pain defines pain as "an unpleasant sensory and emotional experience associated with actual or potential tissue damage or described in terms of such damage."[1] Pain can be broadly categorized as either acute or chronic. Acute pain is a predicted response to a noxious mechanical, thermal, or chemical stimulus such as trauma or surgery. It is for an acute period of time and is often responsive to appropriately adjusted analgesics.[2] Pain is defined as "chronic" when it persists for at least 3 to 6 months or lasts longer than the time in which healing would normally occur.[2]

Pain is subjective, and a known pathophysiologic etiology is not necessary for pain to be experienced. Although the most reliable indicator for the presence and severity of pain is the patient's self-report, the decision to administer pain-relieving therapy should not be based exclusively on the patient's ability to communicate. Nonverbal, and especially noncommunicative, patients, must be carefully and repeatedly evaluated for uncontrolled pain.

Measurement of Pain

Evaluation of pain in an accurate and reliable way is a critical component of patient assessment. The visual analog pain scale and verbal numeric scales are frequently used as pain assessment tools. The visual analog pain scale is usually presented as a 10-cm line anchored by the verbal descriptors "no pain" and "worst imaginable pain." Both of these scales have been shown to have high sensitivity in the measurement of pain intensity, a reflection of their ability to detect change.[3]

Inadequate assessment of pain, lending to inadequate provision of pain relief, is a prevalent barrier to pain management in cognitively impaired adults with either acute or chronic pain. For some cognitively impaired adults, scales such as the Faces Pain Scale Revised (FPS-R), Verbal Descriptor Scale (VDS), Numeric Rating Scale (NRS), and Iowa Pain Thermometer (IPT) can be used and have been shown to have low failure rates and high preference evaluations.[4] Evaluation of pain in the severely cognitively impaired patient may be challenging. For the nonverbal patient, observation of behavior is the best approach for pain assessment.[5]

Pain assessment is especially difficult in children with cognitive impairment. The Face, Legs, Activity, Cry, Consolability (FLACC) tool assigns a value of 0 to 2 for each variable, for a total FLACC score of 0 to 10. This tool has been shown to facilitate reliable and valid observational pain assessment in children with cognitive impairment who cannot report their own pain.[6] It uses pediatric nurses' clinical judgment to determine analgesic choice based on their determination of the score.[7] The FLACC pain assessment tool is also appropriate for preverbal children experiencing pain.[7]

Acute Pain Management

Epidemiology

Approximately 72 million surgical procedures are performed in the United States annually, 3.5 million (4.9%) of which are related to the ear-nose-throat (ENT) specialty. Three million (86%) otolaryngologic procedures are performed in an ambulatory setting. The growth of ambulatory surgery has represented one of the most significant recent changes in surgical practice.[8]

Patient Satisfaction

Potential benefits of providing adequate postoperative pain relief include improved patient comfort, increased recovery speed, reduced postoperative morbidity, and shorter hospital stay.[9,10] Poorly controlled postoperative pain increases morbidity and mortality, and decreases quality of life.[11]

Factors contributing to patient satisfaction with postoperative pain management include how seriously the medical staff takes the complaint of pain, the frequency of breakthrough pain episodes, and actual pain intensity. Patient dissatisfaction is increased if a request for analgesics is followed by inadequate pain treatment. There is not a direct correlation between pain intensity and patient satisfaction. For example, patients who have the opportunity for self-administration of analgesics, as with PCA, report a feeling of autonomy and security, and improved satisfaction compared with those treated with as-needed nurse-administered analgesia.[12] Health care provider knowledge regarding dosing and duration of action of opioids also impacts the quality of postoperative pain management.[13] Therefore, patients treated with standardized pain management by an acute pain service are more likely to report being satisfied with their postoperative pain management.[14]

When evaluating the desirability of the outcome of postoperative pain management, patients place similar importance on analgesic efficacy and the type and severity of the side effects experienced. Common side effects of opioid therapy include sedation, respiratory depression, nausea or vomiting, mental confusion or dizziness, mood change, nightmares or hallucinations, and sleep disorders. Additionally, when comparing intravenous (IV) PCA in the hospital to oral opioids in the hospital versus oral opioids at home, the site of delivery, as well as mode of delivery for opioid administration appear to be of less importance to patients than pain relief and side effects. Patient variability is high regarding willingness to trade pain efficacy for different or milder side effects. These factors may assist with selecting pain treatments that match the patient's needs, thereby improving compliance and patient satisfaction, if pain treatment plans are individualized to each patient and clinical setting.[15]

Opioid Addiction versus Tolerance

A barrier to effective management of postoperative pain is the concern that opioid use will result in addiction. Approximately 10% of patients report preoperative or postoperative fear of addiction from postoperative analgesics. Physician or patient fear of opioid addiction in the acute postoperative setting may prevent needed treatment of pain. Tolerance is loss or reduction in the normal response to a drug over time. In contrast, addiction is characterized by behaviors including impaired control over drug use, compulsive use, continued use despite harm, and craving.[16] In the absence of history of addiction, it is rare to develop opioid addiction in the context of acute pain treatment.[17]

Patient-Controlled Analgesia

Parenteral administration of opioid analgesics via IV PCA is commonly used in the immediate postoperative setting. PCA benefits potentially include improved pain control and patient satisfaction, as well as improved nursing satisfaction and efficiency.[18] The degree of pain relief achievable and the amount of analgesic used with PCA, relative to conventional methods of administration (intramuscular, subcutaneous, oral, continuous, IV intermittent), is variable. Patients who are not satisfied with PCA therapy may either fear opioid overdose or addiction.[19,20] It is reasonable to assume that provision of analgesics in a dose and interval tailored to an individual's specific needs would result in good outcomes regardless of the specific technique used. The choice of opioid should be made based on the patient's clinical history and drug availability. Choice of opioid used with PCA does not appear to affect patient satisfaction.[21]

Using PCA opioids to control pain may be complicated by nausea and vomiting, pruritus, respiratory depression, sedation, confusion, urinary retention, and drug-induced ileus. These adverse effects are characteristic of opioid receptor agonists administered by any route or method of delivery. Comparing the incidence of respiratory depression with PCA and conventional opioid analgesia administration is difficult to study. This is in part due to difficulty in defining an incident of respirator depression as well as the low incidence of occurrence with a resulting need for a large number of patients to show a significant difference.[22] It should be noted that after IV administration, morphine slowly crosses the blood-brain barrier, resulting in delayed onset of analgesic and ventilatory depressant effects. This necessitates added caution when morphine is used for PCA, particularly in the setting of renal insufficiency, which prolongs morphine elimination.[23,24]

To use PCA opioid for pain control, choices must be made regarding selection of drug, demand (bolus) dose, time interval (frequency), and whether to use a basal (continuous) setting and the maximum dose allowed. Table 17-1 lists equianalgesic doses of commonly used opioid analgesics. The typical starting dose for IV PCA would be 1 mg morphine or 0.5 mg hydromorphone, with a 10-minute lockout interval between doses, and no basal infusion. Meperidine is not recommended due to risk of central nervous system toxicity from its metabolite normeperidine.[25] A lockout period helps prevent overdosage caused by overzealous demands for more analgesia. The lockout time should be long enough for the previous dose to have an effect. In view of the high intrinsic potency of fentanyl, it may be reasonable to use a longer lockout period. Regular review is needed in every case to ensure that pain relief is safe and adequate.

Basal (continuous) infusion of opioid, in addition to intermittent PCA bolus doses, is rarely indicated for acute pain in opioid-naïve patients. Use of a basal opioid infusion does not decrease the number of patient-activated PCA opioid doses, so the total dose of opioid is increased.[26] Opioid basal infusion increases risk of opioid adverse effects, including respiratory depression. In our practice, we seldom use a basal opioid infusion except when using PCA in patients with chronic pain and opioid tolerance. For example, if a patient on long-term oral opioid therapy for chronic pain requires surgery (and will not be able to take usual oral medication for some period), a basal opioid infusion may be used to administer opioid equivalent to the chronic opioid dose, with supplemental PCA bolus opioid titrated to control acute pain.

Perioperative Considerations for Older Adults

The number of surgical patients older than 65 years of age is increasing, with the fastest growing segment being those older than age 85 years. Due to increased prevalence of comorbidities, older adults have increased risk for postoperative complications and surgical mortality, mainly due to cardiac and pulmonary dysfunction.[27] Primary concerns

Table 17-1

Equianalgesic Doses of Commonly Used Opioid Analgesics

Opioid Analgesic	Parenteral Dose (mg) = 10 mg Morphine (IM/IV)	Oral Equivalent (mg)	Approximate Plasma $T_{1/2}$ Elimination in Hours
Morphine	10	30	2.9 ± 0.5
Codeine	120	200	3
Fentanyl	0.1	N/A	4
Hydrocodone	N/A	30	4.5
Hydromorphone	2	6	2.5
Oxycodone	N/A	30	3
Methadone	10	10 to 20	30 ± 19
Meperidine	100	300	3
Propoxyphene	N/A	400	14

regard perioperative effects on cardiac, pulmonary, cerebral, and cognitive function. Postoperative opioid requirements decrease with increasing age, due to age-related changes in the metabolism and clearance of these analgesics.[28] Effective analgesia promotes early ambulation, shortened hospital stay, and reduced health care costs.[29] Barriers to adequate pain control in older adults include concerns about drug overdose, adverse effects, and addiction. Also, the increased prevalence of abnormal mental status in older adults complicates perioperative care, including pain management, in this group.[30]

Perioperative Considerations for Patients Receiving Chronic Opioid Therapy

Surgical patients may vary greatly in their intraoperative and postoperative opioid requirements. Patients with a history of chronic opioid use often become opioid tolerant, creating a situation where standard treatment dosages and strategies may be ineffective. Patients with a history of chronic opioid consumption should be expected to require more opioid medication postoperatively than opioid naïve patients. Because tolerance develops to opioid adverse effects, opioid tolerant persons may experience fewer side effects, such as nausea, pruritus, and sedation. Despite receiving appropriately titrated, increased doses of opioid for acute pain, patients with a history of chronic opioid use tend to report higher pain scores.[31]

Considerations for NSAID Use for Postoperative Pain

The use of NSAIDs after surgery, such as tonsillectomy, is controversial. NSAIDs play an important role as adjuvant analgesic agents to opioids, and may improve pain control and/or reduce opioid requirements (and thereby reduce opioid adverse effects). Potential complications of NSAID use include postoperative hemorrhage secondary to impairment of platelet function, renal insufficiency, and acute gastric ulceration. Postoperative hemorrhage is a particular concern following tonsillectomy, with an incidence of 1.5% to 5%, with delayed hemorrhage (>24 hours) being more common than primary hemorrhage (<24 hours).[32] A recent study of pediatric patients undergoing tonsillectomy and adenoidectomy revealed no difference in postoperative bleeding rate in patients provided perioperative ibuprofen versus control, concluding that ibuprofen is not contraindicated in this setting and should be used in the control of postoperative pain if it is indicated.[33] Although post-tonsillectomy hemorrhage is a severe complication, if further research supports that NSAID use does not increase the risk of hemorrhage in this setting, more widespread use of NSAIDs would be indicated to improve postoperative pain control.

Preemptive Analgesia

Preemptive analgesia is pain treatment given before tissue injury to prevent establishment of altered central processing of afferent input from sites of injury, and thereby prevent development of pain hypersensitivity. Preemptive analgesia may reduce the magnitude and duration of postoperative pain. Emphasizing the importance of measures to reduce postoperative pain is the observation that patients with high intensity of acute postoperative pain scores demonstrate a higher risk of developing a chronic pain state.[34] Preemptive analgesia can be established with local infiltration of incision sites, peripheral nerve block, or central neuraxial blockade.

Examination of preincisional and postincisional analgesic medication regimens reveals mixed results. Pharmacologic agents, such as NSAIDs, opioids, N-methyl-D-aspartate (NMDA) antagonists, and α_2-receptor antagonists are effective at synergistically decreasing postoperative pain.[35] However, preemptive administration of these pharmacologic agents is not of increased analgesic benefit when compared with postincisional administration.[34] Gabapentin, which has been used extensively in the treatment of neuropathic pain, is a useful adjunct for the management of postoperative pain.[36]

Preemptive administration of peripheral local anesthetics does appear to offer an advantage over postincisional administration. Peripheral afferent neuronal signaling, which occurs during surgery, produces central nervous system excitability. When done before initiating surgery, wound infiltration with bupivacaine, in comparison to saline, has been shown to reduce plasma β-endorphin levels significantly in the first 48 hours postoperatively, indicating blockade of nociceptor input by the local anesthetic. When preincisional local anesthetic is used, lower reported pain scores and decreased self-administered pain medications by patients is also observed.[37] Preincisional infiltration of local anesthetic and general anesthesia for pediatric tonsillectomy reduces post-tonsillectomy pain and provides a more rapid return to activity compared with use of general anesthesia alone.[38]

Perioperative Regional Anesthesia

Perioperative regional anesthetic techniques may allow for superior postoperative pain control compared with the use of systemic opioids and adjuvant pain medications alone, but regional anesthesia is not used widely for otolaryngologic surgery. Regional anesthesia is a potentially important therapy in otolaryngology because it may provide superior pain control, enhanced recovery, and earlier discharge, as in other areas of surgical practice.[39] Examples of head and neck procedures for which regional blocks can be used, perhaps in conjunction with general anesthesia, include myringotomy and tympanostomy

procedures, sinus surgery, facial plastic surgery, thyroidectomy, and parathyroidectomy.[40]

The trigeminal nerve, the fifth cranial nerve, supplies sensory innervation to the face as well as motor function to the muscles of mastication. It originates at the gasserian ganglion, also referred to as the semilunar ganglion, and is composed of three major branches: ophthalmic (V1) and maxillary (V2), sensory nerves, and mandibular (V3). Branches of the trigeminal nerve are potential targets for multiple regional anesthetic techniques.[41]

The ophthalmic division (V1) enters the orbit through the superior orbital fissure and branches into the supraorbital and supratrochlear nerves as well as the nasociliary nerve. The nasociliary branch carries sensory input to the mucous membrane of the nasal cavity as well as the frontal, sphenoidal, and ethmoidal sinuses. Although blockade of the ophthalmic division of the trigeminal nerve can be useful in sinus surgery, its proximity to vascular structures and other nerves requires a high level experience for its performance due to the increased risk of complications.[42]

The maxillary nerve (V2), called the infraorbital nerve once it reaches the infraorbital fossa, emerges from the infraorbital foramen. Branches of the nerve provide sensory innervation to the lower eyelid and upper lip, the teeth and gums, the nasal mucosa, the palate, and roof of the mouth. The infraorbital nerve also combines with the nasociliary branch of V1 to supply the maxillary, ethmoid, and sphenoid sinuses, as well as the nasal mucosa. The infraorbital foramen is located in a line between the pupil and the corner of the mouth just below the infraorbital rim.[42] The foramen can be approached from an intraoral approach and an extraoral approach.[42]

Nerve innervation of the palate is mainly derived from sphenopalatine branches of the maxillary nerve, which are distributed to the roof of the mouth, soft palate, tonsil, and membrane lining of the nasal cavity. The three main divisions of the nerve, the anterior, middle, and posterior branches, supply the gums and glands of the hard palate, the uvula, the tonsils, and the soft palate.[41]

Mandibular (V3) nerve blocks performed before bilateral mandibular osteotomy for oropharyngeal carcinoma surgery decreases both intraoperative and postoperative opioid consumption.[43] A branch of the mandibular nerve, the mental nerve, emerges at the mental foramen and communicates with the facial nerve. It emerges from the mental foramen, providing sensory input from the skin of the chin and mucous membrane of the lower lip. Blockade of the mental nerve is useful for surgery involving the lower lip and skin of the chin.[41]

The auricular branch of the vagus nerve joins the posterior auricular nerve, and innervates the skin of posterior auricula and external acoustic meatus. This nerve gives sensory innervation to the external auditory meatus and inferior portion of the tympanic membrane, making its blockade useful for myringotomy and tympanostomy procedures. The nerve passes through the tympanomastoid fissure, between the temporal bone and mastoid process. Blockade of the nerve can be performed by pulling the tragus forward and injecting local anesthetic posterior to the tragus.[41]

The cervical plexus is formed by the ventral rami of cervical nerves 1 through 4. The lesser occipital, the great auricular, the transverse cervical, and the supraclavicular nerves comprise the branches of the cervical plexus. Superficial cervical plexus block is useful for tympanomastoid surgery, otoplasty, and cochlear implant, or bilateral nerve block can be used for thyroidectomy.[44]

In some instances, cervical epidural anesthesia can be useful for neck surgery, where it has been described as a primary anesthetic technique for thyroidectomy.[45] Cervical epidural anesthesia typically results in blockade of the superficial cervical plexus (C1-C4) and brachial plexus (C5-T2). Hemodynamics and respiratory rate must be closely monitored because hypotension and ventilatory failure can develop. Epidural analgesia and general anesthesia can be combined to minimize postoperative complications and improve postoperative pain control. A meta-analysis of eight trials comparing preemptive versus postincisional continuous epidural regimens in thoracic and abdominal surgeries concluded that epidural analgesia significantly decreased postoperative pain, but no overall improvement in pain relief was observed with preemptive continuous epidural analgesia when compared with epidural infusion initiated postoperatively.[34] Only limited data are available regarding the perioperative use of epidurals in otolaryngology, and the efficacy of epidural analgesia for acute pain control in this setting needs further evaluation.

Chronic Pain

Chronic pain is one of the leading causes of health care consumption and worker disability in the developed world.[46,47] Uncontrolled postoperative pain can negatively impact surgical recovery and may persist beyond wound healing due to induced changes in the central nervous system.[48] It is important not only to treat pain effectively in the postoperative period, but also to be vigilant for the development of chronic pain afterward.[49,50] Chronic pain should be treated with analgesics and other therapies as needed. When chronic pain persists, referral to a pain management specialist may be appropriate.

Pain Definition and Types

Chronic pain may persist indefinitely, especially when the etiology is unknown or definitive treatment is unavailable. Chronic pain may or may not be associated with a long-term medical illness and appropriate therapy may differ depending upon this distinction. Because of its emotional component, chronic pain is often associated with psychological comorbidities, including depression.[51] Whether depression precedes chronic pain or chronic pain precedes depression is controversial and may vary, but the relationship between the two calls for appropriate treatment of both conditions.

Chronic pain is often a source of frustration for many medical professionals because it may be refractory to treatment. Complicating the issue is the concern of opioid addiction or abuse. Seeking drugs for pain relief is not the same as addiction. The American Pain Society defines opioid addiction as "a pattern of compulsive drug use characterized by continued craving for an opioid and the need to use it for effects other than pain relief." Furthermore, this compulsive craving and seeking of a drug often persists despite known negative consequences. However, the taking of opioids for pain relief does not constitute addiction, regardless of the dose or duration of use. Well-established literature suggests that addiction results from the use of opioids for pain relief in very few patients.[52-54]

Responding to reports of inadequate pain control in the 1980s, the World Health Organization (WHO) developed a stepwise approach to treatment of cancer pain. The steps of this analgesic ladder advocate choosing analgesics primarily based upon pain intensity. According to the ladder, a patient with mild pain should be started on acetaminophen, aspirin, or one of the NSAIDs. Someone with moderate pain should receive low potency opioids (e.g., codeine, hydrocodone), whereas those with severe pain receive potent opioids (e.g., morphine, hydromorphone). Adjuvant drugs (e.g., tricyclic antidepressants, anticonvulsants) should be added to the primary analgesics at each step of the ladder as needed.[55]

The WHO approach also provides a five-component framework for administering analgesics. First, oral administration of analgesics is preferred (whenever feasible) because oral administration is effective, inexpensive, and easily adjusted. Second, analgesics should be given on a routine schedule, using immediate-release (IR) formulations and/or sustained-release (SR) preparations, so that pain relief is continuous. Third, the severity of the pain and its responsiveness to medication should dictate which part of the analgesic ladder should be applied. Fourth, analgesics must be appropriately titrated to each patient in order to achieve optimal pain relief. Fifth, one must vigilantly assess the degree of pain relief both before and after implementing a new pain regimen, and carefully monitor for adverse effects.[2,55,56]

The WHO three-step analgesic ladder has been extensively validated in several studies over the past 20 years and found to be extremely effective in cancer pain management.[2,56] In one 10-year prospective study involving more than 2000 patients, 76% of patients reported good pain relief from analgesics prescribed in accordance with the WHO guidelines.[2,56] Furthermore, these patients experienced a low rate of analgesic-associated complications. Another study involving 174 patients showed that oral drug therapy successfully managed pain in 89% of patients. Greater than 80% noted their pain to range

between "none" and "moderate" with implementation of the WHO guidelines.[2,57]

Despite the efficacy of the WHO guidelines for cancer pain in general, some patients continue to have uncontrolled pain even with optimal use of systemic analgesics. When cancer pain is not controlled with systemic analgesics, a fourth step should be considered to extend the WHO ladder to encompass interventional pain therapies, such as intrathecal catheters with indwelling pumps,[58] and techniques of neural blockade. For head and neck cancers this may include such interventions as trigeminal nerve blockade with local anesthetic or radiofrequency ablation. Other interventions include occipital nerve block, glossopharyngeal block, and sphenopalatine block, depending upon the location of pain.[58]

Even though the WHO ladder has been validated in cancer pain, it has no such validation in noncancer settings.[59] Recently, several guidelines have been proposed for the use of opioids in chronic noncancer pain. These guidelines note that opioid therapy may prove beneficial for some patients and that there exists considerable personal and societal costs of chronic noncancer pain.[59,60] In accordance with good medical practice, such guidelines dictate that opioid therapy should be tailored to the individual patient, and many suggest that opioid should only be prescribed after other therapies have failed.[61] Opioid treatment should include thorough patient evaluation, careful formulation, and clear documentation of treatment objectives and plans, and periodic follow-up to assess treatment safety, efficacy, and patient compliance. One should carefully consider psychiatric consultation for patients with comorbid psychiatric disorders or substance abuse consultation when there is a high index of suspicion for substance abuse. Further studies are needed to substantiate guidelines for opioid use in chronic noncancer pain and to provide guidance regarding the key issue of patient selection.[60-64]

Considerable controversy abounds as to whether or not long-term opioid therapy is appropriate in chronic noncancer pain.[62,65] Beyond the concerns of addiction or diversion, there are considerable side effects to long-term opioid use such as hypogonadism, decreased immune function, constipation, tolerance, dependence, and opioid-induced hyperalgesia.[66] Furthermore, one study looking specifically at chronic facial pain found 75% of patients failed to respond to opioid therapy and many who took chronic opioids had functional decline.[67] Because of the adverse effects of opioid therapy over months to years, other treatment modalities such as anticonvulsants, antidepressants, NSAIDs, or interventional therapies may be preferable.[59,61]

First line agents for chronic pain have been in continuous flux over the last few years. Increased scrutiny has been given to the safety of COX-2 selective and nonselective NSAIDs, including removal of the most specific COX-2 selective inhibitors from the market secondary to concerns for increased cardiovascular risk.[68]

Not only NSAIDs but also most analgesics have a ceiling of efficacy and/or safety. One way to minimize toxicity is to combine lower doses of agents from different classes of drugs to obtain an additive or even synergistic effect while staying within the tolerability limits of each agent. An example of this approach is to use acetaminophen with tramadol. Whereas acetaminophen works centrally as a COX inhibitor, tramadol works both as a partial agonist at the opioid receptors as well as a serotonin and norepinephrine reuptake inhibitor. This is a logical combination that takes advantage of the agents' different mechanisms of action and different onset and duration of action. These agents have efficacy not only in the control of acute pain but also subacute and chronic pain. Combination of tramadol and acetaminophen has been effective in the management of many chronic pain states with associated functional improvement for up to 2 years of treatment. In some settings, this combination offers an effective, safer alternative to NSAIDs, because it lacks typical adverse effects associated with NSAIDs.[69-71]

Adjuvant Analgesics

Anticonvulsant Agents

There is strong evidence for anticonvulsant therapy in the management of neuropathic pain.[72] While carbamazepine has been used extensively in the past for chronic neuropathic pain, newer anticonvulsant drugs, specifically gabapentin and pregabalin, have moved to the forefront in the treatment of neuropathic pain, with evidence supporting the efficacy and safety of these newer agents.[51,72]

Anticonvulsants have a variety of mechanisms of action, working both centrally as well as peripherally by inhibiting excitatory transmission via the NMDA receptor, enhancing GABA mediated inhibition, and antagonizing sodium channel activation. These multiple modes of action allow anticonvulsants to treat neuropathic pain from a number of mechanisms. Different mechanisms may account for why some patients respond to a particular agent and not to others. Recent studies suggest that the newer anticonvulsants have similar tolerability and efficacy as antidepressants in the treatment of neuropathic pain.[73]

Currently, gabapentin is the most commonly used drug for neuropathic pain. It is thought to antagonize voltage-gated calcium channels in afferent neurons and also to centrally modulate GABA activity.[74] Several trials have shown its efficacy to approach that of amitriptyline in the treatment of diabetic peripheral neuropathy (DPN) and postherpetic neuralgia (PHN).[75-77] A common and well-tolerated dosing strategy starts with one 300-mg tablet nightly, and increasing by one tablet every 3 to 7 days until the dose of 300 mg three times per day is reached. Adjustment is continued in 300-mg increments until the patient experiences either acceptable relief or intolerable adverse effects. Maximal benefit at a total dose of 3600 mg daily has been suggested. Fatigue, sedation, nausea, and loss of coordination are the most common adverse effects, but temporarily suspending the dose escalation may minimize the development of these adverse effects. Total daily dose of 1800 to 3600 mg of gabapentin is usually well tolerated.[78] Extremely sensitive patients, such as older adults, should receive more conservative dosing, whereas those with chronic renal insufficiency require dosing based on creatinine clearance.

Another anticonvulsant increasingly used for pain control is pregabalin (isobutyl-GABA). This agent works by mechanisms very similar to those of gabapentin, but tolerability or lack thereof to one of these medications does not necessarily indicate similar results with the other. No head-to-head comparison of gabapentin and pregabalin has been published, but both have similar efficacy in the treatment of DPN and PHN.[79]

Phenytoin, an older anticonvulsant, also suppresses ectopic neural discharges but does so through inhibition of voltage-gated sodium channels and suppression of the release of glutamate.[80] Phenytoin is considered an acceptable second-line agent in patients with trigeminal neuralgia, but the paucity of evidence in the treatment of other neuropathic conditions, combined with the need for serum monitoring and noted adverse effects, have decreased its use, especially since the introduction of safer anticonvulsants.[76,81,82]

Carbamazepine, which has a similar structure to the older tricyclic antidepressants (TCAs), is mechanistically similar to phenytoin. It has shown efficacy over placebo in treatment of PHN and DPN and has remarkable efficacy in the management of trigeminal neuralgia.[51,80] During the initial period of therapy, adverse effects such as hyponatremia, aplastic anemia, and leukopenia may develop. Baseline hematologic and electrolyte laboratory values should be checked and periodically repeated throughout treatment.[80] Oxcarbazepine, a carbamazepine analogue, may have fewer drug interactions and fewer adverse effects than carbamazepine.[82] Oxcarbazepine, like carbamazepine, has shown efficacy against the induction of mechanical hyperalgesia and allodynia in experimental models[80] and has shown efficacy in the treatment of PHN and DPN.[83]

Lamotrigine, a sodium channel inhibitor, works by inhibiting glutamate release. Studies have shown lamotrigine to be effective in DPN, HIV-related neuropathic pain, and central mediated pain. Caution should be used while adjusting lamotrigine because serious rash may occur and its use has rarely been associated with Stevens-Johnson syndrome.[84]

Anecdotal reports suggest that the antiepileptic drugs zonisamide, valproate, and tiagabine may be useful as single agents for neuropathic pain in selected patients or as additions to first-line agents.[85,86] Caution also should be used with these medications, in that zonisamide, like lamotrigine, has been associated with Stevens-Johnson syndrome, and tiagabine has been associated with new onset of seizures.[87,88] Addition-

Table 17-2

Anticonvulsants Used in the Treatment of Neuropathic Pain

Drug	Mechanism of Action	Pharmacokinetics	Adverse Effect	Monitoring
Carbamazepine	Blocks Na^+ and Ca^{2+} channels; modulates descending inhibition	Metabolism: hepatic Elimination: hepatic	Hepatotoxicity, diplopia, nystagmus, memory loss, drowsiness, nausea, gastrointestinal upset	Complete blood count (CBC), platelets, liver function tests (LFTs), electrolytes, thyroid-stimulating hormone
Gabapentin	Antagonizes voltage-gated Ca^{2+} channels	Elimination: renal No alteration of hepatic metabolism of other medications	Edema, somnolence, dizziness, weight fatigue gain	Serum creatinine
Lamotrigine	Blockade of voltage-gated Na^+ and Ca^{2+} channels	Metabolism: hepatic Elimination: hepatic	Rash (5% to 10%), Stevens-Johnson syndrome, hepatic/renal failure, insomnia, nystagmus	CBC, LFT, serum creatinine
Levetiracetam	Unknown	Elimination: renal No alteration of hepatic metabolism of other medications	Asthenia, behavior changes, fatigue, depression	CBC, serum creatinine
Oxcarbazepine	Blocks Na^+ channel	Metabolism: hepatic Elimination: hepatic and renal	Hyponatremia, rash, sedation, gastrointestinal upset, diplopia	LFTs, electrolytes
Pregabalin	Antagonizes voltage-gated Ca^{2+} channels (at α_2-δ subunit)	Elimination: renal No alteration of hepatic metabolism of other medications	Weight gain, fatigue, edema, somnolence, dizziness	Serum creatinine
Topiramate	Na^+ and Ca^{2+} channel blockade, GABA potentiation, glutamate blockage	Metabolism: hepatic Elimination: renal	Open angle glaucoma, nephrolithiasis (1% to 5%), dizziness, cognitive dysfunction, weight loss, paresthesias	Serum creatinine
Zonisamide (sulfonamide derivative)	Blocks Na^+ and T-type Ca^{2+} channel	Metabolism: hepatic Elimination: hepatic	Stevens-Johnson syndrome, rash, nephrolithiasis (3%), hyperthermia, decreased white blood cells, photosensitivity, weight loss, dizziness, fatigue	CBC, LFTs, serum creatinine

ally, valproate has been rarely associated with fatal hepatotoxicity.[89] The use of potentially toxic drugs may be more easily justified in the control of seizures than in the treatment of neuropathic pain (Table 17-2).

Antidepressants

Antidepressants are commonly used in the treatment of neuropathic pain. These medications work not only by treating depression which facilitates pain signal transmission, but also decrease the reuptake of neurotransmitters (dopamine, norepinephrine, and/or serotonin), thereby potentially inhibiting pain neurotransmission.[81] TCAs, such as amitriptyline, have multiple mechanisms of action and have been used with some success for neuropathic pain. Because of potential TCA adverse effects (anticholinergic effects, effects on cardiac conduction and intraocular pressure, and increased orthostatic hypotension), these drugs must be used with caution. More specific serotonin-norepinephrine reuptake inhibitors (duloxetine, venlafaxine) have efficacy in management of neuropathic pain and may be better tolerated than TCAs, but there are few data comparing efficacy of these newer agents with TCAs. Agents with adrenergic mechanism (or mixed serotonergic and adrenergic) such as TCAs, or duloxetine and venlafaxine, are considered to be more effective analgesics than selective serotonin reuptake inhibitors (fluoxetine, citalopram).[90,91]

Most of the adverse effects associated with TCAs, such as orthostatic hypotension, cardiac conduction disturbances, thrombocytopenia, agranulocytosis, and acute angle-closure glaucoma, are caused by inhibition of H_1-histaminergic receptors.[92] Caution should be exercised in treating patients with comorbid depression because the TCAs are more lethal in overdose than other antidepressants. The secondary amines (e.g., amitriptyline, imipramine) are often preferred over the tertiary amines because they tend to have similar efficacy and fewer side effects.[93] Tricyclics are usually started at low doses and increased slowly over several days until the patient notes either acceptable benefit or unacceptable adverse effects. Comorbid conditions and a high variability in an individual's response makes careful titration necessary. After the daily dosage exceeds 100 mg, serum drug levels should be checked even if no adverse effects have been noticed. Patients with nocturnal pain and insomnia may benefit from taking these medications in the evening. Every patient should be educated to look for common adverse

effects such as somnolence, decreased salivation, hyperphagia, constipation, and urinary retention. Close monitoring and open communication allows better vigilance for adverse effects and appropriate interventions such as concomitant use of sialagogues, stool softeners, or in severe cases discontinuation of the medication.[80] Antidepressants are too often discontinued without a thorough trial, secondary to poor management of adverse effects and/or inadequate dosing.[93,94]

Several different antidepressants have been recommended for severe neuropathic pain. While citalopram and paroxetine have shown superiority to placebo in trials of DPN, most clinicians agree that analgesic efficacy of these agents is suboptimal and generally use other agents.[91,95] Bupropion has some efficacy in the treatment of pain and has the added benefits of decreasing nicotine dependence and generally good tolerability.[96] Newer antidepressants such as venlafaxine inhibit norepinephrine and serotonin reuptake but appear to have less adverse effects than the TCAs. Venlafaxine has been shown to approach the efficacy of the TCA imipramine in treatment of neuropathic pain associated with painful polyneuropathy with fewer side effects.[97] Duloxetine, another serotonin and norepinephrine reuptake inhibitor, has efficacy in treatment of pain caused by DPN as well as fibromyalgia, and has become one of the most commonly used antidepressants for pain control (Table 17-3).[98]

Interventional Techniques

Pain related to head and neck cancer is often challenging to manage due to the erosive nature of the malignancy, the dense sensory innervation of this area, and local anatomic distortions from surgery and/or radiation. Although systemic analgesics control most head and neck cancer pain, neural blockade or other techniques may be necessary for refractory pain.[99,100] Careful assessment of the nature and location of the pain is critical to choosing an appropriate intervention. (See Table 17-4 for a list of blocks of the head and neck and their indications.)

Local anesthetics, such as lidocaine or bupivacaine, block sodium entry into axons, effectively halting the propagation of axonal action potentials. These agents can work both at the central and peripheral levels, but need to be injected close to the neural target. Lidocaine may be used intravenously to treat neuropathic pain, but extreme caution must be used to avoid seizures and cardiac toxicity. Inadvertent intravenous injection of local anesthetic during neural blockade should be avoided with frequent aspiration of needle and vigilant monitoring for signs of cardiac or neurotoxicity. Ropivacaine, a newer local anesthetic, may have less cardiac toxicity than bupivacaine. In addition to their effect at the axon, local anesthetics also prevent axonal sprouting and have effects on G-protein-coupled receptors, as well as on the conductance of other ions beyond sodium that may have important roles in the modulation of pain.[101]

Neurolytic blocks, phenol or alcohol, are sometimes indicated for treatment of incapacitating chronic pain in association with end-stage malignancy.[102] Neurolytic blocks in the head and neck can be done percutaneously or endoscopically.[99] They are rarely applied in the head and neck, due to risk of significant complications related to close proximity of targeted nerves to other critical structures. In addition, if tar-

Table 17-3

Antidepressants Used in the Treatment of Neuropathic Pain

Drug	Mechanism of Action	Pharmacokinetics	Adverse Reactions	Monitoring
Amitriptyline	Tricyclic antidepressant inhibition of serotonin, norepinephrine, and dopamine	Metabolism: hepatic Elimination: hepatic and renal	Urinary retention, xerostomia, orthostasis, blurry vision, weight gain, constipation, sedation	Serum levels may need to be monitored at higher dosing levels or in those at higher risk of altered metabolism such as older adults
Bupropion	Selective reuptake inhibition of dopamine and norepinephrine	Metabolism: hepatic Elimination: hepatic and renal	Seizures, insomnia, anxiety	May consider closely monitoring renal and hepatic function in patients with preexisting impaired function.
Duloxetine	Selective reuptake inhibition of serotonin and norepinephrine	Metabolism: hepatic Elimination: renal and hepatic	Nausea, somnolence, constipation, dry mouth, dizziness, sweating, decreased appetite	
Imipramine	Tricyclic antidepressant inhibition of serotonin, norepinephrine, and dopamine	Metabolism: hepatic Elimination: hepatic and renal	Dry mouth, tachycardia, orthostatic hypotension, weight gain, constipation, urinary retention, blurred vision, sexual dysfunction; most side effects are better tolerated than with amitriptyline	
Nortriptyline	Tricyclic antidepressant inhibition of serotonin, norepinephrine, and dopamine	Metabolism: hepatic Elimination: renal	Anxiety, urinary retention, orthostasis, weight gain, blurry vision, constipation, sedation; most side effects are less pronounced than with amitriptyline	Serum levels may need to be monitored at higher dosing levels
Venlafaxine	Selective reuptake inhibition of serotonin and norepinephrine	Metabolism: hepatic Elimination: renal	Insomnia, sexual dysfunction, sweating, headache, anorexia, hypertension	

Table 17-4

Head and Neck Nerve Blocks and Indications

Trigeminal gasserian ganglion block	Facial cancer pain to the distribution of the V2 and V3 divisions of the trigeminal nerve
Mandibular nerve block	Painful malignancy involving the jaw and anterior two thirds of tongue
Maxillary nerve	Painful tumors of the middle third of face (maxilla, cheek, nasal cavity, and hard palate)
Glossopharyngeal nerve	Localized pain arising from the base of the tongue, soft palate, or nasopharynx.

geted nerves are close to the skin, cutaneous ulceration may complicate neurolytic injections.

Neuroablative lesions in the head and neck must be carried out cautiously to avoid increasing patient morbidity through unintended sensory or motor deficits. A local anesthetic trial is often used to aid in the determination of the extent of sensory or motor deficit and success expected from neurolysis. Peripheral neurolysis in the head and neck may be associated with the delayed development of neuritis or deafferentation pain, as well as the risk of inadvertent trauma to nearby essential structures. Therefore one should only consider these blocks in patients with intractable pain and short life expectancy.[99]

Radiofrequency lesioning techniques, which may provide better control of lesion distribution and greater analgesic efficacy, have largely replaced neurolytic blockade of the gasserian (trigeminal) ganglion.[58] Radiofrequency neurotomy is the destruction of neural tissue by using heat generated by a high-frequency electrical current.[58,103,104] Precisely controlled radiofrequency energy is delivered by a wire probe placed adjacent to the neural tissue to be destroyed. Because radiofrequency lesions are limited in size, the area of tissue damage may be more predictable than with neurolytic injections. When a focused lesion is needed, as is the case in the treatment of trigeminal neuralgia, radiofrequency has clear advantages over neurolytic injection techniques; however, injection techniques using chemical agents continue to be the neurolytic technique of choice when the tissue target is large and diffuse (e.g., celiac plexus).

Radiofrequency has been used for pain control in many clinical settings, including trigeminal ganglion ablation, spinal facet denervation, dorsal root ganglion ablation, and sympathetic chain lesioning at different levels (stellate, thoracic and lumbar sympathetic ganglia). There is extensive experience with radiofrequency for trigeminal neuralgia in patients not responding to appropriate analgesics. Radiofrequency of somatic nerves with cutaneous sensation may result in the delayed generation of neuropathic pain (anesthesia dolorosa) and thus is rarely used except in patients with advanced cancer pain or other terminal illness.[58]

Despite the best efforts of internists, surgeons, and pain specialists, some patients will continue to suffer from uncontrolled pain. For these patients, chronic pain may become a disease itself with a negative impact on mood and function for both the patient and his or her family. In these cases, it is important not to become so focused on the pathology that the individual is forgotten. There is a large body of evidence and growing consensus within the professional community that an appropriate referral to a pain psychologist may help the patient to acquire management skills that aid with symptoms and allow for a more active and meaningful lifestyle.[105]

Headache

Headaches are a nearly universal human experience, affecting most people at some point in their life. There is a 78% lifetime prevalence of tension-type headache and a 16% lifetime prevalence of migraine.[106] Headaches may be secondary, due to an identified underlying abnormality, or primary in nature. Although tension-type headaches are the most common primary headache disorder in the general population, migraine is the most common primary headache type leading to physician visits.[107] Primary headaches may be considered episodic or chronic, terms used in the headache field to refer to the frequency of headaches (tension-type, migraine) or the duration of headaches without remission (cluster, new-daily persistent headache, paroxysmal hemicrania, hemicrania continua).

The initial evaluation of the headache patient requires careful history, physical, and neurologic examinations. During these evaluations, the clinician must search for headache "red flags," findings that increase the suspicion for a secondary headache disorder. Suspicious findings in a headache history include, but are not limited to:

- New onset of headaches
- Preceding trauma
- Positional headaches (initiated by standing, lying down, bending)
- Systemic symptoms (fever, chills, weight loss)
- Systemic illness (immunosuppression, hypercoagulable state, cancer)
- Rapid onset of headache ("thunderclap headache")
- Older age at onset
- Focal neurologic symptoms (not consistent with typical migraine aura)
- Headaches due to transient increases in intracranial pressure (coughing, sneezing, Valsalva)

In addition to usual physical and neurologic examinations, patients with headache should also have examination of the eye, temporomandibular joint, cerebrovasculature (temporal arteries, carotid bruits), cervical paraspinal and trapezius muscles, and sinuses. Abnormalities on examination should not be attributed to a primary headache disorder without careful consideration of possible secondary causes. Figure 17-1 is a flow diagram outlining the basic approach to headache diagnosis.

The presence of worrisome features in the headache history or examination raises the suspicion for a secondary headache disorder, which may be clarified with diagnostic tests. Generally, a patient without historical or examination red flags does not require additional diagnostic testing. When a secondary headache is suspected, however, testing must be individualized but may include blood work (complete blood count, complete metabolic panel, erythrocyte sedimentation rate, thyroid function tests, tests for autoimmune disorders, others), brain imaging (computed tomography, magnetic resonance imaging), angiography (conventional catheter, magnetic resonance, computed tomography), cerebrospinal fluid evaluation (including measurement of opening pressure), and cervical spine imaging, among others.

Migraine

Migraine headaches affect one in six people worldwide[106] and result in significant pain, disability, and reductions in quality of life.[108] Chronic migraine, defined as having migraine headaches on at least 15 days per month, affects 3% to 4% of the population and is considered by the WHO to be one of the most disabling illnesses.[109,110]

Migraine is defined as[111]:

- Moderate to severe pain
- Duration of 4 to 72 hours
- Unilateral or bilateral

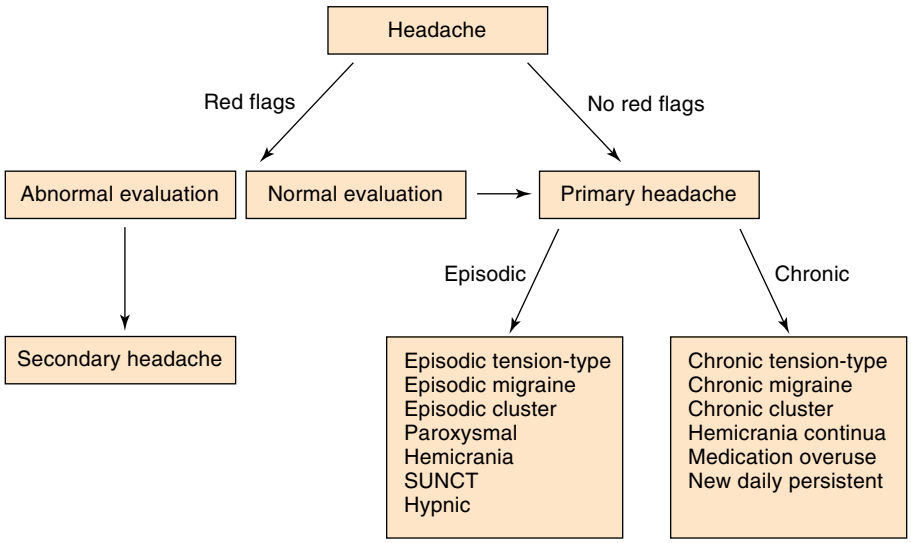

Figure 17-1. Basic approach to headache diagnosis. "Red flags" refers to worrisome features in the headache or medical history, or abnormalities on general physical or neurologic examination. SUNCT, short-lasting *u*nilateral *n*euralgiform headache with *c*onjunctival injection and *t*earing.

- Associated with photophobia/phonophobia and/or nausea/vomiting
- Worsened by routine physical activities
- Throbbing or pulsating in quality

Approximately one-third of patients with migraine have a preceding aura.[112] Migraine aura develops slowly over 5 to 20 minutes and resolves within 60 minutes. This slow progression and timing of resolution helps differentiate symptoms of migraine aura from stroke symptoms. Visual symptoms are the most common and are often positive symptoms (scintillations) followed by negative symptoms (scotoma). Sensory symptoms are second most common and typically consist of paresthesias in the hand of one extremity with ipsilateral progression up the arm and eventually to the lower face. Less common aura symptoms may include numbness, weakness, speech changes, dizziness, gait instability, ataxia, and blindness. However, when confronted with these less common symptoms, suspicion for a secondary headache or an uncommon migraine syndrome (hemiplegic migraine, basilar migraine, retinal migraine) is high.

The treatment of migraine may include acute headache medications as well as prophylactic therapy. All patients should have a method of treating individual headaches. Prophylactic measures may be initiated for multiple indications, including frequent headaches, insufficient response to acute headache medications, prolonged headaches, significant impact on quality of life, significant headache-related disability, and bothersome associated neurologic features (such as may be seen with hemiplegic or basilar migraine).[113]

The acute therapy of migraine is heavily reliant on medications. The triptans are arguably the most effective therapy for acute headache relief in the outpatient setting. There are seven different triptans available that allow for four different methods of administration (oral tablet, orally dissolving tablet, nasal spray, injection). Although there are perhaps subtle differences between the triptans (side effects, elimination half-life, recurrence rate, overall efficacy), they have more similarities than differences.[114] There are limitations to the amount of triptan that can be safely used, and there are multiple contraindications to their use, mostly involving vascular diseases and their risk factors. Other outpatient acute headache therapies include dihydroergotamine mesylate nasal spray (DHE), NSAIDs, antiemetics, and opioid analgesics (opioids should rarely be used for the treatment of migraine headache). Regardless of therapy, it is important to instruct patients to treat early after the onset of migraine. When migraine is allowed to persist and sensitization occurs, therapies for acute onset are much less successful.[115]

Prophylactic therapy for migraine may consist of headache trigger avoidance, daily medication, physical therapy, and biobehavioral therapy. Most medications used for the prophylaxis of migraine are either antidepressants (TCAs), blood pressure medications (beta-blockers, calcium channel blockers), or antiepileptics (topiramate, valproic acid). Other frequently used therapies include riboflavin, magnesium, feverfew, and butterbur. Botulinum toxin injections are increasingly being used, but the exact safety and efficacy is yet to be determined conclusively.[116] Prophylactic therapy is considered successful if there is at least a 50% reduction in headache frequency. Physical therapy, biofeedback, relaxation therapy, and acupuncture may be helpful for the individual migraine patient as well.

Tension-Type Headache

Tension-type headache (TTH) is the most common type of headache and is estimated to affect nearly 80% of all people at some point in their life.[106] The vast majority of patients with TTH do not seek medical care.

TTHs are most commonly bilateral, of a pressure quality, mild to moderate in severity, and not made worse by routine activities.[111] They are not associated with nausea or vomiting, and although there can be mild photophobia or phonophobia (not both), these sensitivities are not as prominent as seen in migraine. TTHs endure from 30 minutes to 7 days. If headaches occur on more than 15 days per month, chronic TTH is diagnosed. TTH may be associated with pericranial tenderness to palpation.

Over-the-counter NSAIDs or acetaminophen is usually adequate for acute TTH therapy. Patients with frequent TTH may require prophylactic measures such as physical therapy, biobehavioral therapy, and daily preventive medications.

Cluster Headache

Cluster headache is one of the trigeminal autonomic cephalgias, a group of headaches also including paroxysmal hemicrania, and *s*hort-lasting *u*nilateral *n*euralgiform headache with *c*onjunctival injection and *t*earing (SUNCT). Cluster headache is 4 times more common in men than women.[117]

Cluster headaches are severe headaches that occur in or around the eye and temporal region.[111] The pain is accompanied by ipsilateral signs of autonomic nervous system activation, which include conjunctival injection, lacrimation, nasal congestion, rhinorrhea, eyelid edema, sweating on the head or face, miosis, and ptosis. In contrast to the patient with migraine, cluster patients tend to be restless during an attack, often pacing the floor or displaying other agitated behavior.

Individual headaches last 15 minutes to 2 hours and occur once every other day up to 8 times per day. Individual headaches may occur with circadian periodicity. Cluster headaches tend to occur in periods lasting from weeks to months separated by periods of remission lasting months to years. Cluster periods may begin at the same time of the year for an individual patient. If the cluster period lasts for more than 1 year without remission, a diagnosis of chronic cluster headache is made.

The treatment of cluster headache depends upon acute and prophylactic headache measures as well as attempts to shorten or abort cluster periods. Acute therapies include triptans, DHE, and inhalation of oxygen. Oxygen is effective in the majority of patients and may be considered the optimal therapy given its relative safety.[118] Oxygen is administered at high flow (8 to 10 L/min) by mask. Triptans generally must be given as injections or by nasal spray to achieve benefit from timely therapeutic onset.

Prophylactic options for cluster headache include verapamil, lithium, melatonin, and methysergide. There is a potential role for valproate, topiramate, gabapentin, testosterone, and dopamine agonists. Verapamil is considered the mainstay of prophylactic therapy.[119,120] Electrocardiographic monitoring is required when treating patients with verapamil.[121] In patients who have significant periods of headache remission, prophylactics are initiated when the cluster period begins and then discontinued after the patient has remained in remission for several weeks.

Steroids may be used in an attempt to shorten cluster periods and to provide temporary relief from headaches. Occipital nerve blockade has also shown promise in this regard.[122]

Hemicrania Continua

Hemicrania continua is a strictly unilateral headache that is continuous without pain-free intervals.[111] It is moderate in intensity but with superimposed exacerbations of pain into the severe range. During these exacerbations, there is presence of ipsilateral autonomic activation which may include conjunctival injection, lacrimation, nasal congestion, rhinorrhea, ptosis, and miosis. It is essential to recognize this headache type since it is completely responsive to indomethacin.

The treatment of hemicrania continua is indomethacin. When this headache type is suspected and in the absence of contraindications to this medication, an indomethacin challenge is performed. This may be done in the clinic via intramuscular injection or as an outpatient using an upward titration of oral indomethacin over several days.[123] In patients who respond, the lowest effective dose is determined and continued with coadministration of gastric mucosal protectants. Attempts to lower the dose or discontinue the medication are made over time.

Medication Overuse Headache

Acute headache medication overuse headache or "rebound headache" refers to daily or near daily headaches that are attributed to the excessive use of acute headache medications. Although the exact definition of overuse varies according to the medication being administered, patients who use medication for acute headache on more than 2 to 3 days per week on average are considered to be at high risk for development of this headache.[111] Patients with frequent and regular use of acute medications are more susceptible to development of rebound headaches. Medication overuse is one of the main factors contributing to the progression from episodic headache patterns to chronic headache patterns (e.g., transformed migraine).[124]

Patients suspected of having medication overuse headache need to be withdrawn from the overused medication. Depending on the specific offending medication this may be done via a slow downward taper, use of long-acting NSAIDs, steroid tapers, or hospitalization for withdrawal of the medication and treatment with intravenous medications.[125,126] The treatment of medication overuse headache can be challenging and often requires a multimodal approach to include prophylactic medications as well as psychological therapy.

Thunderclap Headache

The term *thunderclap headache* refers to headaches that start rapidly and reach severe intensity within seconds. Although a primary form of thunderclap headache exists, there must be a high suspicion for a secondary headache. Because of the potential morbidity and mortality from some of these underlying causes, thunderclap headache should be considered a medical emergency and patients must seek immediate medical attention. Although the possible causes of thunderclap headache are numerous, these include: subarachnoid hemorrhage, reversible cerebral vasoconstriction syndromes, cervical artery dissection, intracranial infection, cerebral venous sinus thrombosis, and spontaneous intracranial hypotension.[127]

Trigeminal Neuralgia

Trigeminal neuralgia, also known as *tic douloureux,* is more commonly seen in women than men (1.5 : 1) between the fifth and seventh decade of life.[128] It manifests as sharp lancinating facial pain that lasts a few seconds up to 2 minutes and occurs multiple times per day. Pain is most commonly located in the second and third divisions of the trigeminal nerve (lower face), but can involve the first division as well (International Classification of Headache). Pain may be triggered by touching certain areas of the face, brushing the teeth, talking, and cold air. Trigeminal neuralgia tends to occur in periods lasting days to months separated by remissions of months to years.

The treatment of trigeminal neuralgia focuses on prophylactic medications. Carbamazepine is considered first line therapy and results in pain relief in greater than three-quarters of patients treated at therapeutic doses.[129] Other medications include: oxcarbazepine, phenytoin, baclofen, clonazepam, valproic acid, gabapentin, and topiramate. If recalcitrant to medical therapy, surgical options for the treatment of trigeminal neuralgia are available.

CHAPTER EIGHTEEN

Sleep Apnea and Sleep Disorders

Stacey L. Ishman

Tamekia L. Wakefield

Nancy A. Collop

Key Points

- Snoring affects at least 40% of men and 20% of women, and often accompanies sleep-disordered breathing. However, only 2% of women and 4% of men older than 50 years of age have symptomatic obstructive sleep apnea (OSA).
- OSA is defined by five or more respiratory events (apneas, hypopneas, or respiratory effort–related arousals [RERAs]) in association with excessive daytime somnolence, waking with gasping, choking, or breath-holding, or witnessed reports of apneas, loud snoring, or both.
- Negative health effects have been attributed to untreated OSA including increased mortality, an increase in cardiovascular disease, and neurocognitive difficulties. In addition, untreated OSA has been demonstrated to be an independent risk factor for insulin resistance, gastroesophageal reflux disease, motor vehicle accidents, and decreased attention, working memory, and executive function.
- The most common symptoms of OSA include loud snoring, restless sleep, and daytime hypersomnolence. However, polysomnography (PSG) is required for diagnosis and is considered the gold standard for diagnosis of OSA.
- Fiberoptic nasopharyngoscopy is an important tool to identify level of obstruction: nasal, retropalatal, or retrolingual. Most people have multilevel obstruction.
- Uvulopalatopharyngoplasty (UPPP) is the most commonly performed surgical procedure for OSA and is often misused as the first line of surgical therapy for OSA regardless of coexistent patient factors such as obesity, retrognathia, and the existence of other sites of obstruction. As a result, it is often unsuccessful in treating OSA in unselected patients.
- Partial midline glossectomy (PMG), lingualplasty, and radiofrequency tongue base ablation are procedures that have been developed in an attempt to address the retrolingual collapse or narrowing that occurs in OSA.
- Surgical treatment of the hypopharyngeal area is comprised of procedures designed to prevent tongue collapse into the airway during sleep. These include genioglossal advancement (GA) and hyoid myotomy (HM), which are both used to create an enlarged retrolingual airway.
- Thirty-one percent of patients whose OSA was diagnosed in a sleep disorder center were found to have coexistent sleep disorders, with the most common being inadequate sleep hygiene (15%) and periodic limb movement disorder (8%).
- Insomnia is defined as difficulty with sleep initiation, maintenance, consolidation, or quality; it is recurrent and causes daytime dysfunction despite adequate occasion and opportunity for sleep.
- Circadian rhythm sleep disorders occur when personal sleep-wake patterns are misaligned with the societal clock on a persistent or recurrent basis, leading to excessive daytime sleepiness or insomnia and resulting in impaired function.
- Parasomnias are undesirable movements or subjective phenomena that occur during sleep; either while falling asleep, while waking up, or during sleep itself.

Over the past decade, interest in sleep and sleep disorders has increased substantially. The majority of this renewed interest within the otolaryngology community has been focused on the sleep-related breathing disorder OSA. As the waistline of the average American has grown, so too has the incidence of OSA. Population-based studies suggest that 2% of women and 4% of men older than age 50 years have symptomatic OSA.[1] Advances have also been made in the understanding of the pathophysiology of OSA, diagnostic methods, and medical and surgical treatments. The recognition that sleep disorders require a multidisciplinary approach has led to the creation of a new medical discipline—sleep medicine—with teams made up of internists, pulmonologists, otolaryngologists, neurologists, pediatricians, psychiatrists, oral/maxillofacial surgeons, dentists, behavioral psychologists, and nutritionists who work together to take care of patients with sleep disorders. Considerable advances have been made in the diagnosis and management of sleep disorders, and otolaryngologists are at the forefront of this new field, providing a host of both traditional and novel operative techniques to facilitate treatment.

Historical Perspectives

The idea of obesity being intimately associated with daytime somnolence seems to have been first written about by Charles Dickens in *The Posthumous Papers of the Pickwick Club*, originally published in 1837. Dickens gives a vibrantly descriptive picture of Joe, a boy so obese that he has difficulty breathing, sounds as if he is snoring even when awake, and frequently falls asleep while standing. In addition, there is evidence to suggest that some of our most noted leaders and dictators suffered from this problem. The 20th president of the United States, William Howard Taft, had a body mass index of 42 kg/m^2 while in office and was reported to snore, to fall asleep during the day frequently, and to have hypertension.[2] Chouard and colleagues describe several reasons to suspect Napoleon I (1769-1821) had OSA in the last decade of his life: he was obese and retrognathic, his neck was short and thick, he had nasal obstruction, he frequently slept during the day, he complained of declining energy and intellect, and he was quite tired looking and somewhat disheveled.[3] In 1956, Drs. A. G. Bicklemann, C. S. Burwell, and colleagues drew on Dickens' description in their case report titled "Extreme Obesity Associated with Alveolar Hypoventilation: a Pickwickian Syndrome." This frequently cited paper served as the first description of the Pickwickian syndrome in an academic journal.[4] Sleep apnea was first described as a clinical entity in 1965, but it was not until the 1970s that Elio Lugaresi's group provided a complete description of the OSA syndrome with its potential adverse cardiovascular effects.

In the infancy of this new diagnosis, treatment options were limited to tracheostomy or weight loss. This changed in the early 1980s with the introduction of the uvulopalatopharyngoplasty (UPPP) as described by Fujita and colleagues[5] and Simmons and colleagues.[6] It was not long after the introduction of UPPP that it was recognized that although this new surgical intervention was helpful in many cases, it left half of the patients with persistent sleep apnea and could be a painful procedure. It was during this same time period that Colin Sullivan, a young Australian medical researcher, developed nasal continuous positive airway pressure (CPAP), which today remains the first-line treatment of adult OSA.

As treatment for OSA has evolved, so too has therapy aimed at treating snoring. The development of office-based surgical treatments, over-the-counter devices, and pharmacologic interventions has increased considerably in recent years.

Classification of Obstructive Sleep-Related Breathing Disorders

Sleep-related breathing disorders range from partial airway collapse and increased upper airway resistance to episodes of hypopnea or complete airway collapse with sleep apnea (Box 18-1). In addition, a number of indices are used to describe sleep-disordered breathing (Box 18-2).

Snoring

Snoring is sound generated by the vibration of the pharyngeal soft tissues. It is often louder during inspiration than expiration. It affects at least 40% of men and 20% of women and often accompanies sleep-disordered breathing (SDB).[7] However, it can occur in isolation and by definition is not associated with symptoms of excessive daytime sleepiness or insomnia. Snoring, in the absence of OSA, is documented when habitual audible snoring occurs with an apnea hypopnea index (AHI) of less than five events per hour without daytime symptoms. Polysomnography (PSG) is not required for diagnosis, but when performed it reveals an audible microphone signal not associated with arousals, desaturations, airflow limitation, or arrhythmias.[8]

Upper Airway Resistance Syndrome

The term *upper airway resistance syndrome* (UARS) was first used to describe patients who do not meet the criteria for OSA syndrome but who experience excessive daytime somnolence and other debilitating somatic complaints.[9] UARS is characterized by respiratory effort–related arousals (RERAs). A RERA is defined as a sequence of breaths over at least 10 seconds with increasing respiratory effort that terminates with an arousal.[10] A RERA is detected using esophageal pressure manometry, which reveals a pattern of progressively increasing negative esophageal pressure followed by an arousal.[10,11] PSG reveals frequent arousals associated with snoring, abnormally negative intrathoracic pressure, or increased diaphragmatic electromyogram activity.[9] The current International Classification of Sleep Disorders does not consider UARS to be a separate sleep disorder, but recommends that it be

Box 18-1

Respiratory Event Definitions and Types

Respiratory Event	Definition
Apnea	A cessation of airflow for at least 10 seconds
Hypopnea	A reduction in airflow (≥30%) at least 10 seconds with ≥4% oxyhemoglobin desaturation OR a reduction in airflow (≥50%) at least 10 seconds with ≥3% oxyhemoglobin desaturation or an electroencephalogram (EEG) arousal
Respiratory effort-related arousal (RERA)	Sequence of breaths for at least 10 seconds with increasing respiratory effort or flattening of the nasal pressure waveform leading to an arousal from sleep when the sequence of breaths does not meet the criteria for an apnea or a hypopnea
Obstructive	Continued thoracoabdominal effort in the setting of partial or complete airflow cessation
Central	The lack of thoracoabdominal effort in the setting of partial or complete airflow cessation
Mixed	A respiratory event with both obstructive and central features. Mixed events generally begin as central events and end with thoracoabdominal effort without airflow

Box 18-2

Indices of Sleep-Disordered Breathing

Indices	Definition
Apnea index	Number of apneas per hour of total sleep time
Hypopnea index	Number of hypopneas per hour of total sleep time
Apnea-hypopnea index	Number of apneas and hypopneas per hour of total sleep time
Respiratory effort–related arousals (RERAs) index	Number of RERAs per hour of total sleep time
Respiratory disturbance index (RDI)	Number of apneas, hypopneas, and RERAs per hour of total sleep time
Central apnea index	Number of central apneas per hour of total sleep time
Mixed apnea index	Number of mixed apneas per hour of total sleep time

Box 18-3

Symptoms of Sleep-Disordered Breathing

Restless sleep
Loud snoring
Observed apnea, choking, or gasping episodes
Excessive daytime sleepiness (EDS)
Morning fatigue or irritability
Memory loss
Decreased cognitive function
Depression
Personality or mood changes
Decreased libido and impotence
Morning and nocturnal headaches
Nocturnal sweating
Nocturnal enuresis

included under the definition of OSA because the pathophysiology is similar.[8]

Obstructive Sleep Apnea Syndrome

OSA is defined by five or more respiratory events (apneas, hypopneas, or RERAs) in association with excessive daytime somnolence, waking with gasping, choking, or breath-holding, or witnessed reports of apneas, loud snoring, or both. Each episode of apnea or hypopnea must last a minimum of 10 seconds, is commonly accompanied by reductions in blood oxygen saturation of at least 3% to 4%, and is usually terminated by brief, unconscious arousals from sleep. Snoring between apneas is a frequent complaint of bed partners and is often the symptom that prompts these patients to seek medical attention; although, excessive daytime somnolence is a common presenting complaint. Automobile accidents and increased cardiovascular morbidity and mortality are frequent complications if OSA is left untreated. Many OSA sufferers complain of awakening from sleep with morning headache, sore throat, and fatigue or a feeling of being unrefreshed regardless of the duration of sleep (Box 18-3). OSA is exacerbated by ingestion of alcohol, sedative use, and weight gain.

Pathophysiology

The obstruction that occurs in OSA results from collapse of the pharyngeal airway during sleep. The etiology and mechanism of collapse is multifactorial but is largely due to the interaction of an easily collapsible upper airway with the relaxation of the pharyngeal dilator muscles, which happens during sleep. Obesity, soft tissue hypertrophy, and craniofacial characteristics such as retrognathia add to this propensity for collapse by increasing the extraluminal tissue pressures surrounding the upper airway. However, structural compromise of the airway alone is not always sufficient to produce OSA. Notably, patients without anatomic abnormalities may also have OSA. This may occur because the complex reflex pathways from the central nervous system to the pharynx, which control the action of pharyngeal dilator muscles, may fail to maintain pharyngeal patency. The three major areas of obstruction are the nose, the palate, and the hypopharynx, although obstructive sleep apnea associated with laryngeal obstruction from bilateral laryngeal paralysis, laryngomalacia, and obstructing laryngeal lesions has also been reported.

Fujita classified the patterns of obstruction by anatomic location in the following manner: type I, collapse in the retropalatal region only; type II, collapse in both retropalatal and retrolingual regions; type III, collapse in the retrolingual region only.[12] Subsequent studies have evaluated the prevalence of retropalatal versus retrolingual obstruction in patients with OSA and snoring and found that both retrolingual (77% versus 40%) and retropalatal (100% versus 70%) obstruction are increased in OSA patients, confirmed by PSG, compared with snorers.[13]

Nasal obstruction contributes to increased airway resistance and may worsen OSA, but it is rarely the sole cause. Nasal obstruction may contribute to open-mouth breathing during sleep, which increases upper airway collapsibility and may decrease the efficacy of dilator muscles.[14] Snoring is often a presenting symptom of OSA and can be caused by nasal obstruction. Surgical procedures aimed at improving nasal breathing have demonstrated subjective improvement in snoring following correction of nasal obstruction.[15] Even though isolated treatment of the nasal airway rarely leads to cure of OSA, it may allow for decreased CPAP levels to be used for subsequent treatment.[16] Nasal obstruction can be caused by bony and cartilaginous deformation or from soft tissue changes. Because there are many causes of nasal obstruction, they all warrant investigation when evaluating a patient with OSA.

Obesity is a major risk factor for OSA. The increased fat deposition around the neck and parapharyngeal spaces is postulated to narrow and compress the upper airway and may offset the effects of dilator muscles that maintain airway patency.[17] Obesity is also thought to contribute to OSA through its deleterious effects on metabolism, ventilation, and lung volume, resulting in a mismatch between alveolar ventilation (V) and pulmonary perfusion (Q). Obesity can significantly reduce lung volume, which results in a reduction of functional residual capacity. It has been observed that changes in lung volume significantly reduce pharyngeal upper airway size through the mechanical effect of tracheal and thoracic traction, referred to as "tracheal tug," increasing the risk for airway collapse.[18]

Adenotonsillar hypertrophy is the major cause of obstructive sleep apnea in children. In adults there are multiple structural characteristics associated with OSA. Craniofacial variations that have been associated with OSA include increased distance of the hyoid bone from the mandibular plane, decreased mandibular and maxillary projection, a downward and posterior rotation of mandibular and maxillary growth, increased vertical facial length, increased vertical length of the posterior airway, and increased cervical angulation.[19]

Neuromuscular tone contributes to the patency of the upper airway. During sleep this tone decreases and the airway tends toward collapse. The genioglossus muscle is considered to be the most important muscle in maintaining airway patency in OSA. Elevated genioglossal and tensor palatini muscle activity has been observed in awake OSA patients compared with normal awake subjects who have lower levels of activity. This suggests that even while the patient is awake, airway dilator muscle activity compensates for a more anatomically compromised upper airway in the OSA patient.[17] Studies are ongoing to determine the extent and importance of neuromuscular tone in maintaining airway patency during sleep.

Consequences of Untreated Obstructive Sleep Apnea

A number of negative health effects have been attributed to untreated OSA including increased mortality, an increase in cardiovascular disease, and neurocognitive difficulties. In a retrospective study, He and colleagues found that untreated OSA patients with an apnea index (AI) greater than 20 had a statistically significant increase in mortality compared with patients with an apnea index less than 20.[20] He also found that untreated patients with an AI greater than 20 had a 63% probability of surviving 8 years compared with 96% in those with an AI less than 20.[20] Additionally, untreated OSA is reported to increase the risk of fatal and nonfatal motor vehicle accidents by 2.5-fold.[21] A significant proportion of the mortality and morbidity related to OSA occurs through its effect on the cardiovascular system, including hypertension, coronary heart disease, congestive heart failure, arrhythmias, sudden death, pulmonary hypertension, and stroke. Untreated moderate and severe OSA has been reported to result in a threefold increase in fatal and nonfatal cardiovascular events, when compared with both healthy men without OSA and men with CPAP-treated OSA.[22] Treatment of OSA with CPAP has also been reported to lower blood pressure by 10 mm Hg.[23]

Untreated OSA has been demonstrated to be an independent risk factor for insulin resistance.[24] Recently, it has been suggested that OSA may contribute to the development of diabetes and metabolic syndrome, the term used to describe the commonly occurring conditions of obesity, insulin resistance, hypertension, and dyslipidemia. However,

further research is needed to determine whether there is an independent link between OSA and metabolic abnormalities.

The prevalence of gastroesophageal reflux disease (GERD) in OSA patients is significantly higher than in the general population.[25-27] Even though these disorders commonly occur together, no temporal or causal relationship has ever been demonstrated between the two. This may reflect the fact that they share similar risk factors. Treatment of OSA with CPAP has been demonstrated to decrease the occurrence of GERD.[28]

Aside from the obvious physical effects of OSA, such as excessive daytime sleepiness and impaired mood, neurocognitive deficits have also been associated with OSA. Untreated OSA has been documented to cause problems with attention, working memory, and executive function, all of which are improved with CPAP treatment.[29] Bed partner dissatisfaction is also a common complaint among OSA patients and treatment has been shown to improve the quality of life in both the treated individuals and their bed partners.[30] Thus the benefits of treating OSA are substantial and well documented.

Diagnosis

The most common symptoms of OSA include loud snoring, restless sleep, and daytime hypersomnolence. However, a broad range of signs and symptoms have been reported to occur in OSA (see Box 18-3). Obesity is a common finding in patients with OSA with reports that 70% of adult patients with OSA are obese.[31] Screening, including a detailed sleep history and physical examination, is recommended for all obese patients. The Epworth Sleepiness Scale (ESS) is a widely used tool that assesses daytime sleepiness (Fig. 18-1). OSA may be suspected in patients with an ESS greater than 10.[32] Sleepiness or fatigue may also be precipitated by a number of other medical conditions that should be considered when evaluating patients for possible OSA (Box 18-4). In addition, the presence of additional sleep disorders should be considered.

Due to the increased prevalence of OSA in patients with hypertension, coronary artery disease, congestive heart failure, cerebrovascular accident, and diabetes mellitus, these populations must be carefully screened for the signs and symptoms of OSA.[33] It has also recently been recognized that OSA may be underdiagnosed in women due to a lower index of suspicion among physicians or underreporting of the classic symptoms by female patients. Women with OSA are more likely to report symptoms of insomnia, heart palpitations, and ankle edema.[34]

Although the presence of daytime somnolence and loud snoring are frequently the signs which prompt OSA suffers to seek medical attention, it is the physical examination findings that strengthen the likelihood of the diagnosis. Body mass index calculation, blood pressure measurement, and neck circumference are important general assessment parameters. In addition, body habitus, mandible and maxilla position and size, and facial characteristics should be noted. Assessment of the nose should include evaluation of any external deformity, adequacy of the nasal valve, septal position, turbinate size, nasal mucosa swelling, and the presence or absence of polyps, purulence, and rhinorrhea. In the oral cavity, appraisal of the tongue size and position, elongation of the palate and uvula, tonsil size, modified Mallampati score, dentition, and crowding of oropharynx should follow. In the neck, neck size, hyoid position, and jaw position, including retrognathia, should be evaluated (Box 18-5).

Fiberoptic nasopharyngoscopy is an important technique for evaluation of the airway. This examination can be performed in multiple positions in awake and asleep patients and is an important tool to identify level of obstruction: nasal, retropalatal, or retrolingual (Figs. 18-2 and 18-3). Numerous studies have described the benefits and limitations of the addition of the Müller maneuver to this examination for preoperative prediction of the effectiveness of surgical interventions.[35,36] The Müller maneuver is performed in an awake patient who generates negative pressure by inhaling against a closed glottis with the nose and mouth closed, which triggers airway collapse (Figs. 18-4 and 18-5). Sher and associates performed both seated and supine examinations using the Müller maneuver in OSA patients, selected those with palatal collapse, and found that 73% of patients had at least a 50% reduction in respiratory disturbance index (RDI) after UPPP.[36] Aboussouan found that using the Müller maneuver to guide the decision on UPPP resulted in an AHI reduction by 50% in 78% of patients who had velopalatal collapse, compared with 36% for multilevel obstruction.[35] Thus, even though the Müller maneuver can help guide surgical decision making when the area of collapse is purely retropalatal, it appears to be less useful in patients who have multilevel obstruction.

To better identify the site or sites of obstruction in patients with OSA, drug-induced sleep videoendoscopy has been used to guide more effective surgical intervention. Sleep is induced via pharmacologic means and standard fiberoptic nasopharyngoscopy is performed to evaluate the site of airway collapse. Sleep endoscopy may hold greater

EPWORTH SLEEPINESS SCALE

Please answer the following questions based on this scale:

0. Would never fall asleep
1. Slight chance of dozing
2. Moderate chance of dozing
3. High chance of dozing

Situation	Chance of Dozing
Reading	_____
Watching TV	_____
Sitting in a public place (e.g., theater or meeting place)	_____
Driving a car, stopped at a traffic light	_____
As a passenger in a car for an hour without a break	_____
During quiet time after lunch without alcohol	_____
Lying down to rest when circumstances permit	_____
Total Score:	_____

Epworth Score < 10 = Normal

Medical Conditions That Produce Fatigue

- Severe anemia
- Endocrine dysfunction, including hypothyroidism and Addison's disease
- Chronic fatigue syndrome
- Pulmonary disease, including asthma, emphysema, and pickwickian syndrome
- Cardiovascular disease, including congestive heart failure and left heart failure
- Neoplasms, including disseminated and central nervous system lesions
- Anticancer chemotherapy
- Collagen vascular diseases
- Chronic infections, including mononucleosis, hepatitis, and influenza
- Depression and other psychiatric disorders
- Malnutrition
- Neurologic disorders, including Parkinson's disease and multiple sclerosis
- Medication side effects

Box 18-5

Physical Examination Findings

Nasal Obstruction
Septal deviation
Turbinate hypertrophy
Nasal valve collapse
Adenoid hypertrophy
Nasal tumors or polyps

Oropharyngeal Obstruction
Large soft palate
Palatine tonsillar hypertrophy
Posterior pharyngeal wall banding
Macroglossia
Large mandibular tori
Narrow skeletal arch

Hypopharyngeal Obstruction
Lateral pharyngeal wall collapse
Omega-shaped epiglottis
Hypopharyngeal tumor
Lingual tonsillar hypertrophy
Retrognathia and micrognathia

Laryngeal Obstruction
True vocal cord paralysis
Laryngeal tumor

General Neck Obstruction
Increased neck circumference
Redundant cervical adipose tissue

General Body Habitus
Obesity
Achondroplasia
Chest wall deformity
Marfan's syndrome

Cardiovascular Signs
Arterial hypertension, especially morning hypertension
Peripheral edema

promise for identifying areas of obstruction because it more closely reflects what occurs in the airway during sleep and may be useful for directing surgical intervention.

A number of radiologic techniques have been used to aid in the identification of the site and severity of upper airway obstruction or collapse in OSA. Because most of the radiologic techniques for evaluation of OSA are performed in awake patients, they provide limited information about obstruction during sleep. The most frequently used imaging modality has been the cephalometric radiograph. The cephalogram is a two dimensional representation of the airway, which is a standardized evaluation system, with broad availability and relatively low cost (Fig. 18-6).[37] These films provide information on both the bony skeleton and the overlying soft tissues. Multiple studies using cephalometry have confirmed that OSA patients have inferior displacement of the hyoid, smaller posterior airway space, and longer soft palates than do non-OSA patients (Fig. 18-7).[38-41] Even so, the differences between OSA and non-OSA patients noted on cephalometry have not been significant enough to allow for the use of lateral cephalograms as a sole diagnostic tool.[42]

Awake computed tomography (CT) provides good anatomic detail of the bone and soft tissue. Like the cephalogram, its has poor sensitivity for diagnosing OSA; however, multiple studies have demonstrated that it is a better modality to illustrate postoperative anatomic changes that correlate with improved PSG parameters.[42]

Magnetic resonance imaging (MRI) provides excellent soft tissue differentiation and does not require radiation exposure. However, it can be hard to tolerate, is expensive, has limited availability, and is noisy, which may preclude asleep evaluations. Like CT and cephalometry, MRI has not been useful in distinguishing OSA from non-OSA patients.[43]

Lastly, fluoroscopy has been used as a dynamic airway examination to directly evaluate the sites of obstruction. Somnoflouroscopy, studies done while asleep, have been shown to improve uvulopalatopharyngoplasty success rates when the site of initial obstruction is identified (67% versus 42%); however, these studies are time intensive and expose the patients to increased radiation, which limits their utility.[44]

Nocturnal PSG is the gold standard for diagnosis of OSA. A full night diagnostic study is considered to be the most accurate instrument for measuring the presence and severity of OSA. The parameters monitored during PSG include electroencephalogram, electro-oculogram, submental electromyogram, electrocardiogram, airflow, thoracoabdominal effort, and oximetry (Box 18-6). The information obtained from the study is analyzed by a trained polysomnogram technologist and interpreted by a sleep physician. Classification of disordered breathing events recorded during PSG have been standardized to guide practice (Figs. 18-8 through 18-10).[33]

Box 18-6

Polysomnography Monitors

- Electroencephalogram C3 or C4, O1 or O2, F1
- Electro-oculogram
- Nasal and oral airflow monitors: thermistors, nasal pressure transducers, or inductance plethysmography
- Submental electromyogram
- Anterior tibial electromyogram
- Body position monitors
- Chest respiratory effort monitor

- Electrocardiogram
- Pulse oximetry
- Tracheal microphone
- Optional:
  - End-tidal carbon dioxide monitor
  - Esophageal pressure monitor
  - Nasal continuous positive airway pressure and bilevel positive airway pressure

Treatment

To provide effective treatment for OSA, careful consideration of the individual patient, available medical and surgical therapies, and inherent risks and complications of those interventions must be taken into account. The deleterious effects of untreated OSA on cardiovascular and neurocognitive health are well documented; however, the treating physician should have knowledge of all available interventions, the

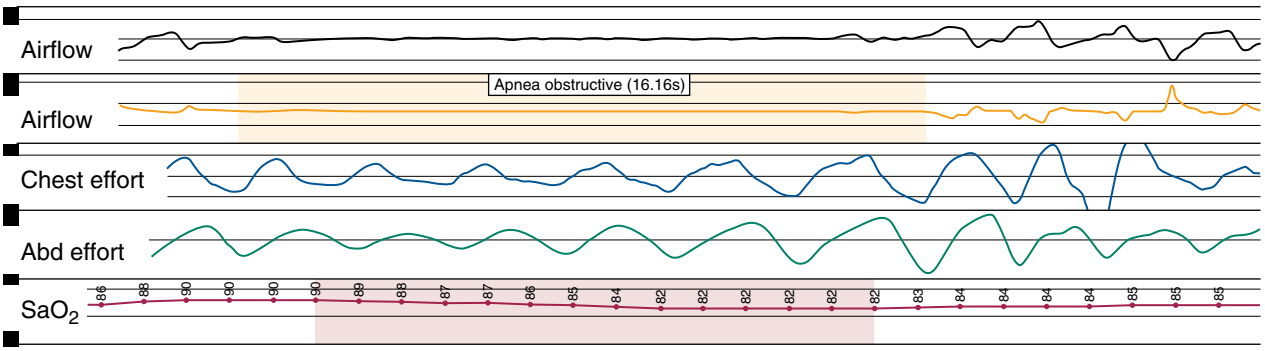

Figure 18-8. Polysomnographic tracing of an obstructive apnea.

success rates, risks of complications, and need for further surgery when outlining a treatment plan.

Medical Treatment

Treatment is generally approached in a stepwise manner and begins with conservative medical measures. Weight loss should be recommended for all overweight patients with OSA. However, sustained weight reduction is difficult and patients often regain the lost weight. Therefore other interventions are often also recommended. Consultation with a bariatric surgeon can be considered when treating patients who are morbidly obese. Recent evidence reveals that surgically induced weight loss significantly improves obesity-related OSA and parameters of sleep quality,[45] and this improvement can occur as early as 1 month after surgery.[46]

Continuous positive airway pressure (CPAP) is considered the gold standard treatment for moderate to severe OSA. Studies have demonstrated CPAP effectiveness in reducing the apnea-hypopnea index and in subjectively improving sleep quality; however, patient adherence remains a significant obstacle.[11,47,48] CPAP acts as a pneumatic splint and prevents upper airway collapse by providing constant positive intraluminal pressure during inspiration and expiration. Numerous effects of CPAP treatment have been described, chief among these being the reduction in AHI, improvement in objective and subjective sleepiness, improvement in overall quality of life, reduction in

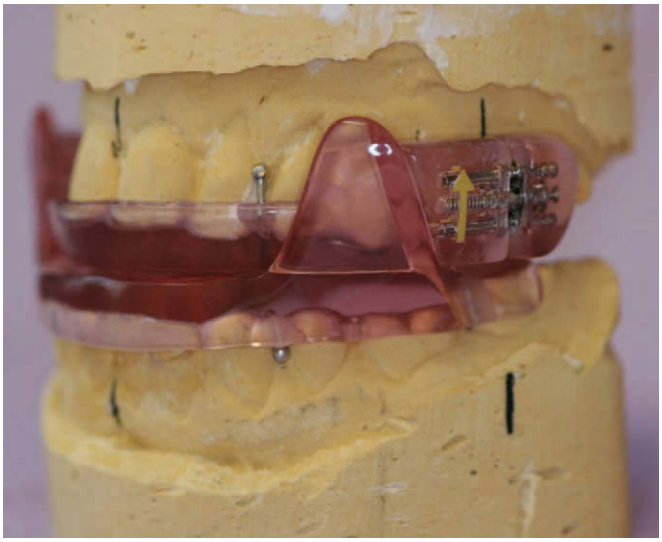

Figure 18-11. Mandibular advancement appliance for mild to moderate sleep apnea.

risk of cardiovascular events, and reduction of the risk of motor vehicle accidents.[20,49,50] Recently, there has also been interest surrounding the beneficial effects of CPAP to cardiovascular health due to decreased inflammation as measured by a decrease in the inflammatory markers C-reactive protein and interleukin-6, improved endothelial function, and reduced diurnal sympathetic activity.[51-53] Bilevel positive airway pressure (BiPAP) and autoadjusting positive airway pressure (APAP) were developed to improve pressure titration and treat patients with neuromuscular disorders and ventilatory disease. BiPAP delivers a separately adjustable lower expiratory positive airway pressure and higher inspiratory positive airway pressure. Although BiPAP has not been shown to improve adherence in an unselected patient population, a change in the method of delivery of positive airway pressure may significantly improve adherence in individual patients.[54] APAP devices autotitrate positive airway pressure to select an effective level of CPAP, which prevents upper airway collapse. The pressure changes in response to variations in airflow magnitude, airflow limitation, snoring, or airway impedance.[55-57]

Oral appliances have been used with success in patients with mild, moderate, and some severe OSA (Fig. 18-11), increasing the posterior oropharyngeal airway. Ferguson and colleagues conducted a crossover study comparing oral appliance therapy and nasal-CPAP therapy and concluded that oral appliances are effective in some patients with mild to moderate OSA (AHI 14-50) and are associated with greater satisfaction than CPAP.[58] Adherence rates of oral appliance therapy have been reported to be as high as 77%.[59] The most often reported complications from oral appliance therapy are tooth and jaw muscle pain, difficulty chewing in the morning, and excessive salivation. Although oral appliance therapy is cost effective and has higher rates of patient adherence, CPAP has proven to be more effective in reducing AHI.[60] Therefore this intervention should be recommended cautiously as first-line therapy for moderate OSA, but may serve as an effective treatment option for patients with mild, symptomatic OSA.

Pharmacologic therapy has been proposed as a treatment alternative in patients intolerant of CPAP; however, there is currently insufficient evidence to recommend the use of drug therapy as primary therapy for the treatment of OSA.[61] The many proposed mechanisms by which drugs may reduce the severity of OSA include increasing upper airway dilator muscle tone, increasing ventilatory drive, and increasing cholinergic tone during sleep versus reducing the proportion of REM sleep, reducing airway resistance, and reducing surface tension in the upper airway.[61]

Medications have been investigated as treatment for OSA. Fluticasone has shown some success in treating OSA patients with coexistent rhinitis. Kiely and colleagues reported that the AHI was lower in 24 patients given intranasal fluticasone compared with those given placebo (23.3 versus 30.3).[62] Brouillette and coworkers gave children with OSA and adenotonsillar hypertrophy a 6-week course of intranasal fluticasone and reported a decreased frequency of mixed and obstructive apneas and hypopneas.[63] Given these demonstrated benefits, treatment with intranasal fluticasone warrants further investigation. Leukotriene receptor antagonist montelukast has also shown promise by reducing the adenoid size and respiratory-related sleep disturbances in children with mild OSA.[64] However, no adult studies have been published and further study is necessary to corroborate this early evidence.

Lastly, modafinil is a central stimulant of postsynaptic alpha$_1$-adrenergic receptors, which acts by promoting alertness. It is currently used for treatment of narcolepsy and idiopathic hypersomnia. Recently, modafinil was used successfully to alleviate residual sleepiness in patients with OSA who were regular users of CPAP but still experienced excessive daytime sleepiness.[65] However, modafinil should not be used in the absence of definitive treatment of underlying OSA.

The use of nasal dilator strips and topical decongestants has been advocated in patients who have OSA and severe nasal obstruction. McLean and colleagues found that treating nasal obstruction with 0.4 mL oxymetazoline 0.05% and nasal dilator strips reduced mouth breathing during sleep and obstructive sleep apnea severity, but did not effectively alleviate obstructive sleep apnea.[66] However, nasal dilator strips have been shown to significantly reduce snoring, mouth breathing, and sleepiness in patients who do not have OSA.[67]

Box 18-7

Surgical Indications for Treatment

- AHI > 5 and < 14 with excessive daytime sleepiness
- AHI > 15
- Oxyhemoglobin desaturation < 90%
- Upper airway resistance syndrome, preferably with objective improvement of neurocognitive dysfunction and medical therapy
- Significant cardiac arrhythmias associated with obstructions
- Unsuccessful or refused medical therapy and desire for surgery
- Medically stable enough to undergo recommended procedures

Surgical Treatment

Factors important in making the decision to treat OSA with a surgical procedure include the patient's wishes, CPAP tolerance, severity of symptoms, severity of disease, patient comorbidities, and site and severity of upper airway collapse (Box 18-7). As mentioned previously, OSA patients are frequently overweight, hypertensive, and have other cardiac risk factors. These patients must be cautiously screened with a comprehensive medical examination before considering surgery for treatment of OSA.

The surgical planning for patients with OSA should include a discussion between the anesthesia team and the surgeon regarding plans for airway management. A stepwise algorithm that is frequently used includes using an oropharyngeal airway to prevent airway obstruction by the tongue, refraining from using paralyzing agents until the patient can be easily mask-ventilated, and preparing alternative methods of ventilation in case of unsuccessful intubation. Also the surgeon should have a frank discussion with the patient about the possibility of tracheotomy. A preoperative evaluation by the primary doctor or the anesthesia team is critical and includes evaluation for latent cardiovascular disease.

Patients with OSA are usually managed using a staged stepwise surgical protocol. The site of obstruction must be determined in each patient to determine the type and extent of surgical intervention. Generally, patients with isolated palatal obstruction undergo palatal surgery and those with obstruction at the base of the tongue undergo procedures aimed at treating this area. Endoscopic examination is performed

Surgical Treatment Options

Nasal Surgery
Nasal septoplasty
Inferior turbinate reduction
Adenoidectomy
Nasal tumor or polyp resection
Nasal valve reconstruction

Palatal Surgery
Palatal radiofrequency
Pillar implants
Injection snoreplasty
Tonsillectomy
Uvulopalatopharyngoplasty/Z-palatoplasty
Transpalatal advancement pharyngoplasty

Hypopharyngeal Surgery
Lingual tonsillectomy
Partial midline glossectomy
Tongue base radiofrequency
Mandibular osteotomy and genioglossal advancement
Hyoid myotomy and suspension
Tongue suspension suture
Maxillomandibular osteotomy and advancement

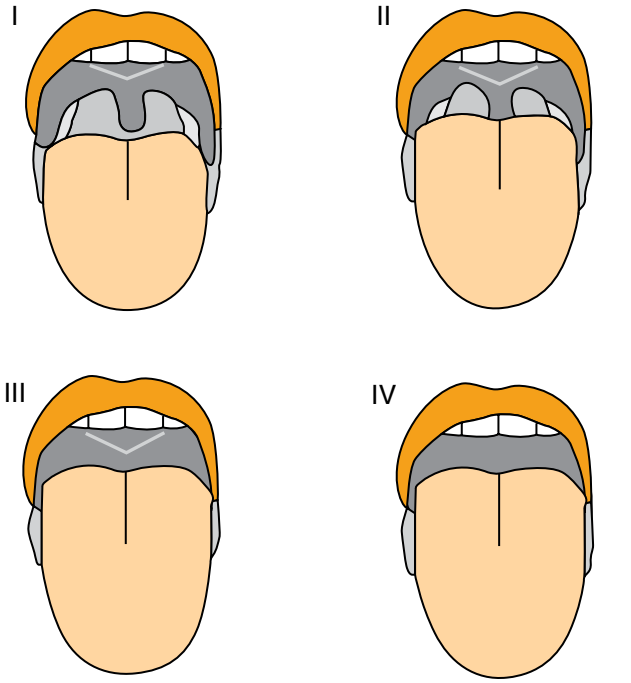

Figure 18-12. Modified Mallampati palate position. **I,** The entire uvula can be seen with the tongue at rest. **II,** A partial view of the uvula is seen. **III,** Only the soft and hard palate can be seen. **IV,** Only the hard palate can be seen.

to determine the site of obstruction. Most patients are symptomatic because both the palatal and base of tongue areas are obstructed. Before therapy is initiated, patients should be counseled regarding the possible need for multiple surgical procedures to achieve a symptomatic cure. Sleep endoscopy may be the optimal method of airway evaluation in these cases (Box 18-8). Patients with laryngeal obstruction should be treated appropriately to alleviate the obstruction and be considered for tracheostomy if improvement is not achieved surgically or with CPAP.

Critical to this decision process is the identification of the site or sites of obstruction. Several endoscopic studies have evaluated the prevalence of retropalatal and retroglossal obstruction in patients with OSA. In 2000, Steinhart and colleagues evaluated 117 OSA patients and found that 100% had retropalatal obstruction and 77% had retroglossal obstruction, thus illustrating that a majority of patients have a combination of the two.[13] In 2005, den Herder and colleagues evaluated 127 patients who underwent a similar evaluation and found that 88% of patients had retropalatal obstruction while 49% had retroglossal obstruction. In this study, 51% exclusively had palatal obstruction whereas only 12% solely had obstruction at the base of tongue.[68]

Nasal Surgery

Nasal obstruction has been associated with poor sleep quality, snoring and OSA.[69-71] Septoplasty, turbinate reduction, nasal valve surgery, and sinus surgery are procedures that have been used to treat nasal obstruction associated with OSA, and the selection of a nasal procedure is based on pathology. However, even though nasal procedures are unlikely to significantly improve OSA when used alone,[16] improving nasal patency may help restore physiologic breathing and may allow for the use of nasal CPAP in patients previously unable to tolerate it. Consideration should be made to address nasal obstruction as an initial step in OSA management so as to facilitate better CPAP adherence.

Palatal Surgery

In 1981, Fujita and colleagues described the first palatal procedure for OSA treatment, the UPPP.[5] UPPP with tonsillectomy was developed to eliminate palatal obstruction by resection of redundant palatal and pharyngeal tissue. It is the most commonly performed surgical procedure for OSA and is often misused as the first line surgical therapy for OSA regardless of coexistent patient factors such as obesity, retrognathia, and the existence of other sites of obstruction.[72] As a result, it is often unsuccessful in treating OSA in unselected patients. The site of pharyngeal collapse has a marked effect on the probability of the success of UPPP. In a meta-analysis of 37 published reports of results from UPPP, success rates were at best 50% and were related to severity of OSA.[73] Success in this case was defined as a respiratory disturbance index (RDI) of less than 20 or an AHI at 10 or less, along with at least a 50% improvement in the RDI.[73] Using a staging system based on palate position, tonsil size, and body mass index (BMI), Friedman and colleagues demonstrated the value of staging OSA patients for the prediction of success for UPPP.[74] In this staging system, palate position (based on the modified Mallampati staging), tonsil size, and BMI are used to stratify patients (Fig. 18-12). Stage I patients have an 80% success rate, stage II patients have a 40% success rate, and stage III patients have only an 8% success rate (Table 18-1). These results demonstrate that clinical staging clearly improves the overall success rate and is critical to identify which patients are unlikely to benefit from UPPP. Complications associated with UPPP include temporary nasal reflux in 12% to 15% of patients, postoperative bleeding in 1% to 5%, infection in 2%, and rare altered speech.[75]

To improve on the traditional UPPP procedure, other techniques have been suggested to address retropalatal obstruction. Woodson and coworkers introduced the transpalatal advancement pharyngoplasty, which aims to decrease retropalatal obstruction by altering the bony hard palate and the soft tissue attachments of the posterior maxilla.[76] With this procedure, a 1-cm portion of the hard palate is removed and the soft palate is then advanced and secured medially and laterally in the tensor aponeurosis, which enlarges the retropalatal region. Woodson and colleagues have reported success with this procedure when used in patients who have persistent retropalatal obstruction after UPPP and in patients with OSA who have small tonsils without the characteristic long, thick, soft palate (Fig. 18-13).[76] Another procedure, the Z-palatoplasty, was introduced by Friedman for use as a primary or revision palatal procedure in selected patients (Fig. 18-14).[77,78]

To reduce the resultant pain, cost, and morbidity of UPPP, less invasive office techniques have been developed. The palatal implant was

designed to reduce soft palate airway collapse and obstruction through placement of three woven implants, which stiffen the palate. The porosity of the implants also encourages the formation of a fibrotic capsule, which connects the three implants and further stiffens the palate. Nordgard and colleagues reported a significant reduction in AHI, daytime somnolence, and snoring using palatal implants in patients with mild to moderate OSA as long as body mass index was maintained.[79] The most common complication of this procedure is partial implant extrusion. Potential advantages include the fact that it can be done in a single office visit, has minimal morbidity, and has been noted to significantly reduce snoring. Due to its low morbidity, the palatal implant procedure is commonly used to treat snoring and may be useful in patients with mild OSA.

Tongue Base Procedures

Partial midline glossectomy (PMG), lingualplasty, and radiofrequency tongue base ablation have been developed to address the retrolingual collapse or narrowing that occurs in OSA. Lingual tonsillectomy may also be helpful in patients with lingual tonsillar hypertrophy. PMG creates a larger retrolingual airway by removal of a midline rectangular strip of the posterior half of the tongue. In selected patients, lingual tonsillectomy, reduction of the aryepiglottic folds, and partial epiglottectomy are also performed.[80] With lingualplasty, additional tongue tissue is removed posteriorly and laterally to that portion excised in PMG. Woodson and colleagues report that lingualplasty resulted in a 79% response rate in patients who had previously failed UPPP.[81] Because of the significant degree of tongue swelling that often occurs after these procedures, they are often performed in combination with a tracheotomy for airway protection.

Radiofrequency tongue base ablation (RFA) decreases upper airway collapse by producing a volumetric reduction in tongue base tissue via the generation of scar tissue. An insulated probe that delivers radiofrequency energy at 465 KHz is introduced into several areas of the tongue base and produces coagulation necrosis and healing by scar. The procedure is often performed in an outpatient setting under local anesthesia and may require multiple treatments to achieve desired results.[82] A review of 11 series showed success rates from 20% to 83% with multiple RFA applications and concluded that this procedure is not adequate as a sole treatment method, especially in light of the fact that most patients require multiple sessions.[83]

Hypopharyngeal Procedures

Surgical treatment of the hypopharyngeal area is comprised of procedures designed to prevent tongue collapse into the airway during sleep. Genioglossal advancement (GA) and hyoid myotomy (HM) both create an enlarged retrolingual airway. In GA, the genial tubercle of the mandible, which is the anterior attachment of the genioglossus muscle, is mobilized by means of limited osteotomy (Fig. 18-15). The segment is then advanced and fixed into place at the inferior aspect of the osteotomy. In four case series, GA performed as a solo procedure has been shown to have success rates from 39% to 78% in patients with severe OSA (mean preoperative RDI 53 to 59).[83] HM requires that the hyoid be mobilized via inferior myotomy and fixed anteriorly and inferiorly by attachment to the thyroid cartilage (Fig. 18-16). Success rates for HM performed with UPPP range from 52% to 78% in three series with patients with mean BMIs less than 30.[83] However, in one series with a patient mean BMI of 34.1, the success rate was only 17% (5 of 29).[84] These procedures result in an enlarged retrolingual airway by fixing the major dilators of the pharyngeal airway forward without changing dental occlusion. Complications associated with GA and HM include permanent numbness in 6%, infection in 2% to 5%, need for a root canal in 4%, and seroma in 2%. In addition, there is a less than 1% risk of mandibular fracture, aspiration, and death.[85]

The Repose tongue suspension procedure fixes the tongue forward, thereby preventing collapse into the airway. Via an intraoral incision made in the frenulum, a titanium screw is placed at the lingual cortex of the geniotubercle of the mandible, and a permanent suture is passed through the paramedian tongue musculature along the length of the tongue, through the tongue base, and then back through the length of the tongue musculature. It is then anchored to the screw, pulling the tongue base anteriorly.[86] When performed with UPPP, reported success

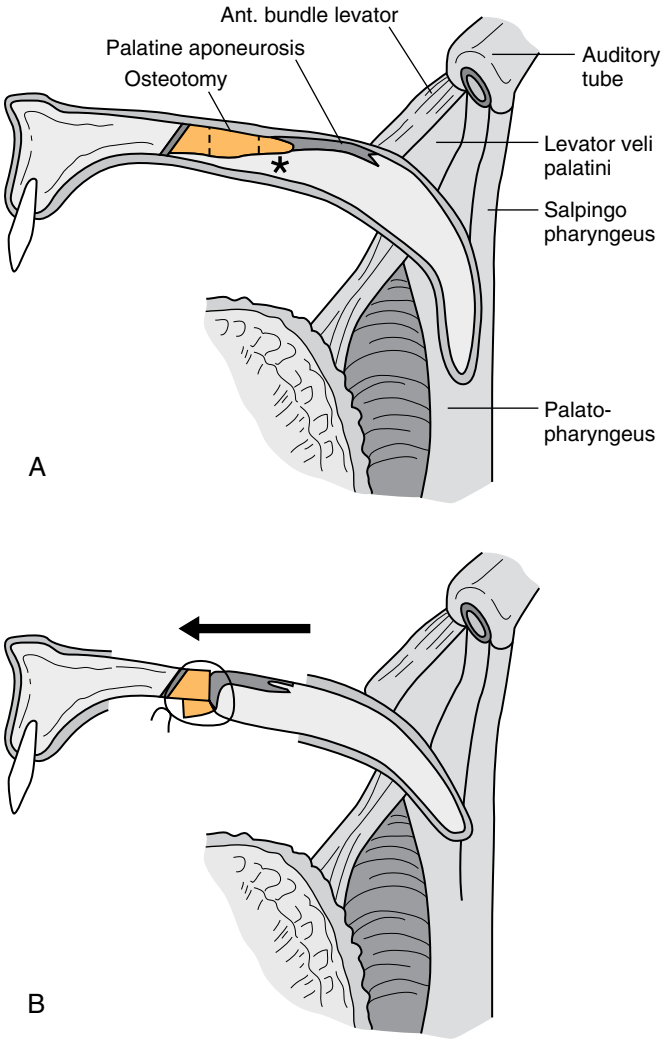

Figure 18-13. Midsagittal depiction of palate showing palatal advancement. **A,** Drill holes are placed from the oral cavity to the nose and are anterior (Ant) to bone removal (*orange*). Transpalatal advancement pharyngoplasty.* Oper Tech Otolaryngol. *2007;18;11.)*

rates range from 20% to 57%[83] although one study demonstrated a 3-year surgical success of up to 78% for patients with severe OSA who refused nasal continuous positive airway pressure.[87]

Maxillomandibular advancement (MMA) increases the retropalatal and retrolingual airway (Fig. 18-17). The maxilla and mandible are advanced by means of Le Fort I maxillary and sagittal-split mandibular osteotomies. This procedure is usually performed after other surgical intervention has been unsuccessful. Potential complications include malocclusion, relapse, nerve paresthesia, nonunion or malunion, temporomandibular joint problems, infection, bleeding, and the need for subsequent dental work. The success rate of this procedure approaches 90%.[88]

Tracheotomy

Tracheotomy represents the traditional gold standard of surgical management of OSA. It relieves OSA by completely bypassing the portion of the airway that most commonly collapses during sleep. However, the associated psychosocial problems, perceived inconvenience, and morbidity rarely make tracheotomy a desirable surgical option. It should be considered in patients who have failed all other OSA treatments, patients who have life-threatening OSA and are unable to tolerate

CPAP, or are neurodevelopmentally impaired.[89] It may also be the best option for patients who are morbidly obese or as an interim measure for patients undergoing base of tongue surgery.

Postoperative Management

With the trend toward multisite surgical treatment of OSA, there may be an increased chance of postoperative airway obstruction due to resultant edema in multiple sites in the upper airway. In addition, postanesthesia sedation along with altered respiration secondary to narcotic pain medications can be additive in patients with an already compromised airway.

In a retrospective review of 135 patients who underwent surgery for OSA, Esclamado and colleagues identified complications in 13% of patients: 14 airway issues such as failed intubation and airway obstruction after extubation (1 of which resulted in death), 3 patients with hemorrhage, and 1 patient with arrhythmia.[90] Patients with intubation problems were more likely to be heavier, whereas the patients with extubation complications had been given significantly more narcotic pain medications during the procedure. Risk of a perioperative complication was unrelated to age, preoperative symptoms, concurrent medical problems, or the performance of simultaneous septoplasty or tonsillectomy. In 1990, Fairbanks did a national survey of 72 sites carrying out UPPP and found that over 9 years there were 16 deaths, with 46 cases of nasopharyngeal stenosis and 42 cases of palatal incompetence. Additional complications reported include hemorrhage and wound dehiscence.[75]

Because of the recognized temporary increased risk of airway compromise after surgery, patient care algorithms have been developed to minimize patient morbidity and mortality.[90,91] Hospitalization is recommended for most patients who undergo airway surgery and admission to the intensive care unit should be considered in multilevel surgery.[92] A prospective evaluation of patients with severe OSA showed that nasal CPAP used for the first postoperative night was effective in keeping oxygen saturations above 90% even though the mean preoperative oxygen saturation level was 51.5%.[93] Based on these findings, it is recommended that patients with severe OSA use CPAP for the first 2 weeks after surgery. In addition, it is recommended that a postoperative polysomnogram be carried out in 3 to 4 months to evaluate the response to surgery.

Sleep Disorders

Otolaryngologists generally focus their attention on the diagnosis and treatment of obstructive sleep apnea (OSA), and little consideration is given to the presence of additional sleep disorders in patients suspected to have OSA. A 2005 study retrospectively reviewed 643 consecutive patients diagnosed with OSA in a sleep disorder center and found that 31% had coexistent sleep disorders.[94] In this population, 19 different sleep disorders were concomitantly diagnosed in patients with OSA, with the most common being inadequate sleep hygiene (15%) and periodic limb movement disorder (8%) (Table 18-2). Therefore, screening for the presence of concurrent sleep disorders is important both at the time of OSA diagnosis and in patients with persistent disease after medical or surgical treatment.

Classification of Sleep Disorders

The second edition of the *International Classification of Sleep Disorders* (ICSD-2) changed the classification of sleep disorders from a dichotomized system of intrinsic and extrinsic sleep disorders to a categoric system with six main disease groupings and two sections of miscellaneous conditions (Box 18-9).[8] These disease categories include insomnia, sleep-related breathing disorders, hypersomnias of central origin, circadian rhythm sleep disorders, parasomnias, sleep-related movement disorders, isolated symptoms/apparently normal variants/unresolved issues, and other sleep disorders. OSA, the sleep disorder most commonly treated by otolaryngologists, is covered in the sleep-related breathing disorders category.

Sleep is divided into rapid eye movement (REM) and non–rapid eye movement (NREM) stages. About 80% of the night is spent in NREM, which is divided into three stages characterized by specific electroencephalographic patterns. Stage N1, previously stage 1, is a

transition stage between sleep and wake in which a mixed voltage pattern emerges with 3 to 7 cycles per second (cps) waves. People may feel that they are awake in this stage. Stage N2, previously stage 2, is identified by the presence of spindles and K complexes and may be the first true sleep stage. Stage N3, previously stage 3 and 4, is also referred to as *slow-wave sleep* and is distinguished by delta waves, which are high-amplitude (up to 2 cps) and make up at least 20% of a 30-second scoring period (also known as an epoch). Stage R, REM, is characterized by rapid eye movements and low-frequency mixed amplitude waves. REM usually alternates with NREM periods in 90-minute cycles with REM periods increasing in length as the night goes on.

Insomnia

Insomnia is defined as recurrent difficulty with sleep initiation, maintenance, consolidation, or quality; insomnia causes daytime dysfunction that exists despite adequate occasion and opportunity for sleep.[95] This may include sleep that is nonrestorative or of poor quality. Using this definition, the NIH State-of-the-Science Conference estimated that insomnia occurs in 10% of adults.[96] Children also suffer from insomnia, which has been reported to occur in 20% to 30% of infants, toddlers, and preschoolers[97] and in 12% to 30% of adolescents.[98] In children, caregivers may report that a child has difficulty with sleep initiation, reluctance to go to bed, or an inability to sleep independently. Daytime symptoms must include at least one of the following: fatigue or malaise, cognitive impairment (attention, concentration, or memory), social/vocational difficulty or poor school performance, mood impairment or irritability, daytime sleepiness, reduced motivation or energy, tendency to be accident-prone in addition to physical symptoms such as headache, muscle tension, or gastrointestinal symptoms, or concerns about sleep itself. There are a number of different subtypes of insomnia (Box 18-10).[8]

Box 18-10

Insomnia Disorders

Adjustment insomnia (acute insomnia)
Psychophysiologic insomnia
Paradoxical insomnia
Idiopathic insomnia
Insomnia due to mental disorder
Inadequate sleep hygiene
Behavioral insomnia of childhood
Insomnia due to drug or substance
Insomnia due to medical condition
Insomnia not due to substance or known physiologic condition, unspecified (nonorganic insomnia)
Physiologic (organic) insomnia, unspecified

Box 18-11

Sleep-Related Breathing Disorders

Central Sleep Apnea Syndromes
Primary central sleep apnea
Central sleep apnea due to Cheyne Stokes breathing pattern
Central sleep apnea due to high-altitude periodic breathing
Central sleep apnea due to medical condition not Cheyne Stokes
Central sleep apnea due to drug or substance
Primary sleep apnea of infancy

Obstructive Sleep Apnea Syndromes
Obstructive sleep apnea, adult
Obstructive sleep apnea, pediatric

Sleep Related Hypoventilation/Hypoxemic Syndromes
Sleep-related nonobstructive alveolar hypoventilation, idiopathic
Congenital central alveolar hypoventilation syndrome
Sleep-related hypoventilation/hypoxemia due to medical condition
Sleep-related hypoventilation/hypoxemia due to pulmonary parenchymal or vascular pathology
Sleep-related hypoventilation/hypoxemia due to lower airway obstruction
Sleep-related hypoventilation/hypoxemia due to neuromuscular and chest wall disorders

Other Sleep-Related Breathing Disorders
Sleep apnea/sleep-related breathing disorder, unspecified

Psychophysiological insomnia is associated with anxiety about sleep and difficulty falling asleep in planned situations. Often, learned behaviors prevent the onset of sleep in these patients. It may occur in up to 2% of the general population.[8] Paradoxical insomnia, though less common, is also associated with daytime dysfunction but it may be far less than would be expected given the patient's complaints. Patients with paradoxical insomnia may report little or no sleep, but there is often a mismatch between perceived sleep time and time recorded by sleep study or actigraphy. Idiopathic insomnia often begins during infancy or childhood, is lifelong, and has no other identifiable cause. Behavioral insomnia of childhood, on the other hand, is related to specific, identifiable limit-setting issues or sleep-onset behavioral patterns that prevent children from falling asleep. These are often associated with caregiver behaviors or patterns and may manifest as requirements for special rituals or extended processes to fall asleep.[99]

Inadequate sleep hygiene is diagnosed when insomnia persists for at least 1 month and includes at least one of the following: improper sleep scheduling including frequent daytime naps; variable bedtime or wake time or excessive amount of time in bed; the routine use of narcotics, caffeine, or alcohol, especially before bed; participation in mentally or physically stimulating activities close to bedtime; frequent use of the bed for other activities such as television watching or reading; or failure to maintain a comfortable sleep setting (including temperature, lighting, and bedding).[8] While sleep hygiene is not often the primary cause of insomnia, it may complicate adequate treatment unless addressed.[100] In addition, inadequate sleep hygiene is often present in conjunction with other sleep disorders and may be diagnosed as a secondary sleep disorder.

Insomnia in very young children is often related to a mismatch between caregiver expectations and childhood development.[99] Behavioral insomnia of childhood should be considered in younger children. Often insomnia in the pediatric population is treated with appropriate sleep hygiene, strict limit-setting, and/or behavioral therapy. In addition, common-sense methods such as decreasing fluids before bed and timing stimulant medications, such as those used for attention deficit–hyperactivity disorder, should be instituted before considering pharmacologic intervention. The occurrence of the delayed sleep phase circadian rhythm disorder (defined later) should also be evaluated in older children and adolescents. In addition, special populations such as those with autism or Asperger's syndrome have been shown to have an increased incidence of insomnia.[101]

Sleep-Related Breathing Disorders

Conditions included in this section are distinguished by disordered breathing during sleep, whether of an obstructive or central nature. This section includes central and obstructive sleep apnea syndromes along with disorders related to hypoventilation or hypoxemia (Box 18-11).

Central sleep apnea is characterized by an absence in respiratory effort, resulting in an absence of airflow. Central hypopneas, which are categorized with central apneas, are characterized by a reduction in respiratory effort, resulting in a reduction of airflow due to nervous system or cardiopulmonary dysfunction, such as chronic obstructive pulmonary disease or congestive heart failure.[102] Patients with central sleep apnea often present with symptoms similar to OSA patients such as excessive daytime sleepiness, snoring, witnessed apneas, and waking up with shortness of breath. Similar to OSA, central sleep apnea in adults is defined by greater than five apneas per hour, although they are differentiated by being central in nature.[8] Infants often outgrow central sleep apnea as they age.[103]

Sleep-related hypoventilation/hypoxemic syndromes are subcategorized as congenital, idiopathic, or due to medical conditions such as parenchymal pulmonary disease, vascular disease, and neuromuscular or chest wall disorders. Hypoventilation is a physiologic condition characterized by hypercapnea with arterial carbon dioxide (CO_2) tension greater than 45 mm Hg in an arterial blood gas measurement.[8] This elevation is precipitated by an imbalance between the elimination and production of CO_2 and is chronic in nature (i.e., not precipitated by an acute event within the past month). Ventilation is usually adequate while patients are awake, but hypoventilation occurs with the shallow breathing and decreased tidal volumes of sleep.[104]

Hypersomnias of Central Origin

These disorders are central hypersomnias not due to circadian rhythm disorders, sleep-related breathing disorders, or other causes of disturbed nocturnal sleep. They are primarily characterized by excessive daytime sleepiness after the previously mentioned sleep disorders have been ruled out. This section includes narcolepsy, recurrent hypersomnia, and idiopathic hypersomnia (Box 18-12).

Daytime sleepiness is characterized by difficulty staying awake or alert, resulting in inadvertent sleepiness or sleep during the day. Sleepiness is most commonly measured by the multiple sleep latency test (MSLT) after a documented night without significant sleep-disordered breathing. The ESS may also be used to screen for sleepiness in this

Other circadian rhythm sleep disorder (circadian rhythm disorder, NOS)
Other circadian rhythm sleep disorder due to drug or substance

population.[105] The MSLT is a test of the tendency to fall asleep in darkened, quiet situations during the day. It is the primary test for daytime sleepiness and is only considered valid if there has been at least 6 hours of polysomnographically characterized sleep before initiation and 2 hours between the nap opportunities. The time to sleep onset and the occurrence of sleep onset REM periods (SOREMPs) is recorded for four or five naps during the day.[106]

Narcolepsy is strongly suspected with two or more SOREMPs and an average nap sleep onset of less than 8 minutes. Characteristic features include sleep paralysis, the inability to move upon awakening in 25%, hypnagogic hallucinations, the sensation of dreaming while awake in 30%, and cataplexy, a sudden and transient loss of muscle tone in response to strong emotions in 70%.[107] Narcolepsy is subdivided into those patients with cataplexy and those without cataplexy. In addition, a cerebrospinal fluid hypocretin-1 level less than 110 pg/mL is highly specific for narcolepsy with cataplexy.[108] Narcolepsy rarely occurs before 4 years of age and only 6% of patients present younger than 10 years of age.[109] Onset primarily occurs from 15 to 30 years of age and has equal prevalence among men and women.

Idiopathic hypersomnia is characterized by severe excessive daytime sleepiness with either normal sleep time (6 to 10 hours) or prolonged sleep time (greater than 10 hours) and great difficulty with awakening either from nocturnal sleep or naps. It also results in an average nap sleep onset of less than 8 minutes on MSLT but with fewer than two SOREMPs (often none), and the REM-intrusion features of narcolepsy are absent. This disorder usually has an onset earlier than 25 years of age and is insidious in nature.[110]

Circadian Rhythm Sleep Disorders

The body's internal clock is located in the suprachiasmatic nucleus. This endogenous system, along with external light and social cues, keeps people regulated on a 24-hour clock. Circadian rhythm sleep disorders occur when personal sleep-wake patterns are misaligned with the societal clock on a persistent or recurrent basis, thus leading to excessive daytime sleepiness or insomnia and resulting in impaired function. There are a number of disorders within this category, but the underlying dysfunction in all of them is that people are unable to sleep when they want or need to sleep (Box 18-13).

The most common of the circadian rhythm disorders is the delayed sleep phase type. It is especially common among adolescents and young adults.[111] In this disorder, sleep onset is delayed, usually more than 2 hours, and often is later than desired. Sleep duration and quality are usually normal, but the natural wake-up time is delayed and if allowed to sleep according to their desired sleep schedule, these patients will have difficulty falling asleep at a conventional sleep time and wake up late after an appropriate sleep duration.

The advanced sleep phase type is also common, but is more frequently seen in older adults.[112] These patients have difficulty staying awake as late as they would like and commonly wake up earlier than desired. They may be less likely to seek medical attention as fewer social problems result from early morning awakening. These patients also have normal sleep duration and quality for age, but their natural sleep-onset time is shifted earlier in time than desired.

The shift work type of circadian rhythm disorder may affect up to 32% of nighttime shift workers and 26% of rotating shift workers.[113] It has been estimated that 18% of the US population may be engaged in shift work that falls at least partially outside the daytime hours of 6 AM to 6 PM.[114] It is characterized by insomnia or excessive daytime sleepiness that is associated with a work schedule that overlaps the normal sleep time and persists for at least 1 month.[8] This tends to remit if sleep onset returns to a more traditional sleep time.

Lastly, the jet lag type of circadian rhythm disorder is a temporary condition associated with travel across at least two time zones, causing insomnia or excessive daytime sleepiness. Its onset is usually 1 to 2 days after travel and resolution depends on the number of time zones crossed and the direction of travel, in that eastward travel or phase advancement is harder to adjust to than westward travel.[115]

Parasomnias

Parasomnias are undesirable movements or subjective phenomena that occur during sleep; while falling asleep, while waking up, or during sleep itself. These phenomena include autonomic nervous system activation and abnormal movements, dreams, emotions, or behaviors.[8] As a group, parasomnias tend to appear early in childhood and often have a steady and gradual transformation with resolution of symptoms that suggests that the etiology may be maturational. Spontaneous remission with age is common, and there are usually no obvious clinical abnormalities while awake. Few pathophysiologic abnormalities have been identified to explain parasomnias. They are categorized as disorders of arousal (during NREM), REM sleep-related parasomnias, and other parasomnias (Box 18-14).

Sleep terrors, sleepwalking, and confusional arousals are disorders of arousal that usually occur in the first third of the night, predominate in childhood, and commonly decrease in frequency with age.[116] Most of these can be treated with reassurance or improved sleep hygiene. Pharmacologic intervention is rarely necessary.

REM-related parasomnias include REM sleep behavior disorder, isolated recurrent sleep paralysis, and nightmare disorder. REM sleep behavior disorder (RBD) results from a persistence of muscle tone during REM and resulting injurious movements while acting out dreams during REM. It is often associated with, and may precede the onset of, neurologic disorders such as Parkinson's disease and Lewy body dementia.[117] PSG is indicated because patients with OSA may have arousals during REM that mimic RBD.[118] Nightmare disorder is characterized by recurrent episodes of awakenings from sleep with

CPAP, continuous positive airway pressure; NREM, non–rapid eye movement; OSA, obstructive sleep apnea; REM, rapid eye movement.

recall of intensely disturbing dreams, usually accompanied by dysphoric emotions such as fear, anxiety, or anger and with full alertness on awakening and immediate and clear recall.[8] It is common in both childhood and adulthood, and may be especially associated with acute stress events or posttraumatic stress disorder. Treatment may include reassurance, cognitive-behavioral therapy, or pharmacologic intervention.[119]

Several parasomnias have been specifically associated with OSA or OSA treatment (Box 18-15). These include OSA-induced arousals from REM sleep that mimic RBD with the occurrence of complex or violent behaviors upon arousal that are dream-related. The second type occurs after an arousal in NREM sleep with similar complex or violent behaviors that can easily be confused with the disorders of arousal or a seizure. OSA-induced arousals in NREM can also lead to sleep-related eating disorder, which itself can lead to worsening clinical OSA. Another associated parasomnia is the OSA-induced cerebral anoxic attack or nocturnal seizure that can also manifest with parasomnia-type complex or violent behavior. Lastly, the use of nasal CPAP for OSA may result in a significant increase in REM (or REM rebound), leading to confusional arousals, sleepwalking, or sleep terrors.[8] Except when RBD is suspected, PSG is rarely necessary in these patients unless comorbid sleep apnea is suspected. However, in patients with sleep-related violent behaviors, excessive daytime sleepiness, frequent events, unusual age of onset, or unusual clinical features, PSG may be indicated.[116]

Hypnagogic foot tremor and alternating leg muscle activation during sleep
Propriospinal myoclonus at sleep onset
Excessive fragmentary myoclonus

Sleep-Related Movement Disorders

SRMDs are characterized by repetitive movements that occur during sleep and lead to sleep disruption (Box 18-16). The most common of these are restless leg syndrome (RLS) and periodic limb movement disorder (PLMD).[120,121] RLS is defined as an uncomfortable sensation in the legs causing an urge to move them. This discomfort is worsened by inactivity, occurs more commonly in the evening or night, and usually is relieved by movement. In children, diagnosis may be aided by a family history of RLS or polysomnographic documentation of greater than five periodic limb movements per hour.[122] Current research investigating the pathophysiology of RLS has implicated low iron levels and the nigrostriatal dopaminergic system. For this reason, evaluation should include ferritin and transferrin saturation levels. Iron deficiency should be treated for ferritin levels below 18 g/L or a transferrin saturation percentage below 16%.[123]

PLMD is characterized by repetitive stereotypical leg movements that occur while sleeping and result in sleep disturbance or daytime fatigue.[124] Unlike RLS, in which daytime symptoms occur, these patients are usually unaware of the leg movements or the sleep disturbance. The prevalence of PLMD is estimated to be between 4% and 11% of people aged 15 to 100 years, and has been shown to increase with age.[121] Because these disorders also have been related to changes in the nigrostriatal dopaminergic system, it is hypothesized that the onset of PLMD may signal a decline in dopaminergic function.[121] A limited number of studies have shown some reduction in PLMD with clonazepam (mechanism unknown) and dopamine agonist therapy.[125-128]

Isolated Symptoms, Apparently Normal Variants, and Unresolved Issues

Conditions highlighted in this group are generally thought to occur on a continuum between normal and abnormal sleep (Box 18-17).[8] This

includes long sleepers, who generally sleep longer than 10 hours a day, and short sleepers, who usually sleep 5 hours a day or less; sleep time definitions for pediatric patients are adjusted for age. A number of conditions associated with myoclonus or jerks during sleep are also included in this section, as is snoring.

Snoring is diagnosed when the audible noise of snoring is recorded by an observer and there are no complaints of excessive daytime sleepiness (EDS), insomnia, or sleep disruption. Results from a 2005 National Sleep Foundation poll found that 59% of 1500 adults reported that they snore.[129] The 1993 Wisconsin Sleep Cohort Study reported that snoring occurs in 28% of adult women and 44% of adult men.[31] The prevalence of habitual snoring in pediatric populations has been reported to be lower at 7% to 13% in children aged 4 years and younger[130] and 10% in middle and high school students.[98] Whereas treatment for snoring has classically been focused on alleviating social concerns, recent data suggest that patients with habitual snoring alone have lower neurocognitive outcomes (including lowered attention, memory, and intelligence scores) and increased behavioral hyperactivity than their nonsnoring counterparts.[131-134]

Conclusion

While the majority of patients referred to otolaryngologists will have sleep-disordered breathing, a significant cohort may also suffer from other sleep disorders including inadequate sleep hygiene, insomnia, circadian rhythm disorders, and limb movement disorders. Diagnosis of concurrent sleep disorders will allow us to more effectively treat patients with EDS and may be especially important in evaluating patients with persistent disease after medical or surgical treatment.

CHAPTER NINETEEN

Aesthetic Facial Analysis

Marc S. Zimbler

Key Points

- After completing the chapter, the reader should have a comprehensive understanding of facial landmarks and aesthetic analysis.
- Both soft tissue and skeletal landmarks should be clearly identified as should a relationship to cephalometric analysis.
- The concepts of facial proportions as well as subunit principles should be clearly understood.
- The works of Powell and Humphreys are rudimentary to topographic facial relationships as well as formulated angles.
- Digital photography and standardized patient photo documentation are reviewed.

Throughout history, mankind has tried to define beauty. Poets, philosophers, and artists have pondered its elusive quality while attempting to quantify that which is evident to all of us. As surgeons, however, we are required to have a more scientific approach to beauty to formulate operative plans with successful surgical outcomes. Common reference points are essential in communicating with colleagues and medical record keeping. Furthermore, we must be able to accurately define specific characteristics that deviate from the norm so that we may identify congenital anomalies and facial deformities.

As early as ancient Egypt, aesthetic facial proportions have been idealized in art. However, it was not until the era of Greek philosophy that the study of beauty became a formal discipline. To Plato and Aristotle, beauty meant symmetry, harmony, and geometry. In the fifth century BC, the Greek sculptor Polyclitus defined perfect beauty as the mutual harmony of all parts, such that nothing could be added or subtracted. Such harmonic proportions were held to be beautiful in themselves, independent of any observer.

These ideas were later revisited by the Renaissance artists, who began to define ideal proportions for the human form. This example is nowhere more evident than in the drawings of Leonardo da Vinci and his Vitruvian man (Fig. 19-1). It was da Vinci, who, through the study of anatomy, formulated ideal facial proportions and divided the profile into equal thirds (Fig. 19-2). Leonardo's scientific accuracy rivaled that of Vesalius, whereas his artistic beauty remains unchallenged. Another Renaissance artist inspired by the Vitruvian notion of perfect proportions was the German printmaker Albrecht Durer. Durer used his own finger as a unit of measurement to construct a proportional system for the entire body, and in 1528 he published a four-book treatise on human proportions. Durer divided the facial profile into four equal parts and recognized that the length of the nose equals that of the ear.

The artistic canons set forth in antiquity and during the Renaissance dominated Western art for centuries. In the twentieth century, anthropometrist Leslie Farkas and colleagues[1] challenged the classic canons by measuring the facial proportions of 200 women, including 50 models. His results concluded that some of the canons are nothing more than artistic idealizations. Nevertheless, although social and cultural factors influence every generation's concept of beauty, the aesthetic canons have withstood the test of time. Currently, the parameters established in the facial plastic surgery literature are based predominately on the works of Powell and Humphreys, who in 1984 crystallized this topic into a single text, *Proportions of the Aesthetic Face*.[2]

Anatomic Landmarks and Reference Points

Facial analysis is dependent on both soft tissue and skeletal anatomic landmarks. Soft tissue reference points are shown in Figure 19-3 and listed in Box 19-1. Skeletal reference points are defined by cephalometric analysis and are shown in Figure 19-4 and listed in Box 19-2.

The Frankfort horizontal plane (Fig. 19-5) is the standard reference point for patient positioning in photographs and cephalometric radiographs. The Frankfort plane is defined as a line drawn from the superior aspect of the external auditory canal to the inferior border of the infraorbital rim while the patient's gaze is parallel to the floor. A soft tissue definition for the inferior aspect of the infraorbital rim is the point of transition between lower eyelid and cheek skin.

Facial Proportions

The initial assessment of the face evaluates symmetry. Symmetry is rarely perfect when comparing halves through a midsagittal plane (Fig. 19-6); nevertheless, midline points should lie on the axis line. Facial width is evaluated by dividing the face into equal fifths (Fig. 19-7). The width of one eye should equal one fifth of the total facial width, as well as the intercanthal distance or nasal base width.

Facial height is commonly assessed by one of two methods. The first method divides the face into equal thirds (Fig. 19-8) as described by da Vinci. Measurements are made in the midline from the trichion to the glabella, from the glabella to the subnasale, and from the subnasale to the menton. The second method excludes the upper third of the face because of common variability regarding hairline position. Measurements are made from the nasion (as opposed to the glabella) to the subnasale and from the subnasale to the menton (Fig. 19-9). With this method the midface represents 43% of the height, with the lower face representing 57%.

Subunit Analysis

The face is divided into aesthetic units (Fig. 19-10) that are further divided into subunits. The major units that are classically defined for facial analysis include the forehead, eyes, nose, lips, chin, ears, and neck. The units and subunits are based on skin thickness, color, texture, and underlying structural contour. Precise planning of surgical incisions

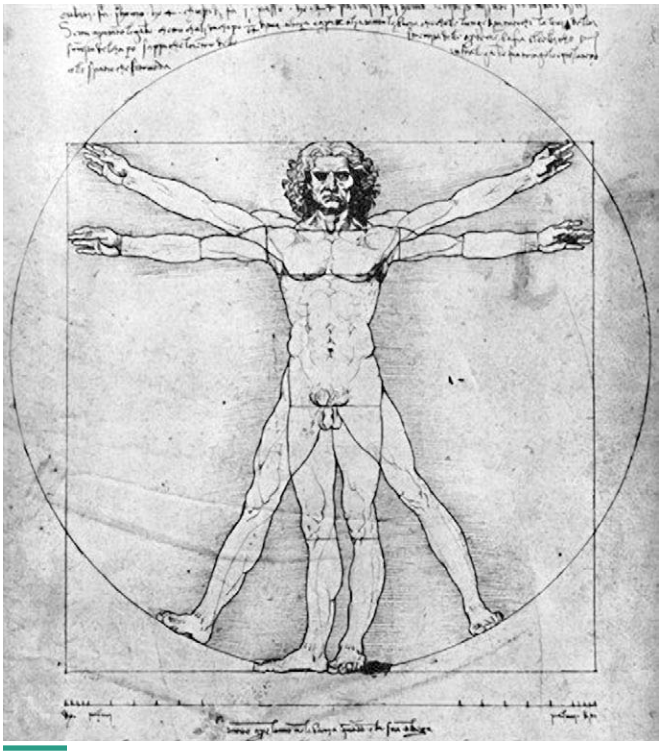

Figure 19-1. Leonardo da Vinci. The proportions of the body according to Vitruvius, ca. 1490. Pen and ink with touches of wash, over stylus 34.4 × 24.5 cm. *(Courtesy of the Galleria dell' Accademia, inv.228, Venice.)*

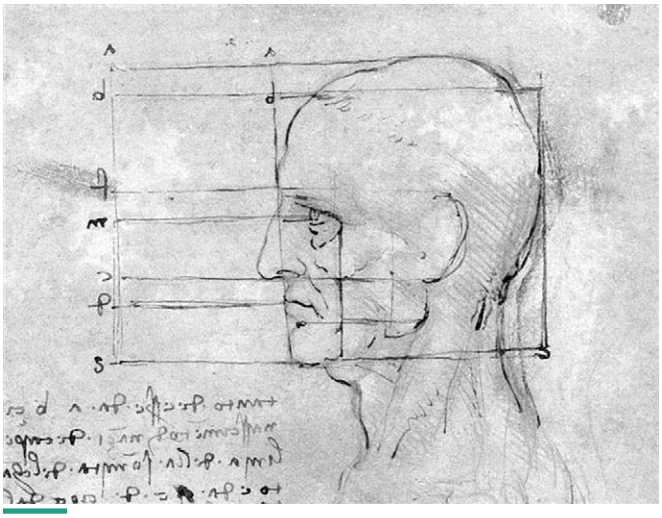

Figure 19-2. Leonardo da Vinci. The proportions of the head, ca.1490. Pen and ink over black chalk, 28.0 × 22.2 cm. *(Courtesy of the Galleria dell' Academia, inv.236v, Venice.)*

and reconstructions require analysis of the entire unit or subunit. Incisions parallel to relaxed skin tension lines (Fig. 19-11) and within unit or subunit borders result in the most favorable scars.

Forehead

The boundaries of the forehead are from the hairline to the glabella and make up the upper third of the face. The contour anatomy of the forehead is most aesthetically pleasing with a gentle convexity on profile. The nasofrontal angle (Fig. 19-12) is created by a line tangent to the glabella through the nasion and intersecting with a line tangent to the nasal dorsum. The range of aesthetic measurements for this angle is from 115 to 135 degrees.

Box 19-1

Soft Tissue Anatomic Landmarks

Trichion (Tr): Anterior hairline in the midline
Glabella (G): Most prominent point of the forehead on profile
Nasion (N): The deepest depression at the root of the nose; typically corresponds to the nasofrontal suture
Radix: Root of the nose, a region and not a point; part of an unbroken curve that begins at the superior orbital ridge and continues along the lateral nasal wall
Rhinion (R): Soft tissue correlate of the osseocartilaginous junction on the nasal dorsum
Sellion: Osseocartilaginous junction on the nasal dorsum
Supratip: Point cephalic to the tip
Tip (T): Ideally, the most anterior projection of the nose on profile
Subnasale (Sn): Junction of columella and upper lip
Labrale superius (Ls): Vermilion border of upper lip
Stomion (S): Central portion of interlabial gap
Stomion superius: Lowest point of upper lip vermilion
Stomion inferius: Highest point of lower lip vermilion
Labrale inferius (Li): Vermilion border of lower lip
Mentolabial sulcus (Si): Most posterior point between lower lip and chin
Pogonion (Pg): Most anterior midline soft tissue point of chin
Menton (Me): Most inferior soft tissue point on chin
Cervical point (C): The innermost point between the submental area and the neck

Box 19-2

Cephalometric Reference Points

(S) Sella: The midpoint of the hypophysial fossa
(Or) Orbitale: The most inferior point on the infraorbital rim
(P) Porion: The most superior point on the external auditory meatus
(Cd) Condylion: The most superior point on the head of the mandibular condyle
(Ar) Articulate: The point of intersection of the posterior margin of the ascending mandibular ramus and the outer margin of the cranial base
(ANS) Anterior nasal spine
(PNS) Posterior nasal spine
(A) Point A, subspinale: The deepest point in the concavity of the premaxilla
(Pr) Prosthion: The lowest most anterior point on the alveolar portion of the premaxilla
(Id) Infradentale: The highest most anterior point on the alveolar portion of the mandible
(B) Point B, supramentale: The most posterior point in the outer contour of the mandibular alveolar process
(Pg) Pogonion: Most anterior point on the bony chin in the midline
(Gn) Gnathion: A point between the most anterior (Pg) and inferior (Me) point on the chin
(Me) Menton: The lowest point on the mandible
(Go) Gonion: The midpoint at the angle of the mandible

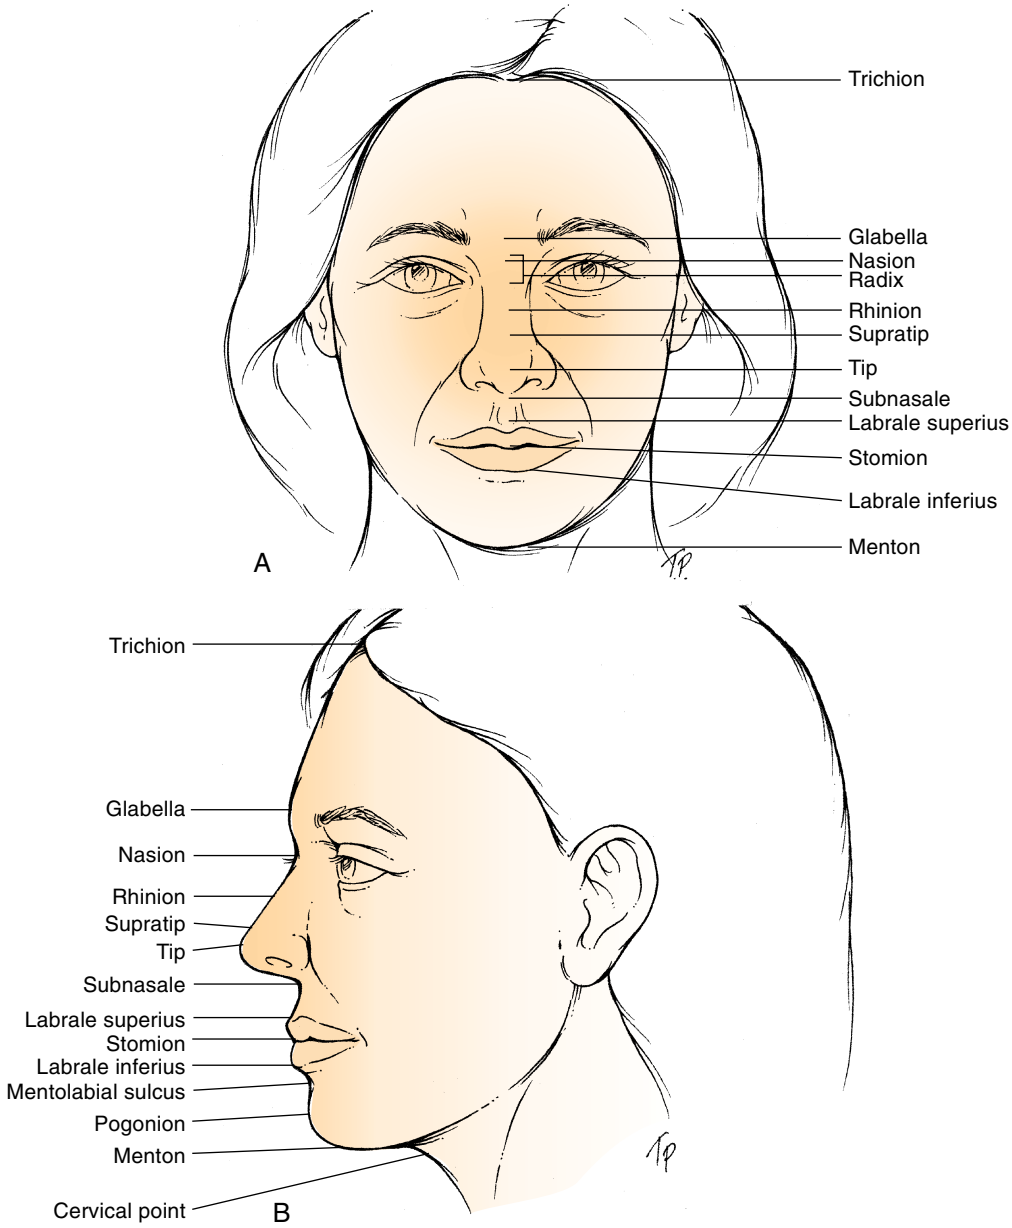

Figure 19-3. Frontal view **(A)** and lateral view **(B)** of soft tissue reference points.

The ideal eyebrow shape follows a smooth and gently curving arc. The brow should begin medially with a slight clublike configuration and gradually taper toward its lateral end. Lateral position for a female is well above the supraorbital rim, whereas for a male it is at or close to the rim. The medial edge of the eyebrow lies on a perpendicular line that passes through the lateral-most portion of the nasal ala and approximately 10 mm above the medial canthus (Fig. 19-13). In women, the highest point of the eyebrow arc is at a line drawn tangentially from the lateral limbus. However, this ideal eyebrow position can vary with fashion trends, and the highest point may actually lie anywhere from the lateral limbus to the lateral canthus. Sheen[3] describes the eyebrow arc as most pleasing when it extends as an unbroken line from the brow down to the lateral nasal tip (Fig. 19-14).

Eyes

The boundaries of the orbits are in the lower third of the upper face and the upper third of the midface. The width of one eye from medial to lateral canthus should equal one fifth of the facial width. The intercanthal distance should equal the width of one eye. Normal intercanthal distances for women and men are 25.5 to 37.5 mm and 26.5 to 38.7 mm, respectively. In general, the eye should be almond shaped with the lateral canthus slightly more superior than the medial canthus. The average palpebral opening is 10 to 12 mm in height and 28 to 30 mm in width. The upper lid crease is the line created by the insertion of the levator aponeurosis and orbital septum into the orbicularis oculi and dermis. The location of the crease averages approximately 11 mm from the lash line but can vary between 7 and 15 mm. The upper eyelid normally covers a small portion of the iris but not the pupil. The lower eyelid is within 1 to 2 mm of the iris on neutral gaze, with the sclera not being visible below the iris margin.

Nose

The boundaries of the nose are within the middle third of the face. On the lateral view, the nasal starting point begins at the nasion, which ideally corresponds to the same level as the upper eyelid's superior palpebral fold (see Fig. 19-3) and ends at the subnasale. Because the nose is the central and most prominent aesthetic unit of the face, it is always analyzed in relationship to other facial structures, most importantly the chin, lips, and eyebrows. The topographic subunits of the nose (Fig. 19-15) have been described by Burget[4] and are essential when

planning reconstructive procedures. The borders of nasal subunits allow for scar camouflage when incisions lie along subunit margins.

Nasofacial Relationships

Powell and Humphreys[2] formulated relationships between the nose and face. They include the nasofrontal angle, nasolabial angle, nasofacial angle, and nasomental angle. The nasofrontal angle (see Fig. 19-12) is described in the forehead section of this chapter. The nasolabial angle defines the angular inclination of the columella as it meets the upper lip. The angle is formed between the intersection of a line tangent to the labrale superius and subnasale and a line tangent to the subnasale and the most anterior point of the columella (Fig. 19-16). This angle should measure 95 to 110 degrees in women and 90 to 95 degrees in men. The nasofacial angle is the incline of the nasal dorsum in relation to the facial plane (Fig. 19-17). It represents the angle formed from a vertical line tangent from the glabella through the pogonion intersect-

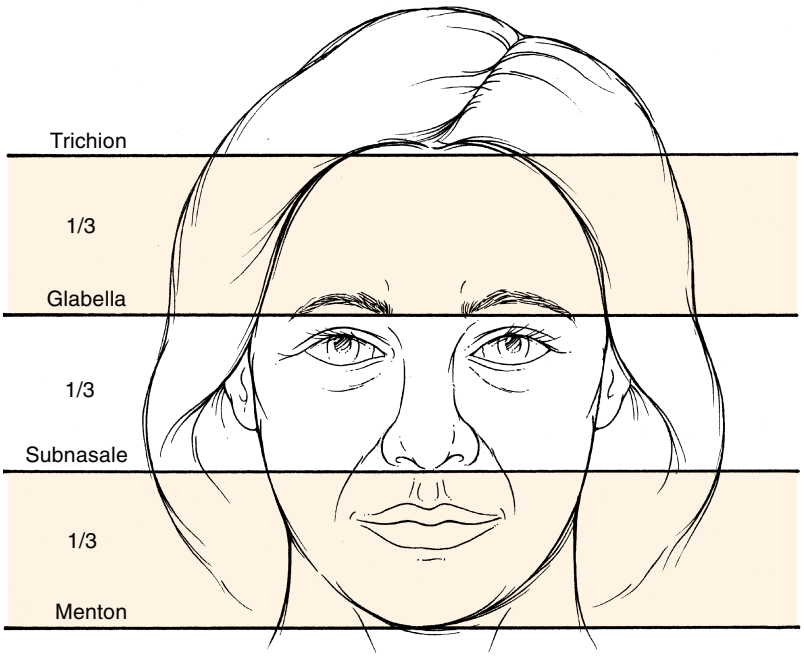

Figure 19-8. Facial height. The facial height is divided into equal thirds. From trichion to glabella, from glabella to subnasale, and from subnasale to menton.

ing a line from the nasion through the nasal tip. This angle ideally measures 36 degrees but can vary from 30 to 40 degrees. The nasomental angle describes the angle between a tangent line from the nasion to the nasal tip intersecting with a line from the tip to the pogonion (Fig. 19-18). The range of this angle is from 120 to 132 degrees, and it can clearly be obscured if the chin or lip position is in facial disharmony.

Nasal Rotation and Projection

Nasal rotation and projection are essential measurements in determining nasal aesthetics. Tip rotation generally occurs along an arc produced by a radius based at the external auditory canal (Fig. 19-19). Rotation increases along the upper portion of the arc and decreases along the lower portion. Several methods have been used to analyze tip projection and, in turn, have defined nasal length. Simons[5] measures tip projection in relation to the length of the upper lip (Fig. 19-20). Nasal projection is approximately equal to the length of the upper lip, giving a ratio of 1:1. Goode's[2] method uses a vertical line drawn from the nasion to the alar groove, a perpendicular line from the alar groove to the nasal tip, and a line from the tip back to the nasion (Fig. 19-21). The ratio comparing the length of the perpendicular line (alar groove to tip) with that of the nasal length (nasion to tip) should be 0.55 to 0.60. When

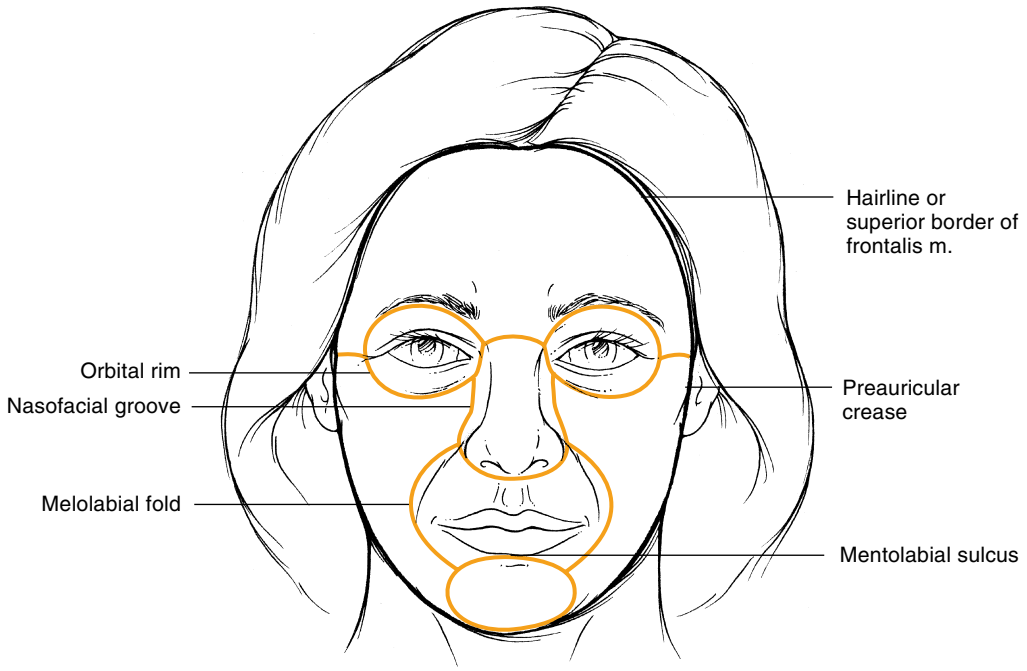

Figure 19-10. Aesthetic units of the face.

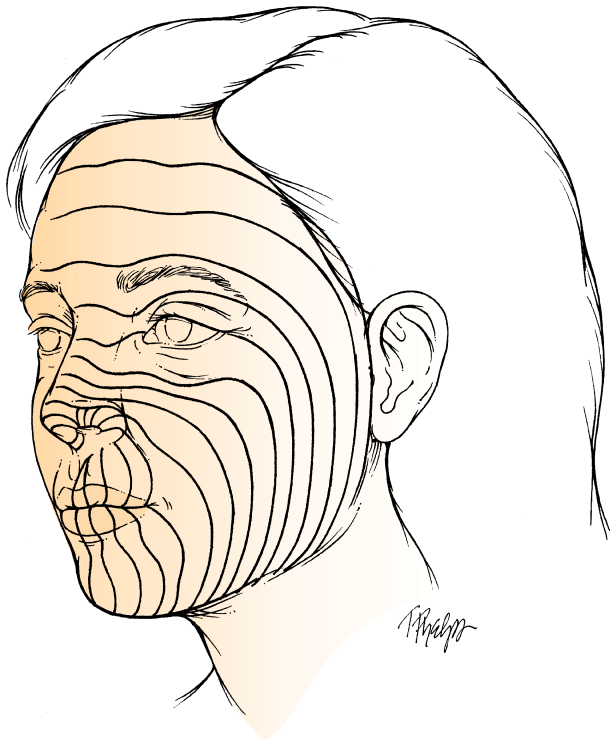

Figure 19-11. Relaxed skin tension lines of the face.

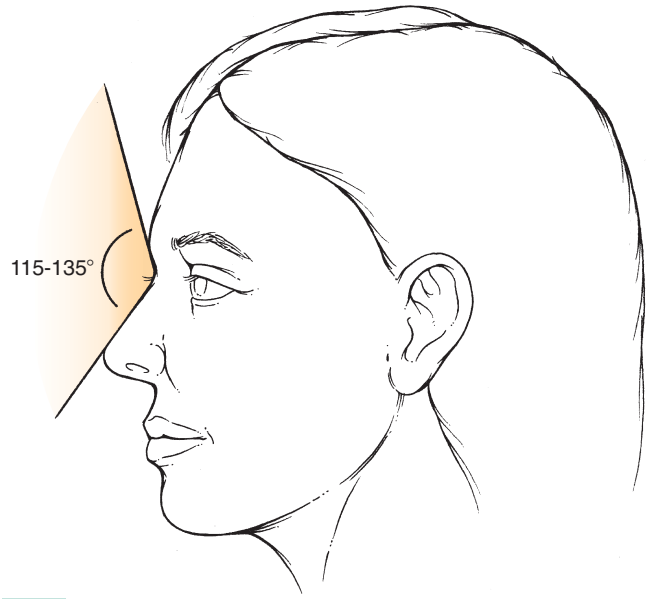

Figure 19-12. Nasofrontal angle (115 to 135 degrees).

these ratios are observed, the nasofacial angle is approximately 36 degrees. Crumley and Lanser[6] use a similar method and use a 3-4-5 triangle, where the hypotenuse is the nasal length and the projection is the smallest arm of the triangle.

Alar-Columellar Complex

On lateral view, the ala-to-tip lobular complex ratio is considered optimal at 1:1 (Fig. 19-22); columella shown at 3 to 5 mm is considered acceptable. From the basal view, the nose should be triangular and divided into three equivalent units (Fig. 19-23).

Lips

The boundaries of the lips are contained within the lower one third of the face. The upper lip is measured from the subnasale to the stomion superius, whereas the lower lip and chin are measured from the stomion inferius to the menton (Fig. 19-24). The subunits of the lip are well defined (Fig. 19-25), whereas the height of the upper lip to the lower lip should have a ratio of approximately 1:2. Horizontal lip position can be determined by two separate methods. The first constructs a line from the subnasale through the labrale inferius to the pogonion (Fig. 19-26). A perpendicular line through the anterior-most point of each lip defines its horizontal position. The upper and lower lip should lie 3.5 and 2.2 mm anterior to this line, respectively. The second method uses the nasomental angle to determine horizontal lip position. The lips should fall just behind this line at a

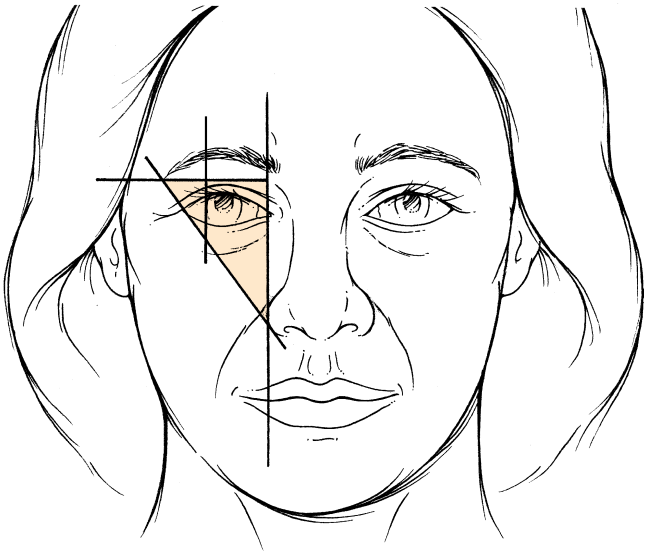

Figure 19-13. Ideal eyebrow position. Medial brow head lies along horizontal tangent with medial canthus and nasal ala. The highest point of brow arch is located above the lateral limbus.

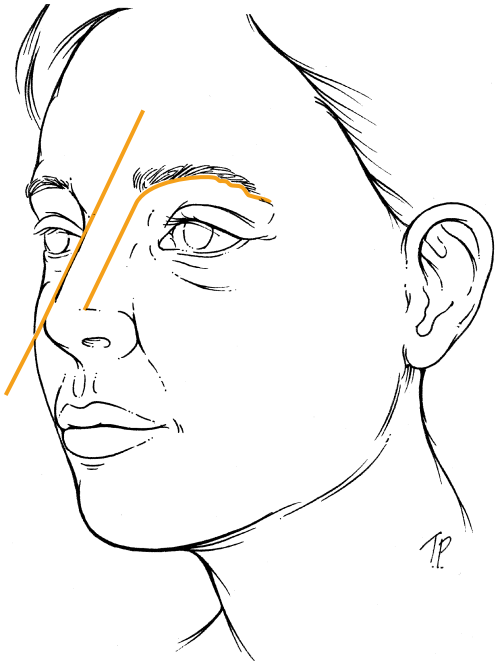

Figure 19-14. Unbroken aesthetic line forms eyebrow to nasal tip.

distance of 4 mm for the upper lip and 2 mm for the lower lip (see Fig. 19-18).

Chin

The boundaries of the chin lie in the lower one third of the face and can be measured from the mentolabial crease to the menton. The chin is a pivotal facial unit when analyzing the nose or neck. Most rhinoplasty analysis begins with proper chin position in relation to nasal projection and facial harmony. Gonzalez-Ulloa[7] described the ideal chin position by a tangential line through the nasion to pogonion, which is almost perpendicular to the Frankfort horizontal plane (Fig. 19-27). An alternative method for analyzing chin position is described in the lip section (See Fig. 19-26), where the mentolabial sulcus lies approximately 4 mm behind this line.

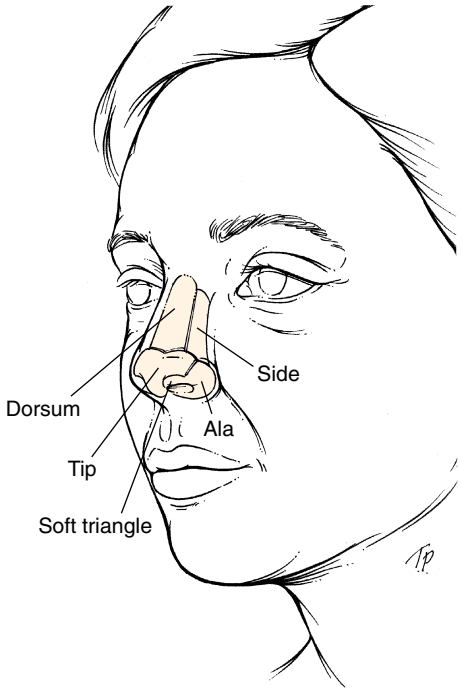

Figure 19-15. Nasal aesthetic subunits adapted from Burget's description.

Neck

The ideal neck has a well-defined mandible from the pogonion to the angle with an acute mentocervical angle. This angle is produced by drawing a line from the glabella to the pogonion and intersecting with a line tangent from the menton to the cervical point (Fig. 19-28). The cervical point is defined as the innermost point between the submentum and neck. It is also important to evaluate chin position when analyzing the neck, because an obtuse mentocervical angle may cause the perception of poor chin projection.

Ears

The width of the ear is approximately one half its length. The ear length should approximate the length of the nose measured from the nasion to the subnasale. The superior aspect of the ear lies at the level of the eyebrow, whereas its inferior aspect is at the level of the nasal ala. The long axis of the ear is parallel to the long axis of the nasal dorsum (Fig. 19-29) and is noted to have a posterior rotation of approximately 15 degrees from the vertical plane. The ear protrudes from the skull at an angle of approximately 20 to 30 degrees, which usually translates into a measurement of 15 to 25 mm from the helix to the mastoid skin.

Skin and Rhytids

When analyzing the face, evaluation of the skin deserves special attention. Skin texture, thickness, elasticity, and solar damage are all critical factors contributing to one's overall facial appearance. In 1988, Fitzpatrick[8] established skin type classification (Box 19-3), and in 1994, Glogau[9] categorized photoaged skin (Box 19-4). Most importantly, however, in the examination of the skin is the analysis of facial rhytids. Wrinkles or rhytids originate from a wide variety of sources that can include chronologic aging, photoaging or solar damage, and skin folding secondary to loss of underlying skeletal or soft tissue support. Hyperdynamic facial lines (Fig. 19-30) are specific wrinkles that are caused by long-term facial muscle animation. Examples of these include horizontal forehead creases, crow's feet, and glabellar lines. Each line is caused by repeated underlying muscle contraction. Hyperdynamic lines should be distinguished from other facial lines such as the melolabial fold, mentolabial sulcus, and the fine crisscross wrinkling found on the cheek and under the eyelids.

Box 19-3

Fitzpatrick Classification of Sun-Reactive Skin Type

Skin Type	Skin Color	Characteristics
I	White	Always burns, never tans
II	White	Usually burns, tans with difficulty
III	White	Sometimes burns, sometimes tans
IV	White	Rarely burns, tans with ease
V	Brown	Very rarely burns, tans very easily
VI	Black	Never burns, always tans

Box 19-4

Glogau Photoaging Classification

Type I: No keratoses, few wrinkles, age 20 to 30, rarely wears makeup

Type II: Early lentigenes, wrinkles on animation, age 30 to 40, sometimes wears makeup

Type III: Advanced photoaging, wrinkles present at rest, age 50 to 60, always wears makeup

Type IV: Severe photoaging, severe wrinkling, age 60 to 70, makeup has minimal benefit

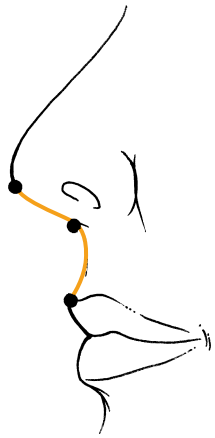

Figure 19-20. Simons' nasal projection is approximately equal to the length of the upper lip with a ratio of 1:1.

Computer Imaging and Digital Photography

Technologic advances in digital photography and computer graphics have revolutionized the way many surgeons obtain and process patient photographs. The immediate availability of photographs for review and the ability to generate computer-modified images provide an easy and effective means of preoperative analysis. Routine office consultations typically include "patient imaging," which has become a vital tool toward preoperative education. It provides the surgeon an opportunity to strengthen communication with the patient regarding realistic expectations of surgical outcome. Added benefits of computer imaging also include photoarchiving and its use as an instructional tool for residents and fellows. Over the past few years, this technology has evolved from being costly, cumbersome, and slow to one that is highly efficient, user-friendly, and reasonably priced.

The essential components for a computer imaging system include a computer, an image capture device or camera, and imaging software. Computer specifications are dependent on the demands and expectations of the surgeon. Additional components that are highly recommended include a CD burner for archiving and storage, a graphics board, digital drawing tablet, and a high-resolution color printer.

As with 35-mm photography, the clarity of digital photography is dependent on the sophistication of the camera and its lens. The resolution of digital cameras is described in pixels, and it currently ranges up to 12.0 megapixels. However, a camera containing 3.0 megapixels is sufficiently suited for the demands of most medical photography. A 3.0-megapixel image printed on 4- × 6-inch glossy photo paper is nearly indistinguishable from a conventional photograph. For

a more professional look with 35-mm like quality and control, a true single lens reflex (SLR) with higher mega pixels is preferred. The additional capabilities include interchangeable lenses and through-the-lens (TTL) metering. The price for advanced digital SLR cameras has dropped dramatically over the past several years, and a 6.0-megapixel camera can be purchased, with lens included, for around $700. Lighting, background, and patient positioning are similar to conventional photography, and shoe mount external flashes are suggested for improved results with minimal shadow.

Once the photographic images are downloaded onto the computer, a variety of image or graphics software may be used to open and alter images. The Mirror Suite (Image Management Plus Simulation) (Canfield Scientific, Inc., Fairfield, NJ) is sophisticated but user-friendly high-end software designed for medical professionals. Image files from the camera once downloaded are automatically tethered into the Mirror Software and saved into patients' charts. The ease and speed of image alteration lies at the heart of this sophisticated software, making patient consultations streamlined and informative. Furthermore, this advanced software has the ability to measure and analyze facial angles for assistance in preoperative analysis and planning (Fig.

Figure 19-32. Preoperative *(left)* and postcomputer imaging *(right)* of combined rhinoplasty and chin augmentation. *(Courtesy of Canfield Clinical Systems.)*

19-31). The cost of such commercially available systems, complete with computer, camera, and software, is several thousands of dollars. More basic systems, however, may be pieced together by a physician to maintain a more modest price.

Computer imaging and its ability to generate altered images for patient education can be particularly helpful during the preoperative rhinoplasty consultation. Computer-generated changes are compared with preoperative images and reviewed with the patient. The surgeon must be conservative with computer-generated changes and avoid overzealous alterations. In this manner, realistic expectations are nurtured, and a common outcome concept can be reached between surgeon and patient. Computer imaging can be particularly helpful to demonstrate to the rhinoplasty patient with microgenia the added benefit of chin augmentation (Fig. 19-32). The computer-generated images assist patients in visualizing the overall improvement in facial harmony.

CHAPTER TWENTY

Recognition and Treatment of Skin Lesions

Andrea Willey

Neil A. Swanson

Ken K. Lee

Key Points

- Recognition and treatment of benign and malignant skin lesions is an important aspect of otolaryngology–head and neck surgery.
- The skin is limited in the number of ways it can respond to stimuli; thus many neoplasms appear similar and features that differentiate them may be subtle.
- Skin biopsy is essential for the definitive diagnosis of many cutaneous neoplasms.
- The proper use of biopsy techniques to establish a histologic diagnosis is critical, because the ability to establish a definitive diagnosis depends directly on the clinical specimen obtained for histopathologic evaluation.
- A wide variety of therapeutic options exist for benign, premalignant, and cancerous skin lesions, the selection of which relies upon the accurate clinical and histologic diagnosis and the technique best suited to the individual lesion.
- Cutaneous neoplasms may be associated with internal malignancies and genetic syndromes that may warrant further evaluation and management from other medical specialties.

Recognition and treatment of skin lesions is an important aspect of otolaryngology–head and neck surgery. Many of the diseases that an otolaryngologist–head and neck surgeon sees can involve the skin. Whether they are a patient's chief complaint or are noted on a routine examination, skin lesions need to be recognized so that proper diagnosis and management are instituted. This chapter provides the otolaryngologist–head and neck surgeon with practical knowledge of benign and malignant cutaneous neoplasms, including epidermal tumors, cystic lesions, vascular tumors, and fibroadnexal tumors. Preferred therapeutic options are reviewed and diagnostic methods commonly used by dermatologists and cutaneous surgeons are presented that can easily be applied by the otolaryngologist–head and neck surgeon. Biopsy techniques used to establish a histologic diagnoses are stressed because the pathologist's ability to establish a definitive diagnosis depends directly on the clinical specimen obtained for histopathologic evaluation. An in-depth discussion of all cutaneous tumors is beyond the scope of this chapter. Recognition and treatment of common neoplasms of the skin are discussed. The management of cutaneous carcinomas and melanoma are discussed in another chapter.

Epidermal Neoplasms

Epithelial neoplasms of the skin can range from entirely benign to highly malignant tumors. Epidermal tumors are so common that few people go through life without acquiring at least one. A great assortment of epidermal tumors under a wide variety of names have been described; the more common and important ones are discussed in this chapter.

The following important factors relevant to epidermal tumors should be noted. First, the epidermis in the healthy person is a relatively thin structure and is the outermost layer of the skin. Hyperproliferation of epidermal cells results in tumors that usually appear superficially and are often associated with scale, ulceration, or changes in skin texture. Dermal tumors and tumors of the cutaneous appendages (adnexal tumors) are usually deeper and therefore more nodular in appearance. Recognizing these differences is one general way of differentiating between the two tumor groups. The second important factor is that there are three types of lesions that occur within epidermal tumors: benign, precancerous, and cancerous. The precise nature of precancerous lesions has been debated widely, but the term persists in the literature; it refers to a group of epidermal lesions of which a small percentage can become malignant. Third, because the epidermis is limited in the number of ways it can respond to stimuli, the clinical presentations of many tumors will be similar and may be subtle, with little outward change in appearance. Even the most experienced dermatologist must rely on a skin biopsy for the definitive diagnosis of epidermal tumors. Finally, many epidermal neoplasms may be associated with internal malignancies or genetic syndromes that warrant further evaluation and management from other subspecialties.

Seborrheic Keratoses

Seborrheic keratoses are common lesions, usually appearing around the fourth decade of life.[1] They can be single or multiple and can occur anywhere on the body, with the exception of the palms and soles. Clinically, they are sharply demarcated and slightly raised, appearing as if they were stuck on the skin's surface (Fig. 20-1). Many have a verrucous surface with a soft, friable consistency; however, others may have a smooth surface. Characteristically, all seborrheic keratoses show keratotic plugs on careful surface inspection. Their color is usually brownish to brown-black, although color can vary from flesh color to

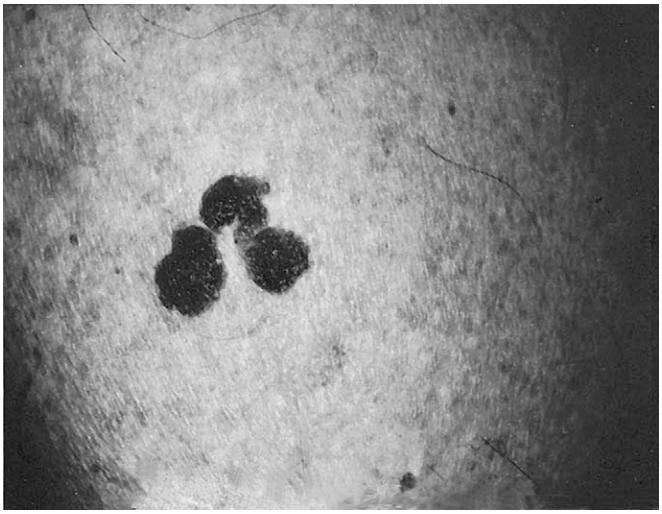

Figure 20-1. Seborrheic keratoses.

deep black. The color within the individual lesion is usually uniform. Lesions can measure from a few millimeters to several centimeters. When subjected to trauma, they can become irritated, thereby causing an inflammatory base and occasional bleeding. Occasionally, seborrheic keratoses are pedunculate, especially on the neck.

The etiology of seborrheic keratoses is unknown, although they may be dominantly inherited. They are benign with no malignant potential, although the appearance of hundreds in rapid "showers" may be a sign of internal malignancy; this is the much-debated Leser-Trélat sign.[2] The most common tumor seen with this association is colonic adenocarcinoma. In the head and neck, the most common mistaken diagnosis is melanoma; therefore the pathologist sometimes receives a widely excised seborrheic keratosis that has been mistaken for melanoma. If the diagnosis is in doubt, a biopsy before definitive treatment should be performed.

Treatment of these lesions varies. Because these lesions are so superficial, they often can be excised flush with the skin, using any of the shaving techniques described later. These lesions also are amenable to light liquid nitrogen freezing, which creates a subepidermal blister and allows for removal of the keratosis with the blister. Because these are truly benign lesions, the best treatment is often no treatment, unless the lesions are cosmetically disfiguring.

Dermatosis Papulosa Nigra

Dermatosis papulosa nigra is a condition found in approximately 35% of black adults; its onset often occurs during adolescence. The lesions are located predominantly on the face, especially in the malar region, but they may also occur infrequently on the neck and upper trunk. They consist of small (1 to 3 mm), smooth, pigmented, stuck-on appearing, hyperkeratotic papules. Although they have the histologic appearance of a fibroma, many clinicians consider these papules to be a variant of seborrheic keratoses. The treatment of dermatosis papulosa nigra is difficult because of pigmentary problems that occur with the treatment of black skin. Options that have been tried include fine-needle electrosurgery followed by use of a small curette, shave excision, light freezing with liquid nitrogen, and dermabrasion. If the lesions are few, we prefer the first two methods. Cryosurgery can produce spotted hypopigmentation in blacks and should be avoided unless other treatment modalities are not available. Dermabrasion can be of two types: using either a 2-mm wheel or a small cone or pear diamond fraise, the lesions can be removed singly, very quickly, and easily. Dermabrasion can also result in mottled pigmentation after healing, which usually will fade with time. If the lesions are multiple and confluent, total regional dermabrasion may be the treatment of choice for the best cosmetic blend. Judicious use of ablative and pigment-specific lasers can be used to treat these lesions focally; however, meticulous technique is required to avoid pigmentary changes common to this patient population.[3]

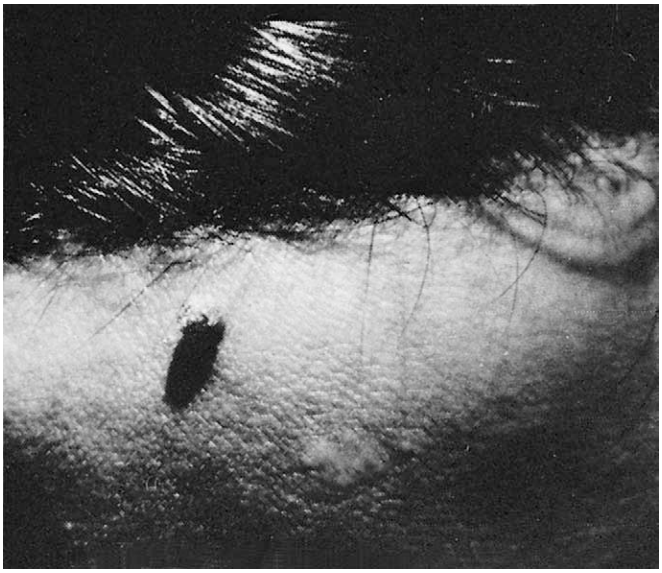

Figure 20-2. Filiform warts.

Warts (Verruca Vulgaris)

Warts are common lesions caused by the human papillomavirus (HPV), which is a deoxyribonucleic acid (DNA) virus. Warts are traditionally classified by clinical appearance and location: verruca vulgaris (or common wart), deep hyperkeratotic palmar-plantar; superficial mosaic-type palmar-plantar; verruca plana; epidermodysplasia verruciform; and condyloma acuminatum. Classification may also be based on the genotype of papilloma virus. Hundreds of DNA genotypes have been identified, each with a distinct type-specific antigen, some of which correlate with various benign and malignant conditions.[4] The most common facial warts include common warts (including filiform) and flat warts which are most commonly associated with the antigenic serotypes HPV-2 and HPV-3. Clinically, these lesions are hyperkeratotic. The filiform wart is often a pedunculate lesion occurring in isolation on the cheek, nasal tip or columella, or eyelid (Fig. 20-2). Common warts can occur anywhere on the face. Flat warts usually occur in younger patients or on the legs of women who regularly use a razor for shaving; they are small (1 to 2 mm), flat-topped, hyperkeratotic lesions, which can coalesce (Fig. 20-3).

Because the virus survives within cells at the base of the hyperplastic epithelium and within the adjacent normal-appearing skin, eradication of warts can be difficult and recurrences are common. Most common treatments involve destruction of the infected tissue. The filiform wart can be anesthetized at its base and excised with scissors, with the base being lightly curetted and fulgurated under low current; this approach affords the best chance for cure. Filiform warts often are too verrucous and hyperkeratotic to be effectively treated with cryosurgery. Common warts that are thinner can be treated effectively with liquid nitrogen cryotherapy, although several treatments are usually needed. Flat warts present a difficult problem. At times, they can be effectively treated with liquid nitrogen. Perhaps the best method is to individually scrape each small wart off of the skin with a small curette, treating, when possible, all of the flat warts in an area at one time. In young children who do not tolerate surgical therapy well, one may use topical tretinoin at a concentration sufficient to produce erythema and irritation in an attempt to stimulate the body's own immunity against the wart virus. In healthy children, avoiding treatment is often best, because the vast majority of warts spontaneously involute once the patient's immune system recognizes the virus.[5]

Related to the poxvirus family is a group of viruses known as the molluscum contagiosum virus family (EM-2). An infection with one of these viruses appears clinically as a variable number of small, discrete, waxy, skin-colored, dome-shaped papillomas, 2 to 4 mm in diameter, with umbilicated centers (Fig. 20-4). Like all viral lesions, they ultimately will involute spontaneously. Histologically, they have a classic

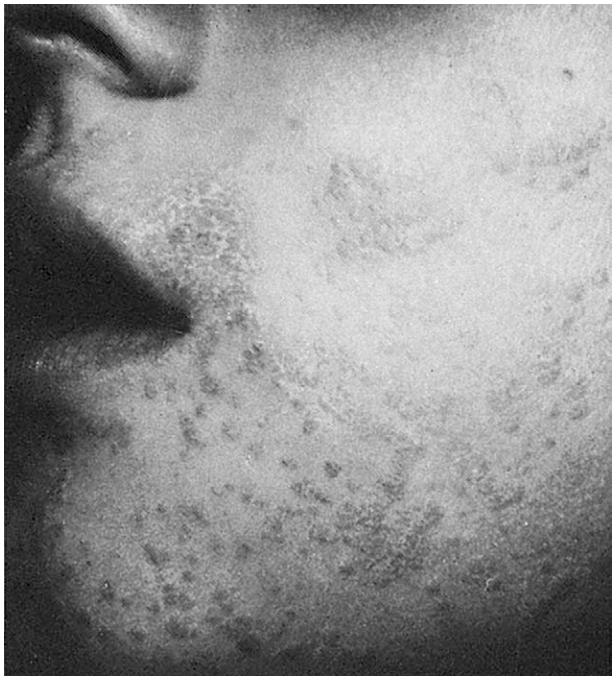

Figure 20-3. Flat warts.

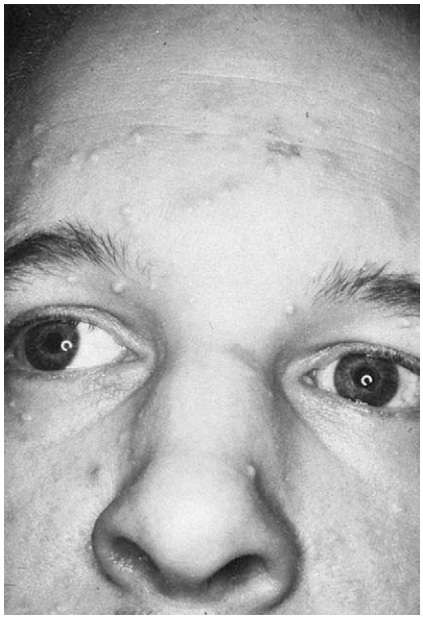

Figure 20-4. Molluscum contagiosum.

appearance of cytoplasmic inclusion bodies, which are the so-called molluscum bodies. The best treatment is usually superficial cryotherapy or curettage, as is the case with common warts. Topical therapies, including imiquimod cream, liquid podophyllin, cantharidin, and more recently, injectable candidal antigens, have been successfully used for the treatment of warts and mollusca.

Actinic Keratoses

Actinic keratoses, also called *solar keratoses,* are precancerous lesions.[6] Studies indicate that squamous cell carcinoma will develop in one or more lesions in 5% to 20% of persons with solar keratoses.[7-10] They are seen on sun-exposed areas of the skin, usually in persons after the fourth decade of life. They are seen most commonly in fair-skinned individuals who get sunburned frequently. Clinically, these lesions are usually erythematous with adherent scale and show little or no infiltration (i.e., they are very superficial) (Fig. 20-5A). Often, the patient can feel the rough, adherent scale before the lesion is clinically visible. Solar keratoses can also be flesh colored or pigmented. They often do not have a sharp demarcation from surrounding skin and can spread peripherally. Occasionally these lesions develop marked hyperkeratosis, giving a clinical appearance of a cutaneous horn. On the vermillion lip, actinic keratoses are known as *solar* or *actinic cheilitis.*

Actinic keratoses lesions are best removed and not watched. The most commonly used method for removing discrete lesions is cryosurgery. Shave excision can also be performed, but it would lead to extensive scarring in areas with numerous lesions. In persons with severe sun damage to the face or with diffuse actinic keratoses, regional treatment with topical 5-fluorouracil, imiquimod, or retinoid creams are effective therapies for an entire region of the body such as the arms, hands, scalp, or face.[11,12] Because proper use results in severe irritation, sound patient understanding and education, and physician reassurance are necessary to ensure adequate compliance. Photodynamic therapy, laser resurfacing, dermabrasion, and chemical peels are also effective field therapies.[13-16]

Basal Cell Carcinoma

Basal cell carcinoma is the most common malignancy in humans,[17,18] accounting for 75% to 80% of new cancers in the United States each year. Depending on the study cited, approximately 86% of lesions occur initially in the head and neck, with 25% of all primary lesions occurring on the nose. Approximately 96% of recurrences are in the head and neck, with 38% being on the nose. Emmett reported that 75.5% of previously untreated basal cell carcinoma found in Australia occurred in the head and neck, 8.4% on the chest and back, and 16% on the arms and legs.[19] When looking at recurrent tumors, 91% occurred on the head and neck, 7.5% on the chest and back, and 1.5% on the arms and legs. Similarly, the primary tumor of metastatic basal cell carcinomas is usually found on the head and neck. However, metastasis of basal cell carcinoma is rare, with reports estimating rates of 0.0028% to 0.1%.[20-22] In this discussion, we outline the epidemiology and clinical and histologic variations of basal cell carcinoma. Management of head and neck basal cell and squamous cell carcinomas are addressed in Chapter 82.

Basal cell carcinoma, which is more common in men than in women, is seen most frequently in individuals between 40 and 60 years of age. With the aging of the sunbathing generation, however, basal cell carcinomas are occurring with increasing frequency in younger people. Scandinavians and people of Celtic extraction (particularly Irish), who frequently have Fitzpatrick skin type I or type II (sunburn easily), appear to be more prone to basal cell carcinoma than those with more darkly pigmented skin. Although uncommon in blacks, predilection for occurrence on the head and neck is the same as in whites.[23] Exposure to sunlight—primarily to the rays in the ultraviolet B spectrum—is the primary risk factor for basal cell carcinoma; this has been shown experimentally and reproduced clinically. The tumor is more common as one approaches the equator and at high altitudes. Basal cell carcinomas occur most commonly on the head and neck areas, with the nasal tip and the nasal ala being the most common; the cheeks and the forehead are the next most common. The left side of the body is more common than on the right, perhaps because of selective sun exposure in individuals whose occupation preferentially exposes the left side (i.e., driving).

Although sun exposure is the primary etiologic agent of basal cell carcinoma, other risk factors include genetics, occupation,[24] immunosuppression, ionizing radiation, and the presence of scars. Farmers, sailors, and fishermen, because of their heavy occupationally actinic exposure, have a higher than average incidence of skin cancer. The most common genetic syndromes include nevoid basal cell carcinoma syndrome and xeroderma pigmentosum.[25] The former is an autosomal dominant condition in which basal cell carcinomas arise on any area of the body, with the predilection being toward sun-exposed sites, beginning at an early age and continuing throughout life. These patients also have skeletal abnormalities, including bifid ribs, jaw cysts, frontal

bossing, and calcified falx cerebri. Xeroderma pigmentosum is an autosomal recessive disease caused by a defect in DNA repair that leads to the development of basal cell carcinoma and other cutaneous malignancies in response to sun exposure and other carcinogens in childhood and early adulthood.

Immunosuppression (iatrogenic or associated with leukemias or lymphomas) has been shown to increase the incidence and aggressiveness of basal cell carcinomas. Chemical carcinogens—notably arsenic—play a tumorigenic role. Arsenic usually comes from well water that has been contaminated with arsenic, but patients with asthma, hay fever, or psoriasis may ingest arsenic in medicinal Fowler's solution. Arsenic-induced basal cell carcinomas tend to be primarily on the trunk and are accompanied by keratoses of the palms and soles, pigmentary changes, and nail changes (Mees' lines). Exposure to ionizing radiation is also an important etiologic factor; tumors can arise in areas of radiation damage, often many years after superficial radiotherapy for acne or tinea capitis, or as a depilatory at an early age. Basal cell carcinoma can arise within a scar or area of trauma. The injury may act as a cofactor, adding to the effect of already existing risk factors, such as sunlight and genetic susceptibility. Smallpox vaccinations and burn scars have been associated with basal cell carcinoma.

To the trained and observant eye, the clinical recognition of basal cell carcinoma is not difficult. Typically, lesions are nodular with a smooth, raised, translucent or "pearly" border with prominent telangiectasia (see Fig. 20-5D).[26] In addition, they may ulcerate and form a crust (see Fig. 20-5C). A typical history involves a pimple-like lesion that bleeds and does not heal. Pruritus is a common early symptom. Basal cell carcinoma may be pigmented (see Fig. 20-5E) yet maintain the clinical features of pearly, translucent borders and telangiectasia. Superficial multicentric basal cell carcinomas are flat and pink with differing, intercommunicating extensions of tumor that may be either scaly or with raised borders.

Other forms of basal cell carcinoma are clinically more subtle, histologically more aggressive, and more difficult to treat. Approximately 20% of primary basal cell carcinomas demonstrate infiltrative growth patterns with significant subclinical disease and high rates of recurrence.[27-29] Importantly, many primary tumors demonstrate histologic heterogeneity with subclinical extension.[30] Morpheaform basal cell carcinomas (see Fig. 20-5F) present as yellowish plaques, which develop telangiectasia, may ulcerate, and may have a sclerotic or scarlike appearance. The margins are often indistinct. Histologically, this tumor extends subclinical, finger-like projections intradermally, which make complete excision difficult. This tumor has a scarlike, stromal matrix that gives it a fibrous, sclerotic appearance and nature.

Recurrent basal cell carcinomas (Fig. 20-6A) present with varying clinical appearance, depending on the type of initial treatment. It may appear at the edge of a skin graft, within a scar created by electrosurgery, under a scar created by cryosurgery, or as a nodule developing within a suture line. Recurrent basal cell carcinomas are often nodular and accompanied by a morpheaform or sclerotic histologic picture in the deeper portions of the tumor. This picture may represent an aggressive histologic de-differentiation of the tumor, a factor that may partially account for its clinically aggressive behavior and resistance to treatment. The majority of recurrent basal cell carcinomas demonstrate infiltrative patterns in the original tumor; aggressive behavior may be predicted by careful evaluation of histologic features.[31]

Figure 20-6. **A,** Recurrent basal cell carcinoma. **B,** Chondrodermatitis nodularis helicis. **C,** Squamous cell carcinoma. **D,** Pigmented squamous cell carcinoma. **E,** Superficial spreading melanoma. **F,** Irregular border of superficial spreading carcinoma.

The typical basal cell carcinoma that occurs in the head and neck of the middle-aged or older fair-skinned person is not difficult to diagnose. One must be aware, however, that this tumor has a variety of clinical appearances, can appear in young people, and can occur in areas other than the head and neck. Any suspicious, nonhealing, pruritic, scaly lesion—especially one that occurs in a sun-exposed area of the fair-skinned individual—should be investigated with a biopsy. Biopsy techniques for basal cell carcinoma are simple. It has been well documented that implantation metastases from basal cell carcinoma do not occur, because the tumor needs a stroma to provide an environment in which to grow. The most appropriate technique is a medium-depth shave biopsy. The depth of the biopsy ideally should be mid-dermis; this depth gives a dermal collagen network that is amenable to any form of therapy. If a morpheaform basal cell carcinoma is suspected, the biopsy specimen often must extend deeper, perhaps through a punch or incisional biopsy. In cases of recurrent or superficial multicentric lesions or large clinical lesions, biopsy specimens should be obtained from multiple sites to assess the true clinical nature and size of the tumor. Biopsies of recurrent deep nodular lesions should be performed in an appropriate fashion to ensure an adequately deep specimen from the dermal nodule; this maneuver can be accomplished by means of an incisional biopsy or a deep-punch biopsy. As a rule of thumb, if the biopsy does not confirm the clinical opinion of basal cell carcinoma and the lesion remains suspicious, an additional biopsy of the lesion is indicated.

Chondrodermatitis nodularis helicis (see Fig. 20-6B) is an inflammatory disease of underlying helical cartilage that can mimic and be mistaken for basal cell carcinoma. The condition usually results from chronic trauma on the most protuberant portion of the ear. Surgery is the treatment of choice.

Squamous Cell Carcinoma

Squamous cell carcinoma is the second most common skin cancer and accounts for 10% to 20% of all cutaneous malignancies. Because of their tendency to recur and metastasize, squamous cell carcinomas carry the highest mortality of nonmelanoma skin cancers and account for the majority of deaths due to skin cancer in adults older than 85 years.[32] The development of squamous cell carcinoma is multifactorial and involves both environmental and genetic factors. Risk factors for the development of squamous cell carcinoma include fair skin; chronic cumulative sun exposure; history of previous skin cancer; age older than 50 years; smoking; chronic inflammatory, infectious, or scarring skin lesions; chemical carcinogens; PUVA; HPV infection; and various genodermatoses. Similar to basal cell carcinomas, the most important factor is ultraviolet radiation. Fair-skinned individuals with longstanding chronic sun exposure, especially those close to the equator and at high altitudes, are at greatest risk. Men are affected two to three times more than women, and multiple cutaneous carcinomas are common.

Whereas the majority of squamous cell carcinomas may be cured if diagnosed and treated early, some behave aggressively with high rates of metastasis. Risk factors associated with high rates of recurrence and metastasis include chronically sun exposed skin, scarred areas in non–sun-exposed skin, tumors greater than 2.0 cm in diameter, recurrent tumors, chronic immunosuppression, poor histologic differentiation, depth of invasion, and perineural involvement.[33,34] The true risk of

recurrence or metastasis for each variable is unknown; however, associations are clearly established. Clinically, squamous cell carcinomas can be separated into actinically induced and those that arise de novo on non–sun-exposed skin. The former are the more common and are associated with a low incidence of metastasis (<1% in most series). Some studies suggest that de novo lesions have a higher metastatic potential; approximately 2% to 6%. The mucosal variant of the squamous cell carcinoma, seen clinically as carcinoma of the lip, has a metastatic potential of up to 13.7%; therefore these distinctions are important in prognosis.[35] The worst prognostic indicator is perineural invasion, which has been shown to metastasize in 47.3% of cases.

Squamous cell carcinoma may present clinically in several ways.[36] Thick, scaling, hyperkeratotic plaques may present on the exposed surface of the body, in particular the ear, lip, or nose (see Fig. 20-6C). Lesions may change slowly over a period of time. If the crust is removed, the base is often ulcerated and has a rolled margin. Lesions may also present as a persistent ulcer, particularly in an old scar, or as a superficial multifocal change in generally sun-damaged skin. The latter is often the most difficult lesion to diagnose, requiring several biopsies at different points. Occasionally, a squamous cell carcinoma will become a vegetative nodular lesion; this lesion often has a cystic feel and can ulcerate and progressively enlarge. Often these exophytic lesions have not invaded deeply. They all have a tendency to ulcerate and become more erosive in appearance than a basal cell carcinoma. As with basal cell carcinoma, they can become pigmented (see Fig. 20-6D) and often appear similar clinically to keratoacanthomas, especially when the latter are in the growth phase. However, these lesions usually grow more slowly than keratoacanthomas, thereby allowing for distinction on clinical as well as histologic grounds. When this occurs, biopsy is always indicated. The treatment of cutaneous squamous cell carcinoma is discussed in depth in another chapter.

Bowen's disease refers to an intraepithelial squamous cell carcinoma or carcinoma in situ. Clinically it presents as a well-demarcated, erythematous, scaling thin plaque that may be easily misdiagnosed as psoriasis, eczema, or tinea. Bowen's disease on sun-exposed skin behaves less aggressively than non–sun-exposed such as the genitalia; if left unrecognized and untreated, it may progress to invasion. Bowen's disease associated with arsenic exposure may be associated with internal malignancies. In the absence of arsenic exposure, however, this association is not well supported.

Keratoacanthoma is a rapidly growing tumor that presents as an exophytic dome-shaped nodule with central keratin on sun-damaged skin (see Fig. 20-5B). The categorization of keratoacanthoma has been controversial, but it is now thought to be a variant of squamous cell carcinoma. There are some unique features that distinguish it clinically from the common type of squamous cell carcinoma. Keratoacanthomas are characterized by a rapid proliferative phase followed by plateau, then involution. Not all keratoacanthomas, however, involute, and predicting which ones will is difficult. The involution phase can sometimes take up to 1 year. Two rare clinical forms of keratoacanthomas deserve mention. The giant keratoacanthoma can reach 5 cm or more and can cause the destruction of underlying tissues. Eruptive keratoacanthomas often present as many hundreds of characteristic papules that measure 2 to 3 mm in diameter. Metastatic keratoacanthomas have been reported, however, and may represent typical squamous cell carcinoma. Keratoacanthomas can be difficult to treat. Surgical excision is the treatment of choice for most keratoacanthomas, with Mohs micrographic surgery reserved for facial lesions. Because of the involution potential of keratoacanthomas, cytotoxic agents can be used to induce involution. We favor methotrexate at a dose of 12.5 to 25 mg/mL, with approximately 0.5 to 1 mL injected into the lesion at 3- to 4-week intervals. Although complete involution may not occur, it may allow for easier surgical management by reducing the size of the tumor.

Melanocytic Neoplasms

The melanocyte is the pigment-producing cell of the epidermis. However, many tumors of this cell line, which is embryologically from the neural crest, occur in the dermis either by migration or because crest cells fail to reach the epidermis during embryogenesis. The most common of these tumors are nevocellular nevi and melanoma. A wide spectrum of melanocytic nevi and pigmented skin lesions exist, many of which appear similar and can be confused with melanoma.[37] This section discusses the clinical manifestations of nevocellular nevi and other melanocytic neoplasms. The presentation, behavior, and treatment of melanoma are discussed elsewhere.

Nevocellular Nevus

Nevocellular nevi, commonly known as moles, are common benign skin neoplasms that appear shortly after birth to late in life. Acquired nevocellular nevi are classified according to their location and stage of development within the skin.

Junctional Nevus

Junctional nevi are tan to brownish macules (flat lesions) of uniform color and smooth border (Fig. 20-7B). Dots of black pigment may be present, but, unlike with melanoma, the normal skin markings are preserved. Lesions vary from a few millimeters to a centimeter or more in diameter. The melanocytes or nevus cells are located at the junction of the epidermis and the dermis (dermoepidermal junction). The lesion can occur anywhere on the body and is the nevus most commonly mistaken for melanoma. When in doubt, one should perform a biopsy of the lesion. Junctional nevi occur anytime after birth and are the common moles found in children before puberty. Their importance lies in their ability to develop into malignant melanoma, although this rarely occurs before puberty. Most junctional nevi remain benign throughout life and can evolve over time into either compound or intradermal nevi. Treatment of these nevi is often dictated by suspicion of melanoma or cosmetic reasons, and usually includes a shave in noncosmetic areas or a fusiform excision with closure in cosmetically important areas. Melanocytes are cold sensitive, and strictly junctional nevi can be removed with deep cryotherapy.

Intradermal Nevus

Intradermal nevi are common mature moles of adults, occurring anywhere on the body but rarely on the palms and soles. It is most common on the scalp or face in adults, varying in size from a few millimeters to several centimeters. It may be flat and smooth or raised and warty, pigmented or nonpigmented, sessile or pedunculate (see Fig. 20-7C). It often contains coarse hairs, reflecting the depth within the dermis of the nevus cells. It is benign and rarely becomes malignant. By definition, all of the nevus cells occur within the dermis. This mole is best treated by shave excision when it is pedunculate and hairless. When it is on the head or neck and contains hair, it is necessary to excise this mole using either the punch excision technique or routine excision to remove the complete depth of the hair follicles within the nevus.

Compound Nevus

Compound nevi, which are a combination of junctional and intradermal elements, are found most commonly in adults. They are brown to black moles, usually less than 1 cm in diameter. A brown macular ring is frequently around the periphery of the lesion. It can contain hair and is often clinically indistinguishable from an intradermal nevus. Although the compound nevus, like any mole, can develop into a malignant melanoma, it usually remains benign and matures into an intradermal nevus. Treatment usually consists of shave or excision and closure. As with intradermal nevi, the choice of treatment depends on location and on the presence or absence of hair.

Blue Nevus

Blue nevi present as dark blue or black hairless flat or raised lesions that are usually less than 0.5 cm in diameter, indurated, and palpable. The overlying epidermis is remarkably smooth and the outline regular (see Fig. 20-7D). Blue nevi most commonly occur on the head and neck, the dorsa of the hands and feet, and the buttocks. They are more common in women than men and usually undergo very little change after their initial presentation. The treatment of these lesions is excision or observation. The excision must be deep, because the pigment often extends deep into the subcutaneous fat, thereby resulting in the deep blue color of the lesion. Malignant transformation of blue nevi is rare;

Figure 20-7. **A,** Lentigo maligna melanoma. **B,** Junctional nevus. **C,** Intradermal nevus. **D,** Blue nevus. **E,** Halo nevus. **F,** Nevus sebaceus.

however, tumors demonstrate highly aggressive behavior, thus these lesions must be carefully evaluated histologically.[38,39]

Halo Nevus

The halo nevus is a phenomenon usually associated with a junctional nevus in children or adolescents. Most commonly found on the back, it is often a benign-looking brown papular lesion in the center of a well-circumscribed pale white circle of depigmented skin (see Fig. 20-7E). This appearance reflects the body's rejection of the nevus cells, because an inflammatory response ensues in which the melanocytes of the nevus and those of the immediately surrounding epidermis are destroyed.[40] Often, when left alone, these nevi disappear.

Spitz Nevus

Spitz nevus is also known as a *juvenile melanoma* or a *compound melanocytoma*. These rapidly growing pigmented lesions occur principally in children, although they can occur in adults. They are usually less than 1 cm in size and are pink or red, or occasionally brown or black. A Spitz nevus may be soft or hard, but is usually dome-shaped and can be either sessile or pedunculated. It can occur anywhere on the body and is often difficult to diagnose clinically. Its main importance is its histologic resemblance to melanoma, with even experienced pathologists having difficulty distinguishing between the two.[41] Very few of these nevi, however, progress to malignancy. Treatment of a Spitz nevus is the same as that for an intradermal or compound nevus.

Congenital Nevi

Congenital nevi are malformations of neuroectoderm comprised of melanocytes, affecting 1% to 6% of the population. There is great heterogeneity in their appearance, size, and location. Lesions may be light brown to black, are variously shaped, usually have sharp borders, are flat to mammillated on the surface, and often contain hair. When large or in conspicuous locations such as the face, they may be associated with significant psychosocial impact on affected individuals and their families.

Congenital nevi are usually present at birth; however, in some lesions pigmentation may occur gradually over the first few years of life. In addition to being aesthetically disfiguring, congenital nevi may be associated with a risk of melanoma, neurocutaneous melanocytosis, or malignant tumor, such as rhabdomyosarcoma, among others. Whether this malignant potential is due to the increased number of melanocytes or to some inherited premalignant tendency in the cells themselves is not clear. Congenital nevi are classified according to size with those less than 1.5 cm being small, 1.5 to 20 cm being medium, greater than 20 cm being large, and greater than 50 cm being giant. The precise risk for development of melanoma associated with congenital nevi is difficult to establish; however, risk clearly correlates with size, with the greatest risk being associated with giant congenital nevi. The risk of cutaneous or extracutaneous melanoma associated with small congenital nevi is estimated at 0% to 4.9% and generally occurs at or after puberty. The risk is 4.5% to 10% in large congenital nevi and usually occurs before puberty in this group.[42,43] Histologic evaluation of changes within congenital nevi should be evaluated by a dermatopathologist experienced in the evaluation of pigmented lesions. Individuals with large congenital nevi are also at risk for development of neurocutaneous melanosis in which proliferation of leptomeningeal melanocytes may be associated with neurologic disease, structural malformations, and malignant degeneration. Giant axial lesions and those

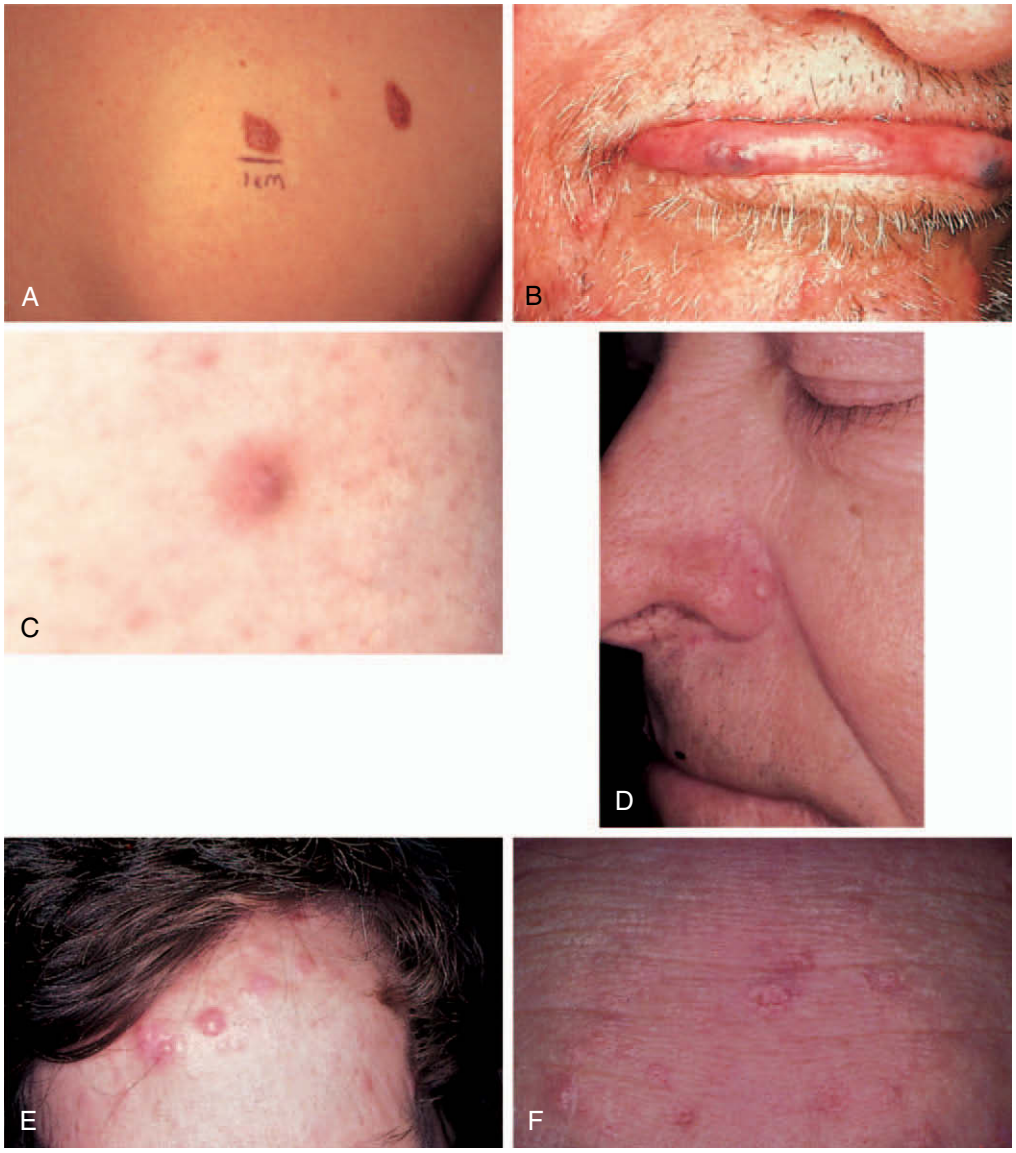

Figure 20-8. **A,** Dysplastic nevus. **B,** Venous lakes. **C,** Dermatofibroma. **D,** Fibrous papule. **E,** Cylindroma. **F,** Sebaceous hyperplasia.

with greater than 20 satellite lesions are at greatest risk.[44] The prognosis for patients with symptomatic neurologic disease is poor. Approximately half of patients with neurocutaneous melanosis develop central nervous system melanoma.[45]

The management of congenital nevi should be individualized based upon nevus size, thickness, location, risk for development of melanoma and other associated conditions, psychological impact, and effects of therapy on the patient and family. Treatment options include surgical excision, dermabrasion, chemical peels, laser therapy, and observation. The timing and choice of therapy should take into consideration the medical, cosmetic, and psychological factors.[46,47]

Dysplastic Nevus

Dysplastic nevus syndrome, described by Clark and colleagues, is also known as the B-K mole syndrome.[48] It consists of the association of familial malignant melanoma, which often occurs in multiple lesions, with "dysplastic nevi" in both the melanoma patient and many of his or her relatives. Dysplastic nevi are usually larger than ordinary melanocytic nevi, ranging from 5 to 15 mm; they present with an irregular border and a haphazard mixture of colors: tan, brown, black, and pink. Centrally, there is often a small, palpable component (Fig. 20-8A). Dysplastic nevi are located on either exposed or nonexposed skin and form throughout adult life, unlike typical nevi that form in earlier years and tend to fade in later years. The idea that a dysplastic nevus may transform itself into a malignant melanoma remains controversial.[49]

Solar Lentigo

Solar lentigo, also known as *actinic lentigo*, are keratinocytic pigmented macules that commonly present on the sun-exposed skin of the head and neck.[50] They commonly occur as multiple lesions and have been referred to as *lentigo senilis.* The lesions rarely occur before the fifth decade of life, they slowly increase in size and number, and they form in more than 90% of whites who are older than 70 years old, most commonly on the dorsa of the hands and on the face. They are not infiltrative, and they possess a uniform dark brown color and an irregular outline. Varying in size from minute to greater than 2 cm, they may coalesce to form larger lesions. Malignant degeneration does not occur. These lesions may resemble seborrheic keratoses in clinical appearance, and both conditions are referred to in lay terms as "liver spots." Solar lentigo, however, are less hyperkeratotic than seborrheic keratoses and have no areas of follicular prominence. It is important to distinguish solar lentigo from melanoma in situ, which may also present as dark brown macules on sun-damaged skin of the head and neck. Solar lentigo can be easily treated with pigment-specific lasers, intense pulsed light devices, cryotherapy, topical retinoids, or chemical peels such as trichloroacetic acid.

Nevus Sebaceus

Nevus sebaceus of Jadassohn is a common benign congenital lesion that presents as a pebbly, flesh-colored, hairless, well-demarcated lesion of the scalp (see Fig. 20-7F) and other areas of the head and neck. The size varies from 0.5 cm to several centimeters. Off the scalp, the lesion can be linear, closely resembling a linear epidermal nevus. Histologically, these tumors evolve in three discrete stages of growth. In the first few months of life, the sebaceous glands in the lesion are well developed. Thereafter, through childhood, the sebaceous glands are underdeveloped and therefore greatly reduced in size and number; in this phase, the diagnosis may be missed. At puberty, the lesions assume a diagnostic appearance, which is histologically characterized by the presence of large numbers of mature or nearly mature sebaceous glands and by papillomatous hyperplasia of the epidermis. During puberty, various benign and malignant epidermal and adenexal tumors develop in nevus sebaceous. Ten percent to 30% of lesions develop neoplasms during adulthood, usually between the fourth and seventh decades. The most common benign neoplasms include trichoblastoma and syringocystadenoma papilliferum. Of primary importance is the occurrence of basal cell carcinoma in 5% to 7% of sebaceous nevi; numerous other malignant neoplasms have been reported, including squamous cell carcinoma, sebaceous carcinoma, ductal carcinoma, and leiomyosarcoma.[51-55] Treatment of nevus sebaceus is complete surgical excision. Complete excision before puberty as a preventive measure had been previously advocated; however, more recently this recommendation has been called into question due to the low incidence of malignant lesions and the ability to identify such changes clinically.[56,57] Others have proposed observation with excision of selected lesions, however many prefer excision for aesthetic reasons.[58]

Cysts

Cutaneous cysts may be located either intradermally or within subcutaneous tissue. These generally spherical growths contain a cavity that may be filled with fluid or contain cellular products or debris. A true cyst has an epithelial lining, whereas a pseudocyst lacks such an organized epithelium. Cysts are generally classified according to the pattern of differentiation they exhibit on histologic examination; many are difficult to differentiate clinically. As a rule, malignant degeneration is rare for all of the cysts described here.

Epidermoid Cysts

Epidermoid cysts are true cysts. Their lining resembles that of the normal epidermis. This lining produces fully matured, keratinized cellular debris, which fills the cavity of the cyst. Epidermoid cysts are thought to originate from the follicular infundibulum of hair shafts and may arise either spontaneously or as a result of inflammation or trauma to the area. Injection of surface epidermal material to deeper dermal or subcutaneous layers as a result of penetrating trauma or the use of needles has also been postulated. These cysts are rarely found before puberty, but they have been found in all age groups after this period. If these cysts appear before puberty or in large numbers, they may be an indication of Gardner's syndrome, which is an autosomal dominant condition that predisposes the patient to intestinal cancer. Although malignant degeneration is uncommon, epidermoid cysts can present a cosmetic problem, and, if they rupture or become infected, they may cause severe pain and scarring. Although some of these lesions occasionally respond to intracystic injections of triamcinolone, surgical excision is the most effective treatment. It is necessary to carefully dissect and remove the entire cyst wall, because retained segments may lead to recurrent growth of the cyst.

Pilar Cysts

Pilar cysts, which are also known as *trichilemmal cysts* or *wens*, are also true cysts; they are clinically indistinguishable from epidermal cysts. The tendency to form such cysts appears to be inherited as an autosomal dominant trait. The lining of the cyst differentiates in a manner analogous to that of the outer root sheath of the hair follicle; this fact allows for its differentiation from epidermal cysts. Most pilar cysts occur on the scalp, and they are uncommon before puberty. Multiple cysts are often present. If a pilar cyst ruptures or becomes infected, considerable pain and scarring may result. As with epidermal cysts, the best treatment is complete surgical excision. Proliferating pilar tumors are uncommon tumors thought to originate from pilar cysts and have the potential for malignant transformation. Although these lesions are uncommon, they may be associated with significant morbidity and mortality and must be excised completely.[59,60]

Dermoid Cysts

Dermoid cysts are rare tumors that are frequently present at birth. They may measure up to 4 cm in diameter, although they are generally less than 2 cm. They may occur anywhere, but they are most common on the face, particularly in the area of the lateral eyebrow, the orbit, and the nose. Dermoid cysts appear to result from the inclusion of embryonic epidermis within embryonal fusion planes. Histologically, these cysts are lined by an epithelium that resembles normal epidermis. They can be differentiated from epidermal cysts by their attachment to adnexal structures, which include hair, sebaceous glands, eccrine glands, and apocrine glands.[61] Treatment is by surgical excision. If a dermoid cyst is located over the nasal root, however, care must be taken, because this tumor may be confused with a nasal glioma.[62]

Steatocystoma Multiplex

Steatocystoma multiplex, an uncommon condition, is often familial, demonstrating an autosomal dominant mode of inheritance. Although lesions can be discovered at any age, they most commonly occur shortly after puberty. The condition presents as multiple 1- to 2-cm cysts, generally located intradermally. They are most commonly found on the anterior chest, but they are also found on the face, forehead, ears, eyelids, and scalp. When punctured, these lesions exude a yellowish, oily fluid and, occasionally, hairs. On histologic examination, these cysts contain a highly corrugated wall of epithelial cells. Embedded within the wall are multiple sebaceous gland lobules, which may be partially responsible for the contents of the cyst. The mode of keratinization of the epithelial lining appears to resemble that of the outer root sheath, and indeed invaginations are often present within the cyst wall that appear similar to hair follicles. Infection with pain and subsequent scarring is a major problem associated with this condition. Treatment is disappointing because of the large number of lesions present, although individual lesions can easily be excised. On the face, cosmetically acceptable improvement has been reported with excision, CO_2 laser, dermabrasion, and oral retinoids.[63-66]

Milia

Milia are small (usually 1 to 2 mm) cysts that differ histologically from epidermal cysts only in their small size. Clinically, they are whitish, smooth globules, most commonly seen on the face. They may arise spontaneously, but they are also frequently present as a result of trauma such as dermabrasion or burns or as a result of bullous diseases. When they arise after trauma or disease as a result of the occlusion of the pilosebaceous unit, they represent a retention cyst. Treatment is the same whether milia arise spontaneously or secondarily and is necessary only for cosmetic reasons; the lesion can easily be shelled out with a hypodermic needle or a comedo extractor. Because they may occasionally number in the hundreds, this treatment can be a considerably tedious chore.[67]

Mucous Cysts

Mucous cysts are pseudocysts, because no true lining is present; they are also called *mucous retention cysts* or *mucoceles*. These lesions are usually located on the mucous surface of the lower lip and are asymptomatic. They are generally less than 1 cm in diameter and, if superficial, may appear slightly bluish and translucent. They appear to be the result of traumatic rupture of the ducts of minor salivary glands. With leakage of the contents into the tissue, an inflammatory process ensues, with the resultant formation of granulation tissues surrounding the cystic space. Mucous cysts may resolve spontaneously or can otherwise be treated by the intralesional injection of low-dose triamcinolone (2.5 mg/mL), excision, or marsupialization.[68]

Vascular Neoplasms

Cutaneous neoplasms of vascular origin are common and have a variety of presentations. They may be true proliferative tumors, or they may be ectatic vascular malformations present in the dermis or subcutaneous tissue. Differentiation may be toward blood vessels, lymph vessels, or both. These lesions may be congenital or arise later in life. Most vascular anomalies are benign. However, they may cause serious psychological or physical problems (because of impingement on important anatomic structures), and, importantly, they may be markers of more serious underlying diseases or syndromes. Vascular anomalies are generally classified as tumors and malformations.[69-71] Vascular tumors are characterized by abnormal endothelial proliferation and include infantile hemangioma, kaposiform hemangioendothelioma, tufted angioma, and pyogenic granuloma. Vascular malformations include lesions with anomalous vessels without an increase in cellular turnover and are further classified according to the predominant vessel type (capillary, venous, arteriovenous, lymphatic). These lesions present at birth and are present throughout life.

Infantile Hemangiomas

Infantile hemangiomas are the most common benign soft tissue tumor of childhood, occurring in approximately 10% of children. The incidence is greater in females than males and is increased in premature infants. Infantile hemangiomas are uniquely characterized by rapid proliferation during the first months of life followed by slow involution over several years. While most are of little significance, some have the potential for serious complication. The pathogenesis is not known, although positive staining for GLUT-1 (erythrocyte-type glucose transporter protein), which is normally expressed in endothelial cells of placenta, has suggested origination or transplantation from placental cells, although this has not been proven.[72]

Historically the term hemangioma has been used to describe a variety of vascular anomalies, which led to much diagnostic confusion. The recent identification of specific immunohistochemical markers that distinguish infantile hemangiomas from other vascular malformations has allowed for classification based on biologic markers. The term infantile hemangioma is used exclusively to describe lesions with this distinct presentation and clinical behavior; older terms such as *cavernous hemangioma* and *strawberry angioma* have been abandoned.[73]

Hemangiomas most often occur on the head and neck, although any area may be affected. When first noted at or shortly after birth, they are generally macular pink or bluish lesions. During the first year of life, hemangiomas exhibit a rapid growth phase, and the lesions become raised, dome-shaped to polypoid, and bright red to deep purple. After the first year of life, they enter a quiescent phase that is followed by a period of spontaneous involution. Hemangiomas may be superficial, deep, or mixed, and thus may vary in appearance significantly depending on the location, size, depth, and stage of development. Superficial hemangiomas develop into bright red noncompressible, partially blanching plaques. Deep lesions become partially compressible dermal nodules with a blue hue, often with overlying telangiectasia. Mixed lesions occur in 25% to 30% of lesions. In addition, there is great variation in the degree and rate of growth and involution of hemangiomas. In general, rapid proliferation occurs in the first 6 months, slow growth in the second 6 months, and involution occurs at a rate of 10% per year, with the majority of lesions completely involuted by the age of 10 years. Following involution the affected skin may not appear normal and may have residual telangiectasia, atrophy, scarring, and fibrofatty masses.

Although most hemangiomas are small and innocuous, a minority may present serious medical and psychological complications and may be associated with structural anomalies and neurocutaneous syndromes. The visible presence of hemangiomas and concerns for permanent disfigurement can lead to significant psychosocial stress that can be life altering for the child and family. Nasal tip lesions may distort the nasal anatomy and lead to significant deformity. Hemangiomas in the periorbital area may obstruct the visual axis or compress the orbit, leading to amblyopia and permanent visual loss. Lesions on the oral mucosa and perineum have a propensity for ulceration and bleeding during the rapid growth phase. Hemangiomas in the "beard area" may be associated with airway compromise. A small number of hemangiomas involve a large area of segmental distribution within developmental subunits. Segmental hemangiomas may have associated structural abnormalities with a high risk of serious complications. PHACES syndrome is a constellation of structural anomalies, including *p*osterior fossa malformation, *h*emangioma, *a*rterial anomalies, *c*oarctation of the aorta, *e*ye abnormalities, and *s*ternal defects that are associated with segmental hemangiomas.[74,75]

The heterogeneity of presentation of infantile hemangiomas and the potential risk of serious complications introduces complexity to the management of these lesions.[76] The majority of hemangiomas involute spontaneously with little consequence, thus treatment is primarily that of "active nonintervention," which involves close observation during the proliferative phase and familial education and support. Treatment with pulsed dye lasers may be helpful for ulcerated lesions, but has been less useful for deeper lesions. Recent advances in laser therapy using combinations of visible and near infrared wavelengths, however, may have additional benefits for the treatment of hemangiomas. Lesions that threaten to impinge upon important anatomic structures, especially the eye or the respiratory tract, require treatment with systemic corticosteroids. Recalcitrant, life-threatening hemangiomas that are resistant to steroid therapy may require interferon-α 2a or 2b or vincristine chemotherapy, which may have significant adverse side effects. Surgical excision with purse-string closure has been demonstrated to be a valuable intervention for many lesions, particularly those on the face, at all stages of hemangioma development.[77]

Cherry Angiomas

Cherry angiomas are also called *senile angiomas* or *De Morgan's spots.* They may occur anywhere on the body but are most commonly found on the trunk and usually appear during young adulthood. They are generally 1- to 3-mm, bright-red, slightly raised, dome-shaped lesions. The lesions consist of multiple dilated capillaries found in the upper dermis. Cherry hemangiomas are benign and unrelated to systemic or congenital disease. Treatment is not necessary but may be desired for cosmetic reasons; these angiomas respond to both superficial electrodesiccation and laser surgery.

Pyogenic Granuloma

Pyogenic granuloma are common acquired vascular lesions of the skin and mucous membranes. They are most common in children and young adults, or during pregnancy, but may occur at all ages. The pathogenesis is unknown. Pyogenic granuloma most commonly occur at sites of trauma on the distal extremities and the face, and occasionally gingival mucosa, but may present on any part of the body. Histologically, the appearance is that of a polypoid, lobulated mass of newly formed capillary blood vessels surrounded by an edematous stroma.[78] Clinically, pyogenic granuloma present as dark red pedunculated nodules often with a surrounding collarette of scale at the base. Pyogenic granuloma are prone to ulceration and bleeding, which often brings the patient to medical attention. Because of their rapid and exuberant growth, these lesions are sometimes mistaken for a malignancy. The differential diagnosis includes malignant melanoma, Kaposi's sarcoma, metastatic carcinoma, bacillary angiomatosis, and angiolymphoid hyperplasia with eosinophilia. Occasionally, the lesion spontaneously resolves. Lesions associated with pregnancy frequently involute after delivery; most often, however, the lesion must be treated surgically. This treatment is easily accomplished by surgical excision or curettage with electrodesiccation.

Salmon Patch

The salmon patch nevus is the most common vascular malformation of infancy, occurring in 30% to 40% of newborns. Salmon patch nevi are thought to represent persistent fetal circulation and present as pink macular patches on the posterior neck, scalp, glabella, forehead, and upper eyelids. When located on the nape of the neck, it is referred to as a "stork bite"; when present on the eyelid or glabella, it is referred to as an "angel's kiss." Eyelid lesions generally resolve within the first year of life, and the glabellar lesions also spontaneously involute but

take somewhat longer. The nuchal lesions may persist into adult life, although some spontaneously fade.

Port Wine Stain

Port wine stain, or *nevus flammeus,* is a congenital vascular malformation that presents in approximately 0.3% of newborns. Port wine stains show no tendency to fade and, in fact, generally darken and thicken with age, becoming deeply violaceous and nodular during adult life. These lesions are often unilateral and may follow a trigeminal distribution on the face. Extensive areas of facial skin, oral mucosa, and conjunctival membranes are often involved, although any area may be affected. Although port wine stains are usually limited to the skin, their psychosocial impact may be great. Lesions present initially as pink or pale red patches that, with time, progress through deepening shades of red to take on a deeply violaceous hue. With increasing age, the ectatic vessels become progressively more dilated and may become nodular and protuberant. Their prominent location on the face may have a significant psychosocial impact on developing children. Large nodular lesions may also tend to bleed and become crusted. The treatment of choice is the flashlamp-pumped pulsed dye laser. With repeated treatment sessions, significant fading can occur, although only a small percentage of these nevi resolve completely.

Port wine stains may indicate more serious underlying disease associated with several congenital syndromes.[71] Sturge-Weber syndrome (leptomeningeal nevus flammeus) is a port wine stain located along the distribution of the trigeminal nerve and angiomas within the meninges, with progressive calcification in these areas. Abnormalities associated with this condition include intractable seizures, developmental delay, and ocular abnormalities such as glaucoma. Increased incidence of Sturge-Weber syndrome is associated with involvement in the distribution of the three branches of the trigeminal nerve, bilateral involvement, and upper and lower eyelid involvement. Klippel-Trénaunay-Parkes-Weber syndrome (osteohypertrophic nevus flammeus) is characterized by hypertrophy of the soft tissues and bones of the lower extremity accompanied by a venous varicosity and an overlying port wine stain.

Telangiectasia

Telangiectasia are permanent vascular dilations caused by a variety of processes that affect blood vessel endothelium and its supporting structures. They may be congenital or acquired and may be of only cosmetic concern; however, they can be associated with internal disease or genetic syndromes. Clinically telangiectasias are easily recognized and blanch readily with diascopy.

Spider Angioma

Spider angioma, or *nevus araneus*, is a common type of telangiectasia often presenting on the face, upper body, and distal extremities. Spider angiomas may occur on mucous membranes, in which case the differentiation from hereditary hemorrhagic telangiectasia must be made. Clinically, lesions appear as a central, raised, small body that may be pulsatile with multiple legs fanning out from the center. They may be associated with liver disease, pregnancy, and estrogen therapy; however, spider angiomas are often idiopathic, presenting in 15% of healthy children and adults. Treatment is by obliteration of the central feeding arterial, which can be accomplished with electrocautery or photocoagulation.

Hereditary Hemorrhagic Telangiectasia (Rendu-Osler-Weber Syndrome)

Hereditary hemorrhagic telangiectasia is a dominantly inherited condition that affects blood vessels throughout the body.[79] It is characterized by ectatic vessels of the skin, mucous membranes, and viscera. Often the presenting symptom is spontaneous epistaxis, which may begin during early childhood but more likely appears at puberty or during adult life. Telangiectasia generally begin around and after puberty. The superficial telangiectasia assumes three morphologic forms; the most common lesions are punctate, but they may also be linear or spider-like. The mucous membranes are almost always involved, with lesions occurring on the lips, oral and nasal mucous membranes, nasopharynx, and throughout the gastrointestinal tract. The lesions may ulcerate and frequently bleed. The condition is associated with pulmonary, cerebral, and hepatic arteriovenous malformations. Bleeding may occur from any of the vascular lesions throughout the body and may be fatal. The diagnosis is generally made when the combination of frequent hemorrhagic episodes, vascular ectasias, and a family history is recognized. Genetic testing is available for prenatal diagnosis. Importantly, because catastrophic hemorrhage can occur in children with clinically silent disease, screening imaging for cerebral and pulmonary arteriomalformations is indicated in children who have a family history. Treatment is aimed at control of specific hemorrhages and of anemia, if it arises. Individual cutaneous lesions may be treated by electrocauterization and photocoagulation.

Venous Lake

Venous lakes present as deep blue, cutaneous nodules that occur most frequently on the face, lips, and ears of elderly patients (see Fig. 20-8B). Sometimes called *senile angiomas,* they are composed of dilated thick- and thin-walled, otherwise normal-appearing vessels. The lesions may thrombose and involute, but frequently they persist. They are of no significance other than a cosmetic nuisance and may be treated with vascular-specific lasers.

Fibroadnexal Tumors

Fibroadnexal tumors are derived from components of the deeper layers of the skin. They generally show differentiation toward the specific cell or tissue of origination and may be derived from any of the neurogenous, fibrillar, glandular, or pilar components of the dermis, as well as the subcutaneous tissue.

Acrochordon

Acrochordon (skin tag, fibroepithelial papilloma) are extremely common lesions, occurring most often during middle to late life. They are flesh-colored, pedunculate tumors that are generally up to about 2 mm in diameter. They are soft and most commonly occur in flexural regions such as the axillae, the sides of the neck, inframammary areas, and the upper eyelids. The lesions are composed of mostly loose fibrous tissue (similar to that of the superficial dermis), and they are covered by a thin epidermis. No adnexal structures are present. The lesions are easily removed by simple sharp-scissors excision or light electrodesiccation.[79]

Keloids and Hypertrophic Scars

Keloids and hypertrophic scars are uncontrolled proliferative responses to trauma by the fibrous tissue of the dermis.[80] Hypertrophic scar is a thickened scar that does not extend beyond the margins of the original injury, whereas a keloid is an exuberant growth extending beyond the borders of the initial scar. Keloids are most commonly seen in blacks. The epithelium overlying the tumor is frequently thinned and shiny, and the tumor may be tender and pruritic. The areas of predilection for keloids include the sternal area, the shoulders, and the upper back; they are also frequently seen on the earlobes after ear piercing and on the face. These tumors may be flat or extremely protuberant, dome shaped, or bosselated. They are most common in the second and third decades of life, becoming less common with age. Histologically, they present with distinctive keloidal collagen. Hypertrophic scars usually occur on sites of increased skin movement and tension; there is no racial predilection. Treatment of keloid and hypertrophic scars is challenging. Excision of these tumors generally has resulted in regrowth. Some success has resulted from radiation therapy, pressure, cryotherapy, injection of high-potency corticosteroids, interferon and fluorouracil, topical silicone dressings, and pulsed-dye laser treatment. Simple surgical excision is usually followed by recurrence unless adjunct therapies are used.

Dermatofibrosarcoma Protuberans

Dermatofibrosarcoma protuberans (DFSP) is an uncommon soft tissue sarcoma of low to intermediate malignancy with low metastatic risk, however with aggressive local behavior and high recurrence rates. All ages may be affected. It usually presents a pink to reddish protuberant

mass on the trunk or extremities; however, approximately 15% occur on the head and neck. Metastasis occurs in 1% to 4% of lesions, although approximately 10% demonstrate a high grade of malignancy with high risk of metastasis. Ninety percent of DFSP demonstrate translocation of chromosomes 17 and 22, in which the platelet-derived growth factor (PDGFB) gene is fused with the collagen 1 alpha gene, leading to upregulation of PDGFB expression in the tumor. Histologically DFSP are characterized by monomorphous spindle cells arranged in a storiform pattern. Less common variants include the Bednar tumor (laden with melanin) and myxoid variants. Small lesions may clinically and histologically resemble benign fibrous histiocytomas (dermatofibroma). Positive staining with CD34 differentiates these two entities. Some tumors demonstrate fascicles of spindle-shaped tumor cells with atypia, high cellularity, and an increased mitotic rate; clinically these tumors exhibit a more aggressive course with a greater probability of recurrence and metastasis.

Complete surgical resection of the tumor is the treatment of choice. Lower recurrence rates have been demonstrated by Mohs micrographic surgery with microscopic margin control, providing a distinct advantage over wide local excision.[81] Head and neck lesions tend to have high recurrence rates, and may particularly benefit from the use of Mohs surgery techniques. Some success has been demonstrated with pretreatment of advanced and metastatic DFSP with imatinib mesylate, a selective inhibitor of PDGFB kinases, before Mohs surgery, suggesting it may have a primary role in the treatment of DFSP in future.[82]

Atypical Fibroxanthoma

Atypical fibroxanthoma is a low-grade malignant spindle-cell tumor that most commonly occurs on the sun-exposed areas of the elderly. They are believed to be of fibrohistiocytic origin and to be a superficial variant of a malignant fibrous histiocytoma.[83] The lesion is a pink to translucent nodule, generally 1 to 2 cm in diameter. Ulceration is not uncommon. Clinically these tumors may be mistaken for several different types of malignancies, including basal cell carcinomas, squamous cell carcinomas, and melanomas. The risk of metastasis is low, although local and distant metastases have been reported. Histologically, these lesions have a bizarre appearance, with large and atypical epithelioid and spindle cells, and multinucleate giant cells. Surgical excision is the treatment of choice. Accumulating data suggest lower recurrence rates with Mohs micrographic surgery.

Neurofibromas

Neurofibromas are soft, dome-shaped, flesh-colored lesions that may be located anywhere on the body; they may vary greatly in size, from quite small to large pedunculate lesions. Neurofibromas are derived from the Schwann cells of cutaneous nerves.[84] On histologic examination, they present as nonencapsulated, loose, spindeloid tumors. Solitary lesions may be easily excised. These tumors may be indicative of the genetic neurofibromatosis syndrome, which may be associated with severe neurologic problems as well as a risk of malignant degeneration of the tumor. When a neurofibroma is found, a careful search for other manifestations, which include café-au-lait spots and axillary freckling as well as a family history, should be carried out to rule out the syndrome.

Angiofibroma

Angiofibroma (adenoma sebaceum) is present as part of the genetic syndrome tuberous sclerosis. The autosomal dominant syndrome has variable expressivity; the finding of even one angiofibroma requires genetic counseling, because the patient may pass on a much more severe form of the disease to offspring.[85] Angiofibromas present as small dome-shaped papules, 2 to 3 mm in diameter, that are flesh colored or reddish brown. They are most commonly present on the sides of the nose and the medial cheeks. The original name is a misnomer, because, on histologic examination, no sebaceous components are noted. The tumors are composed mostly of fibrous tissue and have an angioid component. Laser therapy with a 532-nm KTP laser has been shown to be effective treatment with long remission periods, although new lesions develop with time.

Fibrous Papule

The fibrous papule is a common lesion, generally occurring on the nose—especially the alae—in older persons (see Fig. 20-8D). However, it can also be seen on the medial cheeks. These lesions present as small, 0.5-cm, dome-shaped, flesh-colored papules. Although they are rather common, some confusion persists regarding their origin and histologic nature.[86] They have been regarded as perifollicular fibromas, involuting melanocytic nevi, angiofibromas, or simply the result of trauma, such as folliculitis or excoriating pimples. Histologically, the lesion presents as a papule that is composed of numerous spindle-shaped and stellate cells, with occasional multinucleate cells present. Once the lesions have grown, they are generally quite stable and may be present for years; they may be treated by excision or curettage and electrodesiccation. They are of no significance unless related to tuberous sclerosis.

Trichoepithelioma

A trichoepithelioma is an uncommon entity that most often presents as small rounded nodules on the cheeks, eyelids, and nose. It appears to be dominantly inherited; however, pedigrees indicate a greater preponderance of affected females. The lesions are skin-colored to slightly pink and gradually increase, with time, in both number and size. A few telangiectatic vessels may be present, and there may be a slightly translucent quality to the lesions, which may lead to confusion with basal cell carcinoma; however, the lesions rarely ulcerate. If ulceration does occur, basal cell carcinoma should be considered. The histologic appearance of these lesions also closely resembles basal cell carcinoma, and distinguishing between the two is often difficult.[87] There are basophilic cells similar to those seen in basal cell carcinoma. The cells are arranged in masses, which may have fully keratinized centers. Occasionally the presence of a solitary lesion makes differentiation from basal cell carcinoma somewhat more difficult, and, unless definite differentiation toward hairlike structures is present, the tumor should be treated as a carcinoma. When multiple lesions are present, treatment is difficult because of the large number of tumors. Some success has been obtained with dermabrasion or laser resurfacing of the entire affected area.

Cylindroma

Cylindromas are slow-growing appendageal tumors derived from follicular epithelium. They may assume apocrine phenotype and usually present as solitary pink to red dermal nodules on the head, neck, and scalp. They present predominantly in older women with a 9:1 female-to-male ratio. The presence of multiple cylindromas is associated with the Brooke-Spiegler syndrome,[88] in which an autosomal dominantly inherited mutation in the CYLD tumor suppressor gene leads to the development of multiple cylindromas, trichoepitheliomas, and spiradenomas primarily located on the head and neck.[89,90] Multiple cylindromas may literally cover the scalp, resulting in a syndrome called "turban tumors" (see Fig. 20-8E). Individual tumors can reach 2 to 3 cm in diameter. Histologically, these tumors are composed of nests of darkly staining epithelial cells surrounded by a narrow band of hyaline material. The solitary lesion must be differentiated from basal cell carcinoma. Surgical excision is the only treatment. When large areas of the scalp are involved, this may be quite difficult and may require grafting. Although usually benign, cylindromas may undergo malignant transformation with subsequent local invasion and metastatic disease.

Hidrocystoma

A hidrocystoma may be either eccrine or apocrine in origin.[91] In either case, the tumor usually presents as a solitary lesion and is most frequently seen on the face, especially around the eyelids. The lesion consists of translucent nodules with a firm, cystic consistency. The eccrine hidrocystoma is generally from 1 to 3 mm in diameter, whereas the apocrine hidrocystoma may attain a diameter of 1 cm. Both may have a bluish hue. The two types are distinguishable by histologic criteria. Microscopic examination reveals differing cellular detail and secretion patterns for the two types. In either case, treatment is excision.

Syringoma

Syringomas are benign tumors that originate from the eccrine sweat gland duct; they appear more often in women than in men.[92] Syringo-

mas are most commonly located on the face, with the lower eyelids being the most common site. They generally occur in adolescence or early adulthood and may be eruptive or occur in crops. They present as small 1- to 5-mm papules that are usually flesh colored but may be slightly translucent or yellowish. They may resemble trichoepitheliomas, but their location and histology help differentiate them. Histologically, these tumors appear as small nests of cystic ductal structures or as solid epithelial strands, many of which may have a characteristic tail-like projection. They are not associated with underlying abnormality. They do not tend to involute, however, and may present a cosmetic problem when located on the face. They can be treated with a pulsed ablative laser (CO_2 or erbium) or with light electrocoagulation using a fine epilating needle.

Sebaceous Hyperplasia

Sebaceous hyperplasia occurs mainly on the face, particularly the forehead, and represents benign enlargement of the normal sebaceous gland (see Fig. 20-8F). It is frequently called *senile sebaceous hyperplasia*, because it is usually seen in older persons.[93] One or hundreds of lesions may be present. They may be from 2 to 5 mm in diameter, and there is usually a central umbilication. These lesions are soft and yellowish and must be differentiated from basal cell carcinoma. Histologically, they present as hyperplastic sebaceous lobules that are otherwise normal in appearance. They are only a cosmetic problem; solitary lesions can be easily treated with a shave excision, electrodesiccation and curettage, or cryosurgery. When the lesions are numerous, surgical excision is not warranted. Therapy with systemic 13-cis retinoic acid has also been described.

Xanthelasma

Xanthelasmas present on or close to the eyelids as soft, yellowish, irregular papules. They usually appear in middle age and can affect either sex, and they are not often associated with xanthomas elsewhere on the body. Frequently, they are an isolated finding and do not always signify elevated serum triglyceride levels, although each patient should be examined for the existence of such a systemic problem.[94] Histologically, these lesions present as an accumulation of xanthoma cells, which are lipid-laden histiocytes. Treatment is the application of 50% to 65% trichloroacetic acid, light cautery, or excision.

Lipoma

Lipomas are single or multiple benign tumors composed of adipose tissue. They are soft and may be lobulated or rounded and cystic in nature, and they are generally freely movable. Except in rare syndromes, lipomas are nontender. They generally occur on the trunk, but they may also occur on the neck or any other part of the body. Histologically, they present as proliferations of normal-appearing fat cells that may be surrounded by a thin connective-tissue capsule. Single lesions present only cosmetic problems, and they are generally easily excised. Despite attaining sizes of more than 1 inch in diameter, they may often be expressed through a small, 4-mm punch hole.[95]

Treatment Methods and Biopsy Techniques

Excisional Surgery

The shave biopsy is one of the most commonly performed procedures for cutaneous lesions.[96,97] It is a rapid means of removing tissue either as part of therapy or to establish diagnoses. A shave can be performed using various techniques, with the depth of the shave depending on the angle of the blade as it enters the skin. Usually a No. 15 or No. 10 Bard-Parker blade is used. One should remember that the sharpest point of the No. 15 blade is the rounded tip, whereas the No. 10 has its sharpest edge along the belly of the blade. The shave should be performed using the sharpest portion of the blade. One of the sharpest blades is the Gillette Blue Blade; it is excellent for shaving lesions. A blade breaker or hemostat can break the Blue Blade into any size or shape desired. The blade can then be held between the thumb and forefinger and flexed, thereby allowing for the performance of a superficial shave in which the blade sculpts along the contour of the surface being excised (e.g., the ala of the nose or the helix of the ear). Hemostasis can then be achieved with aluminum chloride. Monsel's solution (ferric subsulfate) should be avoided on the face or cosmetic areas because of the ability of macrophages to phagocytose the iron, thereby causing a tattoo.

The punch, a fixed-diameter surgical knife, is an extremely valuable tool to a dermatologist for excision or biopsy. It comes in various sizes, from 2 mm to 1 cm, with 0.5-mm increments. Punches can be purchased as disposable instruments (Baker) or as permanent, sterilizable instruments. The most common sizes used for biopsy are 3 mm and 4 mm; however, a 2-mm punch can provide a cosmetically elegant biopsy of sufficient size for the pathologist. Whenever possible, the 4-mm punch should be used. All punch-biopsy incisions should be closed. Some tricks help with the use of a punch. By putting tension on the skin perpendicular to the anticipated line of closure (skin tension lines), one can cause the circular punch to leave an oval or ellipse for easier closure. The incision is usually closed with sutures or the recently introduced single-shot staple. A valuable trick is to use a punch to excise intradermal nevi. By selecting a punch that just fits around the nevus, one can easily excise it to the depth necessary to remove the entire lesion. Another trick, which can be used when nevi occur in areas of neutral skin tension or where skin tension lines are not obvious (e.g., the chin), is to use the punch to help determine the best lines of closure. If the surgeon uses a punch excision with no tension placed on the skin, the resulting circle will usually form itself into an oval along lines of facial expression and help in the determination of skin closure lines. Often the skin closure lines can occur at an angle that is perpendicular to what one might expect.

The wedge excision or biopsy, which is a variation of the fusiform excision (ellipse), can be used to remove lesions cosmetically or to perform biopsies. As a biopsy technique, it is either incisional or excisional. Whenever possible—especially when dealing with pigmented lesions—the excisional biopsy is preferred to give the pathologist the best chance for an accurate diagnosis. When the wedge procedure is performed as an incisional biopsy of a large, nodular lesion, the narrowest possible wedge (greater than the classic 3:1 length-to-width ratio) is made at the edge of the lesion so that one end of the wedge is through normal skin; then one side of normal skin is available through which to pass suture. This is an especially important advantage if the other side of the wedge is within friable tissue.

Scissors excision is a valuable method of cosmetically removing benign skin tumors. In the experienced hand, scissors can be used to produce an often-elegant cosmetic result very quickly. Scissors are best used on raised, pedunculate skin lesions in which the pedicle can be easily and rapidly cut with scissors. Our preference is to use fine-tipped, curved Iris or Gradle scissors. Tricks similar to those used for the shave biopsy apply to scissors excisions. Raising a bleb of anesthesia under a pedunculate lesion allows for better access to the base. Scissors are an excellent tool around the eyelids. Often a small chalazion clamp can be placed around a lesion, thereby permitting easy excision with fine scissors. Filiform or pedunculate lesions on the eyelids can be lifted with fine forceps and then cut with curved scissors. This procedure produces a small ellipse upon release of the eyelid skin, which either heals by itself or with the placement of one small stitch. Scissors can also be used for biopsies of oral mucosa. Again, a chalazion clamp can be placed on the lip, or a stitch can be placed around the area of the biopsy. One can then pull up on the stitch, thus creating a tent of tissue that can be scissors excised at the base to obtain a biopsy specimen.

A curet is a valuable tool to the skin surgeon. One should have a variety of sizes of curets available; larger curets are used to debulk or remove larger tumors, and smaller curets are used to do the same for small tumors or to help track small extensions of cutaneous tumors, such as basal cell carcinoma. A curet is held like a pencil, with the ring or small finger placed on the skin to anchor and stabilize the hand. Normal skin has a "gritty" feel with the curet, whereas abnormal skin or tumor often feels mushy or soft. One way to remove multiple molluscum contagiosum lesions on the face, for example, is to individually curet each small lesion (a small curet is used). If anesthesia is required, one can use either the usual local anesthetic or one of the refrigerant anesthetics, which both induces some anesthesia in the skin and hardens the lesion; hardening allows the lesion to be easily flicked off with a curet. A curet is often used in conjunction with electrosurgery.

Electrosurgery

Electrosurgery is a useful way to remove small benign lesions, to assist the curet with the removal of malignant lesions, and to assist the surgeon with the obtaining of hemostasis. Most electrosurgery performed in the office requires nothing more than a hyfrecator-like unit. This versatile instrument is easy to use because the patient does not need to be grounded, and the electrodesiccation or fulguration is at a more superficial depth than the electrocoagulation or cutting seen when a patient is grounded. Most of these electrosurgical units have two current settings. The low current is best for light electrodesiccation of benign lesions. One can also purchase a fine steel tip or place a 30-gauge needle on the standard tip; this tip can then be threaded down adnexal structures to treat benign adnexal tumors or to coagulate arterial vessels that are feeding vascular lesions. The high current setting, which is a more destructive mode, is used to burn tumor and surrounding tissue, such as during electrodesiccation or fulguration of basal cell carcinomas. Bipolar units, with the patient grounded, can be used to help sculpt lesions, such as in the case of a rhinophymatous nose.

Cryosurgery

Cryosurgical removal is the treatment of choice for many lesions. Systems vary from elaborate cryospray and cryoprobe units to something as simple as a Styrofoam cup containing liquid nitrogen to be applied with a cotton-tipped applicator. The superficial use of cryosurgery destroys tumor tissue, often with excellent cosmetic results. Hypopigmentation and other sequelae can develop, however, which make the use of cryosurgery in darker skin more difficult.

Chemical or Abrasive Surgery

Many superficial cutaneous lesions of the head and neck can be removed with the application of a chemical or with the use of abrasion. The chemicals most commonly used as peeling agents are trichloroacetic acid and phenol. The concentration of trichloroacetic acid used varies from 35% to 70%. Phenol is usually used as a concentrated solution (88%) or mixed as Baker's solution. These chemicals can be used to peel benign pigmented or melanotic lesions, with good success. The most common form of abrasion is spot dermabrasion. Our favorite tool is the Bell hand engine with the diamond fraise or wire brush. The fraise can be purchased in varying sizes and shapes; small, 2-mm wheel, cone, or cylindric fraises are excellent tools for removing multiple small epithelial tumors.

Laser Surgery

The use of lasers in surgery and medicine has rapidly advanced in recent decades and continues to play an important role in the treatment of many cutaneous neoplasms on the head and neck. Innovations in optical technology have allowed for improved therapeutic efficacy and safety and the ability to treat patients with an increasing number of medical and aesthetic indications. Advances in visible and near infrared lasers and broadband light sources, including the development of longer pulse durations, broader spectrums, and combined wavelengths, continue to improve the treatment of numerous benign vascular and pigmented lesions. Far infrared lasers including CO_2 and erbium:YAG lasers remain a useful tool for the safe and effective treatment of numerous benign epidermal lesions, and can be the treatment of choice for some premalignant epidermal lesions, including actinic keratoses and actinic chelitis.[98,99] They may have a role in the treatment of some in situ carcinomas, although they may be less suitable without the evaluation of tissue margins. The basic principles of laser surgery are discussed in detail in Chapter 3; specific use of lasers used to treat vascular lesions is discussed in Chapter 201.

CHAPTER TWENTY-ONE

Scar Revision and Camouflage

J. Regan Thomas

Steven Ross Mobley

Key Points

- The ideal scar is narrow, flat with surrounding skin, parallel to the relaxed skin tension lines (RSTLs), or camouflaged within natural anatomic lines.
- Available scar revision techniques include excision, irregularization (including Z-plasty, W-plasty, and geometric broken line closure (GBLC), and dermabrasion.
- Adjunctive techniques include steroid injection, silicone sheeting, and cosmetics.

The head and neck is a prominent part of the human body and can frequently be injured as a result of trauma, burns, or surgery. With superficial injuries, most facial wounds will heal with little to no scar formation. However, once the reticular dermis has been violated, some amount of residual scarring is destined to occur. Several factors that are beyond the surgeon's control can affect the final appearance of the scar, including the mechanism of injury, position of the wound, health status of the patient, the patient's skin type, and the tendency to form robust scars. Factors that are under the surgeon's control include proper realignment of wound edges, conservative débridement of injured tissues, meticulous handling of tissues during primary repair, and aesthetically favorable alignment of scars whenever possible.

After complete maturation and healing, an ideal scar should be flat and level with the surrounding skin, a good color match with the surrounding skin, narrow, parallel to the RSTLs (Fig. 21-1) or on the border of aesthetic facial subunits, and without straight, unbroken lines that can be easily followed with the eye (Fig. 21-2).[1] Scars with aesthetically unfavorable characteristics include those that are wide or misaligned with relaxed skin tension lines or aesthetic subunits, and those that are thickened, hypertrophied, or keloid (Fig. 21-3).[1] The facial plastic surgeon has many options to improve, but not eliminate, these aesthetically unfavorable scars. Successful application of various treatments requires an understanding of which techniques are best indicated when performing scar revision or treating hypertrophic and keloid scars.

Successful scar revision begins with a precise analysis of both the scar and the patient's expectations. Patients often have the false perception that plastic surgery can make an existing scar invisible. The surgeon should educate the patient on the true realistic goal of surgery, which is to modify the scar to a point of maximized camouflage within the natural shadows, lines, and borders that exist within the head and neck.

Indications for Revision

The surgeon should first begin with a detailed analysis of the scar. Experience has shown that many scars that are narrow, well positioned along aesthetic subunit borders, or in parallel with RSTLs will continue to mature, improve, and become less noticeable over a period of 12 to 36 months.[2]

More commonly, patients will have scars that are amenable to improved surgical camouflage. Indications for scar revision include scars that are (1) widened, (2) perpendicular to RSTLs, (3) webbed, (4) pin-cushioned, (5) long and linear and misaligned with RSTLs, (6) hypertrophied, (7) interrupting an aesthetic unit of the face, (8) adjacent to, but not lying within, a favorable site, or (9) causing distortion of facial features or anatomic function. Many of these scars should be considered for revision after the first 60 to 90 days of scar maturation has occurred. In fact, early revision with realignment of the scar may allow it to mature more rapidly.

Numerous techniques are available when planning scar revision. This chapter organizes the techniques into the following categories:

1. Excision
2. Expansion with excision
3. Irregularization
4. Dermabrasion
5. Steroids
6. Silicone sheeting
7. Adjunctive

Excision

A cardinal principle of surgery is that the best treatment of any complication is primary prevention. For scar revision, this translates into the use of proper technique when closing any wound primarily. When presented with wounds that were not closed properly, re-excision with meticulous closure may be all that is needed. Re-excision should be done by use of fusiform shape with 30-degree angled ends positioned within RSTLs when possible (Figs. 21-4 and 21-5). A slight vertical bevel outward from the original scar will prepare the wound edges for proper everted closure. Routine undermining of 1 to 2 cm around the periphery of the wound allows reapproximation of the skin edges with minimal tension. The use of buried subcutaneous sutures further decreases wound edge tension. Final eversion of the wound edges is achieved with properly placed monofilament interrupted sutures. Vertical mattress sutures can also prove helpful when wound edge eversion needs to be maximized.

Figure 21-3. Scar on right cheek with unfavorable characteristics: depressed and not in alignment with relaxed skin tension lines.

Expansion with Excision

Serial Excision

Wide scars, birthmarks, and skin grafts with poor match to surrounding tissues can all be candidates for serial excisions. In some ways, this is a variant of tissue expansion in that scarred skin is excised and adjacent normal skin brought into the defect area. Like tissue expansion, this technique relies on the skin's biologic creep (ability to stretch over time) and is limited by the given amount of stretch attainable during each excision. Typically, older patients and those with increased skin laxity will require fewer excisions than younger patients with increased skin tone. As with all techniques of scar revision, the patient must be well informed as to the proposed number of excisions and must understand that serial excision can require months to years to complete.

Tissue Expansion

When treating larger scars, the best camouflage is afforded when abundant amounts of similar-appearing tissue can be brought into the repair. Tissue expansion can be a powerful tool to help create excess amounts of surrounding tissue. Tissue expanders are available in a variety of shapes and sizes. Studies on the gain of surface area afforded by the three most commonly shaped expanders have determined that rectangular expanders provide the greatest expansion at 38%, crescent-shaped expanders provide 32%, and round expanders provide only 25%.[3] As a general rule, the base of an expander should be approximately 2.5 to 3 times as large as the area to be reconstructed.[4]

The effects of tissue expansion on skin have been debated. Is new skin actually produced or is the existing skin simply thinned and stretched? The currently accepted understanding regarding tissue layer expansion is that (1) the epidermis is thickened, (2) melanin production increases, (3) mitotic activity increases, (4) dermis thins (30% to 50%), (5) collagen synthesis is enhanced, (6) hair follicle number remains unchanged, (7) hair density decreases, (8) muscle thins and can atrophy, and (9) blood vessels proliferate.[5] Interestingly, epidermal changes and increased melanin production seen during expansion resolve a few months after surgery.

Implantation of the expanders must take into account the neurovascular supply and final positioning of the skin to be transferred. A second pocket is created for the injection port, which should be several centimeters away from the expansion device and in an area that is easily accessed. Expander systems with external injection ports may be needed in select patients. A 23-gauge or smaller needle is used to inject the expander. Expansion can proceed until the skin blanches or the patient complains of discomfort. Intervals between injections can be from 4 to 14 days, ideally two to three times per week. By properly selecting the correct expander device and understanding the principles of tissue expansion, reconstruction of larger and more complex scars can be successfully achieved.

A critical point of understanding for the clinician is the temporary psychological toll that is placed on the patient undergoing expansion. Tissue expanders can cause impressive disfigurement of the head and neck, which naturally results in significant emotional stress to the patient (Fig. 21-6A). Repeated acknowledgment and affirmation of the patient's uneasy feelings regarding the appearance of the expanders help support the patient throughout the expansion process. It is helpful to remind the patient that the disfigurement is temporary and that the

final reconstruction will warrant the time spent dealing with the expansion devices (see Fig. 21-6B).

Irregularization

The human eye is more likely to perceive scars that are long, linear, and not in alignment with RSTLs and aesthetic subunits. To best camouflage these types of scars, the three most common techniques are Z-plasty, W-plasty, and geometric broken line closure (GBLC). All three of these techniques convert linear scars to irregularized zigzagged scars that are less noticeable to the casual observer. When irregularization alone is needed, GBLC and W-plasty are the treatments of choice. However, when both irregularization and lengthening of the scar are needed, a Z-plasty technique is the technique of choice.

Z-plasty

The Z-plasty is one of the oldest and simplest techniques for scar irregularization. A "classic" Z-plasty involves the transposition of equilateral 60-degree triangles (Fig. 21-7). When these triangular flaps are transposed and closed, the original direction of the scar is rotated, and the scar is lengthened by 75%. When lesser amounts of lengthening are required, a 30-degree or 45-degree Z-plasty can be used that will lengthen the scar by 25% and 50%, respectively. Longer scars may benefit from multiple Z-plasties. This can be particularly helpful when correcting scar contractures along anatomic concavities. Consecutive Z-plasties allow for the redistribution of forces more evenly along the entire length of the scar and help camouflage the scar into the surrounding RSTLs (Fig. 21-8). Another common indication for multiple Z-plasties is when wounds or skin flaps have healed with a "pin-cushioned" appearance. Placing several small Zs around the perimeter of the wound allows interdigitation of flap with surrounding skin (Fig. 21-9). The resultant interdigitated skin edge provides excellent camouflage, especially if it is later treated with light dermabrasion.

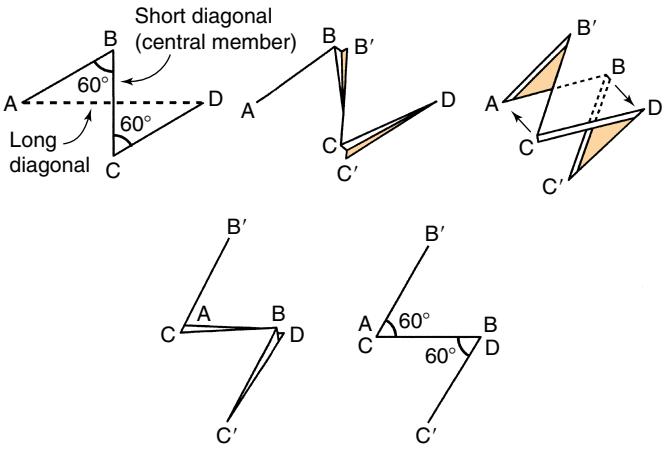

Figure 21-7. Classic equilateral triangle 60-degree Z-plasty. *(Adapted from Thomas JR, Holt GR.* Facial Scars, Incisions, Revision & Camouflage. *St. Louis: Mosby; 1989.)*

W-plasty

The most common application of W-plasty is when several Ws are used in series in a technique originally described by Borge as "running W-plasty." This is a useful irregularization technique that often uses shorter limbs compared with Z-plasty and does not create lengthening of the scar.

The technique begins with the marking out of a series of consecutive triangles (Ws) along the wound or scar edge. The arms should be between 5 and 7 mm in length, and one arm of the triangle should be drawn in parallel to the RSTL (Fig. 21-10). After excision of the triangles, superficial undermining of adjacent tissues is performed, and the triangular shaped flaps are then imbricated. Care should be taken to preserve the subcutaneous scar tissue, because this can provide a stable bed for new scar healing. These wounds are also amenable to postoperative dermabrasion to further camouflage the wound.

Geometric Broken Line Closure

GBLC is an excellent technique of scar revision that creates an "irregularly irregular" scar without affecting its length. The geometry of the resultant scar is less predictable by the casual observer's eye and frequently goes unnoticed. This technique is particularly well suited to scars that traverse broad flat surfaces such as the cheek, malar, and forehead regions (Fig. 21-11).

The design of a GBLC is a series of random, irregular, geometric shapes cut from one side of a wound and interdigitated with the mirror image of this pattern on the opposite side (Fig. 21-12). As in running W-plasty, the length of the geometric shapes is between 5 and 7 mm. Principles of undermining and leaving deeper scar tissue in the bed of the wound are similar to those previously described. Two-layered closure is performed, and the suture line is often reinforced with adhesive medical strips. The patient is typically seen back in 1 week for suture removal, with repeat taping of the wound edges for the next 2 weeks.

Dermabrasion

Dermabrasion is a method of controlled superficial skin ablation useful for smoothing out surface contour irregularities and softening the appearance of suture lines after primary closure or irregularization. We routinely use dermabrasion as a preplanned adjunctive procedure to any irregularization scar revision procedure. Dermabrasion is best per-

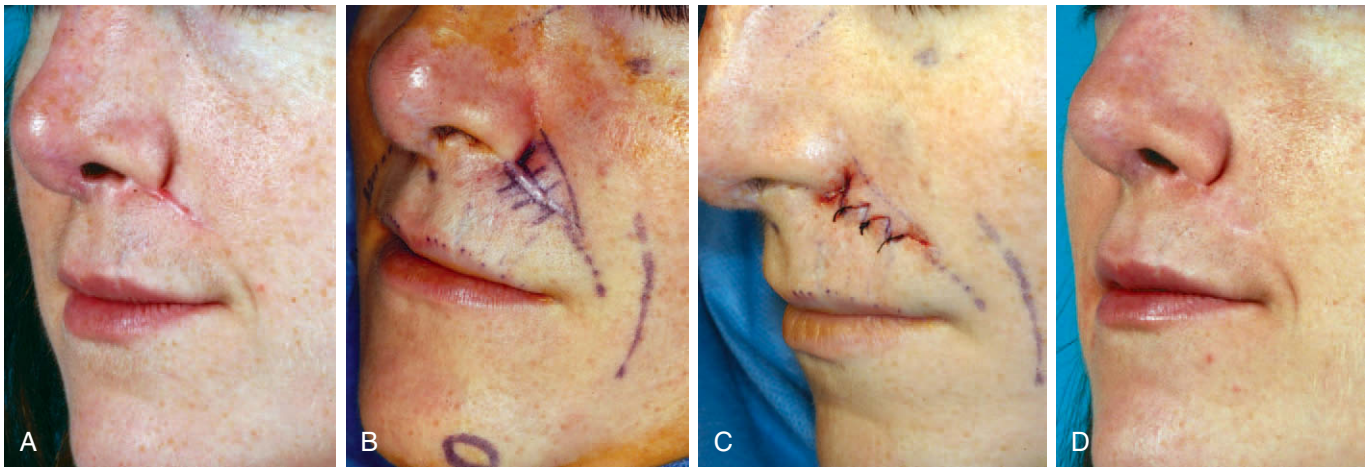

Figure 21-8. A, Preoperative appearance of scar on upper lip region. **B,** Operative plan for multiple Z-plasty technique. **C,** Appearance after transposition of Z-plasty. **D,** Postoperative appearance.

formed at the 6- to 8-week interval. There is evidence to suggest that rewounding during fibrillogenesis (i.e., 4 to 8 weeks after injury) may promote reaccumulation of hyaluronic acid in the wound matrix, thereby stimulating more epidermal cells to migrate and proliferate in the wound, improving the final appearance of the scar.[6]

The best candidates for dermabrasion are those with lighter complexions, because the risk of postabrasion dyspigmentation is lowest in these individuals. It is prudent to avoid dermabrasion in patients with human immunodeficiency virus or hepatitis because of the risks to health care personnel from airborne pathogens. The use of 13 cis-retinoic acid and its effect on healing after dermabrasion has been debated in the literature. Conflicting reports exist, and until the controversy is resolved, prudence would suggest waiting 6 to 12 months before performing dermabrasion on anyone with a prior history of 13 cis-retinoic acid use.[7,8] Patients with a history of herpetic infection should be placed prophylactically on antiviral therapy. Others have advocated placing all patients on prophylactic antivirals.[6]

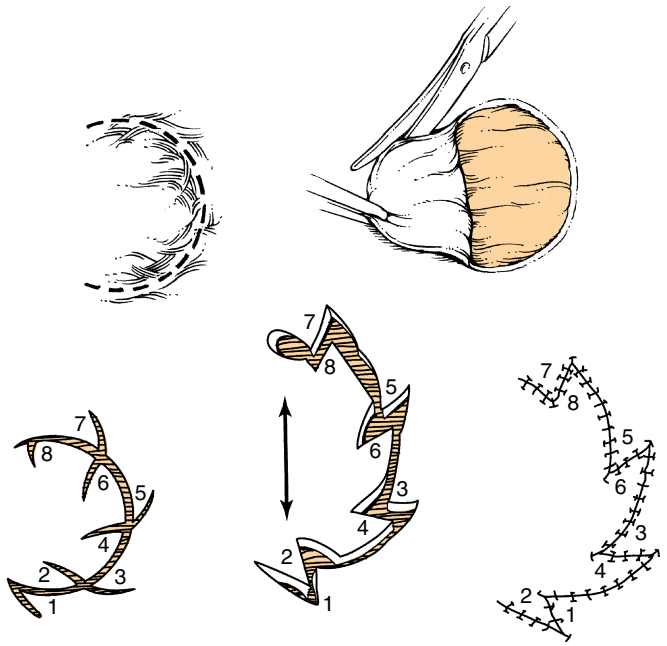

Figure 21-9. Multiple small Z-plasties to improve the appearance of circumferential or pin-cushioned scars. *(Adapted from Thomas JR, Holt GR.* Facial Scars, Incisions, Revision & Camouflage. *St. Louis: Mosby; 1989.)*

Diamond fraise bits are preferred, because they are easier to control and remove the skin less aggressively than wire brush fraises. The handpiece is generally held 90 degrees to the direction of wheel rotation and is advanced at right angles to the direction of wheel rotation (Fig. 21-13). Preparation of the area to be dermabraded can be accomplished with local anesthesia both for nerve block and infiltration. Infiltration not only provides anesthesia but can also cause distention of the skin, which aids in the technique. Preferably, local anesthetic without epinephrine is used to allow for more clear visualization of capillary bleeding that is seen with dermabrasion. As one enters the superficial papillary dermis, small capillary loops are identified as pinpoint bleeding. As the papillary dermis is penetrated more deeply, small parallel strands of white-colored collagen can be appreciated. Once this is seen, dermabrasion is taken to the appropriate depth. Preservation of the reticular dermis with its adnexal structures allows for the proliferation of undamaged epidermal cells across the abraded surface. The periphery of the treated area should be feathered with fine diamond fraises to allow for a smooth transition between treated and untreated areas.

Immediately after treatment, an occlusive dressing such as polyethylene oxide hydrogel (Vigilon) is applied. This is left in place for 48 hours, and then the patient is instructed to keep the area moist at all times with bacitracin for the next 7 to 10 days. After that, the patient can use a thick moisturizing lotion such as Eucerin. Re-epithelialization is usually accomplished after 5 to 7 days, but post-treatment erythema can often take 2 to 3 months before resolution (Fig. 21-14). This should be clearly communicated to the patient before the procedure. Women are usually less bothered by this, because they can begin to cover the area with make-up once re-epithelialization is complete.

Steroids

Intralesional corticosteroids can be an effective adjunct in the treatment of healing wounds, hypertrophic scars, and keloids. Steroid injections

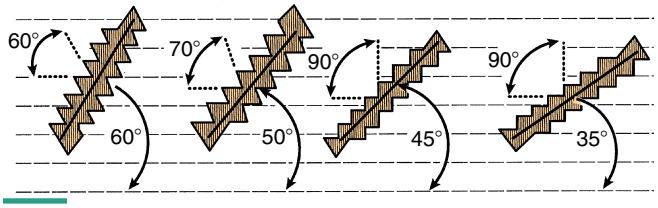

Figure 21-10. Running W-plasty with one area of triangle aligned in parallel with relaxed skin tension lines (RSTL). As scar inclination decreases, the degree of the angles should be increased to keep one arm of the triangle aligned with RSTL. *(Adapted from Thomas JR, Holt GR.* Facial Scars, Incisions, Revision & Camouflage. *St. Louis: Mosby; 1989.)*

into areas of scar revision can be useful when persistent tissue edema detracts from the wound's appearance. Small doses of triamcinolone (10 mg/mL) injected into the dermis or the dermis subcutaneous junction can provide the surgeon with an ability to "sculpt" an otherwise normally healing wound and hasten the resolution of edema. For example, intralesional steroids can help lessen the "pin-cushion" edema seen frequently in local flap reconstruction techniques such as bilobed flap repair (Fig. 21-15). Steroids can cause hypopigmentation and telangiectasias when injected in higher concentrations into the dermis. One should avoid the injection of steroids into the subcutaneous fat, because this can lead to deformity from fat atrophy. Judicious use and conservative clinical judgment are usually all that is needed to prevent these untoward events.

Topical steroids can also be used when one is trying to diminish minor wound erythema that can be a normal part of the healing process. This has an application in younger patients and those with more sebaceous skin who are prone to erythematous wounds. Also, after dermabrasion of other resurfacing procedures, short-term low-dose topical steroids can be applied after re-epithelialization is complete.

Silicone Sheeting

The topical application of silicone gel sheets to the surface of keloids has been shown to be beneficial to the improvement of scars. Ohmori[9] studied the effects of silicone sheeting on 46 patients with 48 keloids in all areas of the body. By use of a study-defined grading scale, he reported excellent and good results in 60% of patients and fair to poor results in 40%. Katz[10] investigated the use of silicone sheeting for both

keloids and hypertrophic scars. Fifty-six percent of keloids demonstrated measurable improvement. Zero of five patients with a history of hypertrophic scarring had recurrence of their hypertrophied scars after excision and postoperative silicone sheeting. Typically, patients are encouraged to wear the silicone for a minimum of 8 to 12 hours per day and to use it for 6 to 12 months. The use of topical silicone sheets should be considered in any scar that is not ideal secondary to being slightly raised or possessing hyperpigmentation.

The biophysical properties of silicone sheeting have been studied, but still the mechanism by which silicone sheeting may improve scar healing is not well characterized.[11,12] Changes in pressure, temperature, and oxygen tension have all been studied and found to be negligible. Silicone sheeting has been shown to increase scar hydration by reducing evaporation by more than 50%. This is postulated to cause a decrease in capillary activity and perhaps collagen deposition. It can be stated with reasonable confidence that silicone sheeting seems to have a favorable effect on wound healing and exposes the patient to little or no morbidity from the treatment.

Adjunctive Procedures

Cosmetics and Hairstyling

Although not routinely thought of as part of the medical management of scar revision, cosmetics and hairstyling can play an important role in these patients. Surgeons who routinely perform scar revision are encouraged to seek out aesthetic professionals in their area that have interest in helping with the care of these patients. The physician's familiarity with these adjunctive professional services is often met with great pleasure by the patient who is eager to look normal and regain confidence in his or her appearance.

CHAPTER TWENTY-TWO

Facial Trauma: Soft Tissue Lacerations and Burns

Justin D. Hill

Grant S. Hamilton, III

Key Points

- Examination and repair of facial soft tissue trauma must be systematic and thorough.
- Treatment of traumatic injuries is often a process of restoring facial appearance and function rather than a single procedure.
- A high index of suspicion and careful examination are required to rule out potentially occult injuries to the facial nerve, parotid duct, canalicular system and underlying maxillofacial skeleton.
- Identification and repair of facial nerve and parotid duct injuries should be done as soon as possible.
- Adequate anesthesia is essential for optimal repair and may be established through direct infiltration, topical application, or regional blocks.
- Pediatric patients may require sedation but often respond favorably to a graduated approach, a calm demeanor, and gentle technique.
- Eversion of wound edges is critical to the favorable appearance of a scar and is best accomplished with appropriately placed vertical mattress sutures.
- Microvascular replantation of well-preserved tissue avulsions and amputations of the nose, ears, lips, and scalp is a proven option for severe injuries to these unique structures.
- Salivary fistulas and sialoceles resulting from parenchymal injuries often respond to conservative therapy. Surgical repair of ductal injuries is the preferred method of treatment.
- Favorable outcomes in facial burns depend on aggressive wound care followed by early excision and grafting.
- Rapid rewarming is the most important component of frostbite injury treatment.

Traumatic injuries to the soft tissues of the head and neck are a common problem encountered by otolaryngologists. Whether these patients present acutely or after a delay, it is important to follow specific principles and a systematic approach to assessment and repair. An optimal outcome requires a combination of technical expertise and an ability to gain the confidence of patients and families affected physically and psychologically by traumatic injuries. The ultimate goal of treatment should be a repair that is acceptable to both the patient and the physician and that most closely approximates preinjury appearance and function. For some patients, repair of their injuries is a single event; for others, it is a process, requiring patience, forethought, and excellent rapport. Facial trauma often occurs in the setting of other, potentially more serious injuries and is therefore prone to benign neglect, requiring vigilance on the part of the treating physician to ensure that every patient is treated appropriately.

Etiology

The most common causes of traumatic injuries to the face include motor vehicle accidents, interpersonal violence, activities of daily life, sports-related injuries, work-related injuries, and bites, both human and animal.[1,2] Although generalized facial trauma, including bony trauma to the maxillofacial skeleton, is more common in men than women at approximately a 2:1 ratio, soft tissue facial trauma appears to have no distinct sex predilection and occurs in a wide range of ages, although the majority of injuries occur during the first 3 decades of life.[3] Motor vehicle accidents are a common cause of facial injuries, affecting approximately 50% of survivors. The use of seatbelts alone, or in combination with airbags, has been shown to reduce the frequency and severity of facial injuries; however, airbags alone have not demonstrated the same benefit.[4]

Approach to Traumatic Injuries

History

Every clinical encounter begins with an accurate and thorough history followed by a detailed physical examination. The approach to patients with facial trauma is no different. However, because these patients often have a wide range of concomitant injuries, access to the patient for a history and physical examination may be limited on initial presentation. Multiply injured patients require systematic evaluation according to Advanced Trauma Life Support (ATLS) protocol. Patients with severe or life-threatening injuries to the chest, abdomen, or extremities present a unique challenge. A cursory head and neck examination by first responders and even other physicians may reveal seemingly uncompli-

cated facial injuries, which when evaluated carefully demonstrate significant structural or functional compromise such as a facial nerve or parotid duct injury, lid laceration with exposed cornea, retained foreign bodies, or canalicular injury. Every possible attempt to gain an accurate history and perform a complete examination should be made before opportunities for optimal repair are missed.

An often neglected component of the history is premorbid appearance and function. It should not be taken for granted that a patient with facial weakness on examination had normal facial nerve function before the injury. Details like this must be obtained to prevent unnecessary workup and treatment. If possible, it is helpful to have a photo of the patient from friends or family when significant disfigurement occurs. Even a driver's license photograph may be helpful. Although a photograph may not change overall management, it does provide a frame of reference for patient and family expectations of repair and gives the surgeon an opportunity to better see the patient as a person rather than as another injured face.

The social context in which injuries take place is as important as the physical context. Injuries from interpersonal violence make up a large component of facial trauma. Assault and abuse victims may not volunteer the mechanism or the assailant without confidence that the health care system will protect them from immediate and future harm. Depending on their age and development, children may not be able to volunteer details of abuse, requiring a thorough history from parents or caregivers and witnesses in an effort to identify discrepancies. More than 50% of victims of child abuse demonstrate injuries to the face, although injuries to the face alone are not sufficient to suspect abuse.[5] Abuse should be suspected when the described mechanism does not fit the injury pattern or when the child displays signs of abuse elsewhere.

A detailed history of the mechanism is crucial. The traumatic event should be reconstructed as accurately as possible, including time, location, involved parties, degree of contamination (e.g., dog bite or clean laceration from a sharp object). In motor vehicle injuries, pertinent components include speed of impact, the victim's use of a seatbelt or helmet, deployment of airbags, whether the victim was ejected from the vehicle, the presence of broken glass, chemicals, or fire at the scene, and the involvement of drugs or alcohol. In injuries resulting from tripping or falls, it is important to ascertain the height of the drop, the nature of the landing area, and whether the patient struck any objects. The level of consciousness during and after the injury should always be determined. In cases of assault, the type of weapon, information about the assailant, and any prior history of assault should be determined.

Assurance of tetanus prophylaxis is imperative. Tetanus-prone wounds are typically deep lacerations, avulsions, or puncture wounds contaminated with soil, feces, saliva, or mineral debris. If the immunization status is unknown or if the patient has not completed the series of tetanus immunizations, tetanus immunoglobulin (TIG) and vaccine (tetanus toxoid) should be administered. All other patients who have completed a primary immunization series should receive toxoid unless they have had a booster or completed the series within the last 5 years.[6]

Physical Examination

Many soft tissue injuries to the face occur in the setting of underlying trauma to the maxillofacial skeleton, and a thorough examination must be performed with this in mind. Although the focus of this chapter is on injury to the soft tissues, an adequate evaluation of facial trauma includes an assessment to rule out fractures. A systematic approach is essential to prevent errors, both in diagnosis and management. Every practitioner caring for a trauma patient is obligated to follow ATLS protocol regardless of that caregiver's role in treatment.[7] An orderly approach using the ABCDE mnemonic with primary and secondary surveys assures that the most threatening conditions are dealt with first and that nothing is missed. A seemingly innocuous forehead laceration in the emergency department triaged quickly to the "facial trauma service" may mask occult intracranial or cervical spine injury depending on the mechanism—something that could be missed by simply focusing on fixing the laceration rather than treating the patient. Vigilance must be exercised in patients transferred from other institutions, and experienced surgeons recognize that an assessment from a transferring provider may not be an adequate substitute for their own careful examination.

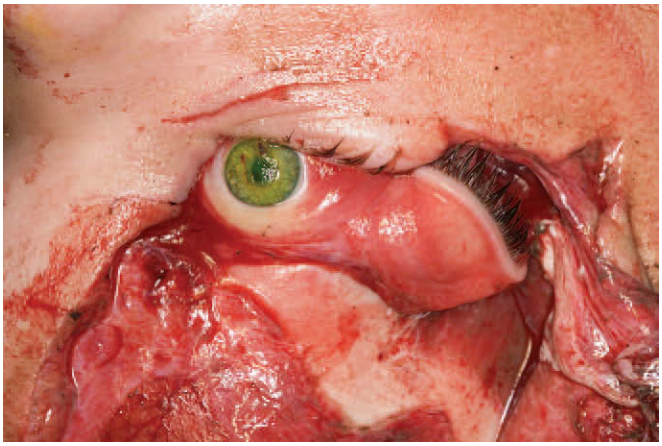

Figure 22-1. Complex laceration involving the eyelids resulting in exposure of the globe. This wound demands immediate attention to prevent corneal exposure and ocular injury.

The examination begins with careful investigation of problems with airway, breathing, and circulation—immediate or impending. Airway compromise is rarely associated with superficial soft tissue trauma alone; however, severe hemorrhage with collection of blood in the upper airway can rapidly compromise airway, breathing, and circulation, particularly in a combative or obtunded patient.[8] The airway is secured by controlling hemorrhage with direct pressure or identification and ligation of the injured vessel. This must be performed with caution, however, to avoid injuring other important structures such as the facial nerve or parotid duct in attempts to quickly stop hemorrhage by clamping a bleeding vessel in the wound bed. Another injury requiring immediate intervention is that of corneal exposure from eyelid laceration or avulsion. Immediate corneal protection prevents potentially devastating ocular injury (Fig. 22-1).

A general assessment of surface anatomy includes assessing the scalp and facial features in repose to evaluate for asymmetries that suggest underlying skeletal or neurologic injury. The remainder of the examination is conducted systematically. The exact order of the examination is unimportant, but the same sequence should be used every time to ensure a comprehensive assessment of injuries. Facial bones are palpated for deformities, step-offs, and mobility including the entire skull, orbit, zygoma, maxilla, palate, and mandible. Computed tomography (CT) scans and plain films are not an adequate substitute for this examination. Whereas most traumatic soft tissue injuries to the face are often obvious on initial inspection, certain areas require careful examination to rule out more significant injuries. Otoscopy often demonstrates a blood-filled canal in patients with facial lacerations who are transported supine. After removal of blood and debris, closer inspection may reveal lacerations in the ear canal in the setting of a skull base fracture even in the absence of hemotympanum. A thorough examination of the eyes and periorbital areas includes the medial canthus, fornix, conjunctiva, cornea, and orbital rims. A careful examination of these areas is even more crucial in an obtunded patient who cannot volunteer symptoms of visual loss, ocular or conjunctival foreign body, or diplopia. When there are lacerations of the upper or lower eyelids in the medial canthal region, one must rule out disruption of the lacrimal apparatus. The long-term sequela of canalicular disruption with subsequent blockage of a tear drainage pathway into the nose is epiphora and is not present on initial examination. A positive fluorescein instillation test (Jones test) effectively rules this out, although probing the lacrimal punctum and ducts with lacrimal probes while examining the wound before repair is safe, reliable, and relatively straightforward. Every patient should have visual fields tested, and motility and acuity assessed and documented. Patients with any periorbital or ocular trauma should also be evaluated by an ophthalmologist for a full examination, including a dilated retinal examination.

All examination findings, both positive and negative, should be documented, including the time at which the findings were noted. Simple omissions in the medical record can lead to significant difficulties in ongoing diagnosis and management in addition to unnecessary medicolegal liability.

Anesthesia

Complete assessment of wounds is often only possible after establishing adequate anesthesia. Additional patient discomfort during wound exploration and repair is unnecessary and creates an adverse environment for a technically successful repair. Comfortable working conditions for both the patient and the physician can generally be established with local anesthetics through topical application, infiltration, or nerve blocks of the trigeminal distribution. Lidocaine, with or without epinephrine in concentrations from 0.5% to 2%, is a commonly used agent for infiltration or regional block. Lidocaine is well tolerated by nearly all patients with minimal side effects and a safe dosing range.[9] Widely quoted maximum doses for local anesthetics actually have little basis in human studies or evidence-based medicine and are largely extrapolated from animal data and case reports of toxicity.[10] These theoretical guidelines suggest that toxicity from lidocaine, in the form of central nervous system disturbances (e.g., seizures or cardiac dysrhythmias), will develop with doses greater than 5 mg/kg of patient body weight or 7 mg/kg if epinephrine is added. Toxicity, however, is probably multifactorial, taking into account fluid status, age, site of injection, medical comorbidities, and other injuries.[11] Even so, in the multiply injured patient requiring repair at separate sites by more than one practitioner, the aggregate dose of local anesthetic should be tracked and documented by all parties involved to avoid toxicity. In children, doses may be inadvertently high because of the patient's smaller body mass.

Lidocaine alone has a modest vasodilatory effect on capillaries and can impair hemostasis during closure. The addition of epinephrine in a dilution of 1:100,000 to 200,000 encourages hemostasis and mitigates systemic absorption but requires caution in certain circumstances. Dense infiltration of macerated wound edges or long, tenuous flaps of avulsed skin with epinephrine may compromise otherwise salvageable tissue and should be avoided. The need for local infiltration can be markedly reduced or obviated by a well-performed regional block. Physicians involved in the treatment of soft tissue trauma should become facile with their use. Near-total anesthesia of the face for soft tissue work can be accomplished by selective blocks of the infraorbital, supraorbital/supratrochlear, zygomaticotemporal, zygomaticofacial, dorsal nasal, great auricular, and mental nerves.[12] Appropriate use of these blocks decreases the overall dose of local anesthetic required and the pain associated with the injection of local agents. They are also helpful when infiltration of wound edges would distort important landmarks such as the vermillion border. Significantly, in a cooperative patient, establishment of good regional anesthesia may eliminate the need to perform a repair under general anesthesia in the operating room. Longer acting local agents such as bupivacaine may also be used for direct injection into the wound edge, or, more appropriately, for a long-acting block in select cases. Bupivacaine does have a narrower therapeutic window than lidocaine with potential for cardiotoxicity.[13] Ropivacaine is another well-established long-acting local agent with a better dose-dependent toxicity profile than bupivacaine; however, higher cost may be a barrier to its use at many institutions.

The four chief causes of pain associated with injection are the temperature of the injectate, the acidity of the solution, the speed of injection, and the size of the needle. These factors are all easily addressed to minimize the discomfort of the patient. Warming the local agent to body temperature decreases the pain of injection.[14] Similarly, buffering 1% lidocaine with 8.4% sodium bicarbonate solution in a ratio of 9:1 brings the pH of the solution up from 4 to a value around neutral. The only real tradeoff with buffering is the resultant diminished duration of effect, which can be as short as 30 minutes.[9] Injecting slowly with small needles, 27 or preferably 30 gauge, also decreases pain. It is much easier to inject with a small needle when a small syringe is also used because there is a smaller discrepancy between the diameter of the syringe and the diameter of the needle. A calm, comforting demeanor, combined with appropriate technique, enables the surgeon to provide the patient with adequate anesthesia without any additional pain or anxiety. With children, it is best to take a graduated approach. Frequently, by the time the consultant is seeing the patient, the initial psychological trauma has abated and the child is fairly calm. One could first talk to the child about something other than the injury. Also, the clinician should explain everything he or she is going to do in advance. The patient's anxiety only increases when awaiting a "surprise attack." Next, the clinician should "examine" part of the patient's body that was uninjured. This nonpainful touching can set the precedent that not everything is going to hurt. Next, the wound is gently examined. Gentle irrigation with warm saline is rarely painful and allows the wound to be cleaned and thoroughly examined. At this point, careful infiltration of local anesthesia with a small-bore needle is almost always possible. Most patients fall asleep during the wound closure. However, for some pediatric patients, the idea of the needle trumps all efforts to alleviate anxiety. Rather than restraining a child to anesthetize a wound through injection, the clinician should choose topical anesthesia or conscious sedation.

Topical anesthesia first gained popularity in the form of a solution of 0.5% tetracaine, 1:2000 adrenaline, and 11.8% cocaine, known as TAC anesthesia, after comparable efficacy and safety were demonstrated relative to injection with lidocaine.[15-17] Based on the potential systemic toxicity and security concerns of the cocaine component of TAC, a variation on this technique, known as LAT (4% lidocaine, 1:2000 adrenaline, and 1% tetracaine), has been shown to be equally effective. It is also one-tenth the cost of TAC—a significant savings.[18] Even though LAT and TAC have become agents of choice for anesthetizing simple lacerations in children and select adults, their role in more complex wounds has yet to be defined. In an uncomplicated laceration, it is relatively easy to uniformly administer a topical agent to all areas of the wound bed.[19] Typically, an anesthetic solution is applied by saturated cotton tips or sponges and replaced every few minutes until anesthesia is obtained. This usually takes about 10 minutes. However, large, irregular wounds filled with clot or debris that would impair administration and require débridement are not candidates for this method. TAC should also be avoided near mucous membranes because of reports of systemic toxicity associated with high mucosal uptake of cocaine. It is important that adult patients understand that there is a possibility of testing positive for cocaine after TAC administration.[20]

Some children require sedation in addition to adequate local anesthesia. Conscious sedation or procedural sedation of children is a safe and effective way to diminish the potentially significant psychological distress associated with repair of soft tissue injuries.[21] Administering sedation to children requires training, experience, skill, and appropriate institutional resources. In the emergency setting, this is best administered by trained nursing staff under the direction of a physician or other provider certified to perform procedural sedation in children. This allows the surgeon to focus on the patient's injuries without the added responsibility of drug administration and monitoring. Despite its benefits, sedation does add to emergency department length of stay and cost of treatment, warranting judicious use when the child may tolerate repair with local anesthetic alone. This should not be used as an excuse, however, for withholding sedation for seemingly uncomplicated lacerations in children who are clearly distressed by the prospect of local anesthesia. Several agents have been demonstrated to be effective, including midazolam, ketamine, and fentanyl; these are often used in combination. The most common adverse effects are hypoxia and vomiting, which are usually minor and self-limited or resolve with minimal intervention.[22]

Cleaning

Carefully irrigating and cleaning wounds and surrounding skin is important not only for decreasing risk of infection but also to improve visualization of wound characteristics in preparation for repair. In the multiply injured, obtunded, or sedated patient, meticulous cleaning is even more important. It is not an uncommon scenario to encounter an unconscious patient in the trauma bay, positioned supine with an endotracheal tube and bite-block in the mouth, a nasogastric tube taped in place, a cervical collar around the neck, and dry, crusted blood, dirt,

or debris concealing soft tissue injuries. With so many impediments to a thorough examination, cleaning the entire head and neck is critical to avoid missing injuries. This includes hair-bearing scalp and facial hair where many soft tissue injuries are easily hidden. Hair may need to be shaved or trimmed to adequately clean, assess, and repair injuries. Eyebrows may be trimmed conservatively or shaved if necessary, although it may take 6 months for them to fully regrow.[23]

In most cases, simple antimicrobial cleansers such as chlorhexidine are adequate. Saline alone does little to remove bloody crusts. Warm saline is slightly better. Warm saline with dilute peroxide is better still, although studies showing fibroblast and keratinocyte inhibition in vitro with peroxide and povidone-iodine have led to many authors voicing caution regarding their liberal use in open wounds.[24] For most wounds, warm saline under moderate pressure will be adequate for irrigating debris and foreign material. Retained foreign bodies left unrecognized can develop into a significant problem and are a well-known cause of medicolegal action related to repair of traumatic injuries. Fortunately, the limited depth of soft tissue in the face relative to other areas of the body allows for most foreign material to be identified in the course of routine wound exploration.

Imaging is helpful in certain circumstances. Glass is a common foreign body associated with motor vehicle trauma and is easily detected with plain films. However, the utility of these studies is limited to wounds deeper than the immediate subcutaneous fat.[25] Contrary to commonly held assumptions, a negative CT scan does not rule out a retained foreign body. The radiodensity of substances such as wood, plastic, and vegetative material are so low that imaging frequently misses them. Wood, however, is often visible on magnetic resonance imaging (MRI). There is an increasing body of literature in support of the use of ultrasound to detect the presence of radiolucent foreign bodies.[26] Most foreign bodies in the head and neck, however, are discovered in the course of a detailed history, careful examination, and meticulous wound exploration. Loupe or microscope-assisted magnification is often helpful.[27]

Embedded debris in a wound bed may require gentle scrubbing for complete removal. This must be balanced against the potential for additional disruption of tissue. However, traumatic tattooing can easily occur when pigmented debris left in the wound bed is subsequently covered by epithelium as the wound heals.

This is most noticeable when debris is left embedded in dermis that has been denuded of epithelium. Judicious use of solvents such as acetone may even be necessary to help remove petroleum-based products. Time spent removing debris likely to cause permanent pigmentation will benefit both patient and physician in that delayed treatment of traumatic tattooing is difficult and often has disappointing results (Fig. 22-2).

Figure 22-2. This patient presented approximately 1 week after a blast injury. Traumatic tattoos are evident. Targeted surgical débridement of each lesion was unsuccessful and the patient subsequently underwent successful laser removal of most of the pigment.

Infection Control

There are no convincing data on the role of routine antibiotic administration for soft tissue injuries. Wounds treated within 8 hours and those created surgically are generally considered "clean," indicating a presumed safety of primary closure. It is also generally accepted that in highly vascular areas such as the face, this margin of safety may be extended to 24 hours. Few data exist, however, regarding precise cutoff points to determine which wounds are too contaminated to safely close.[28] The general principle of increasing bacterial counts as a function of time should be kept in mind. Even in wounds without a significant amount of exogenous bacteria, normal skin flora such as staphylococci and streptococci and mixed flora in wounds involving mucosa will proliferate. Heavily contaminated, partially devitalized, extensive, or deep wounds with oral contamination may benefit from at least a single dose of broad-spectrum antibiotics. Even animal bite injuries of the face may be adequately treated without routine antibiotic prophylaxis.[29] Human bites are notoriously contaminated with various aerobic and anaerobic bacteria and recent studies support the use of antibiotic prophylaxis with broad-spectrum agents.[30]

Repair

Throughout the assessment and repair of injuries, clear communication with the patient and any attendant friends or family is essential. Informed, written consent should be obtained before repair. It is also important to help the patient set reasonable expectations for the outcome, keeping in mind that for more severely injured patients, treatment of their injuries will likely constitute a process rather than a single event. Allowing patients to see their injuries either with a mirror or photograph, although potentially distressing, often aids in this endeavor. Ideally, photodocumentation should be performed throughout the encounter, obtaining images of the wound at presentation, after prepping, and again after repair. Photographs are a key component of the medical record for both medical and legal reasons but also for patient education. Patients who are not able or willing to gain an assessment of their wounds before repair will have an opportunity to better understand the extent of their injury by reviewing the photographs at a later time.

Depending on the nature of the wound, a great deal of the surgeon's work can easily be degraded by poor wound care from other health care providers, family, and patients. It is important to educate all parties involved regarding the appropriate wound care regimen. Abrasions, for example, depend as much on ongoing wound care for optimal healing as they do on initial cleaning and débridement. Close follow-up in the acute phase is therefore often necessary, especially in multiply injured patients in whom wound care can sometimes suffer at the expense of efforts to treat more severe injuries.

The first step to performing a technically successful repair is preparation of the work environment. Excellent lighting, comfortable positioning for both the patient and physician, appropriate instruments for soft tissue work in the face, available support staff, and adequate anesthesia are all essential. The absence of any of these elements compromises the primary focus of the surgeon. If necessary, the patient may be transferred to an appropriate venue for repair such as the operating room or minor procedure room. Facial soft tissue work demands instrumentation such as fine tooth forceps, small needle holders, skin hooks, tissue scissors, suture scissors, and a scalpel handle with replaceable No. 15 and 11 blades (Fig. 22-3).

Loupe magnification is also often helpful in improving the precision of repair.

A variety of suture materials and tissue adhesives are available for closure, the choice of which depends upon characteristics of the wound, the patient, and the surgeon. Deep suturing is usually performed with interrupted, inverted, absorbable sutures, although permanent sutures may be used sparingly when deep closure is subject to ongoing forces of tension or muscle contraction. Commonly used absorbable sutures for deep closure include polyglactin 910 (Vicryl), polyglecaprone 25 (Monocryl), polydioxanone (PDS II), polytrimethylene carbonate (Maxon), Polysorb, and Caprosyn.

Epithelial closure is commonly performed with permanent monofilament sutures such as 6-0 or 7-0 nylon or polypropylene (Prolene).

Figure 22-3. A basic set of fine instruments for facial soft tissue repair, including needle drivers, forceps, scissors, and skin hooks.

Absorbable suture with minimal tissue reactivity, such as fast absorbing gut, is also useful, especially in children or patients in whom suture removal may be difficult.[31] A child who requires sedation for repair is unlikely to tolerate removal of permanent sutures. Similarly, adult patients who are unwilling, unable, or unlikely to follow up for suture removal are better served with absorbable sutures than permanent sutures left in too long or removed by inexperienced hands.

Tissue adhesives now have a proven role in wound closure with acceptable results compared to suture techniques in simple lacerations.[32] Even though caution is appropriate in entirely sealing off a heavily contaminated wound such as a human or animal bite, there is no evidence that routine lacerations appropriately cleaned and irrigated have increased rates of infection with tissue adhesive than with suture. They can even be combined with fast absorbing gut on skin, preventing premature suture removal. There are limitations, however. Octyl cyanoacrylate combined with a subcutaneous 4-0 Vicryl closure has approximately the same tensile strength of percutaneous 5-0 nylon suture and cannot be relied upon to close a wound on tension without some widening of the scar.[33] For tissue adhesives to be used effectively, epithelial edges must sit in good approximation before application to prevent glue from entering the wound, resulting in a wider scar or even wound breakdown.[34] Eversion of the wound edges is more difficult with adhesives.

Eversion is critical to the favorable appearance of the final result. Because scars contract as they heal, a laceration that is flat when reapproximated will become inverted. An inverted scar, unless coincidentally located in a wrinkle, will create an obvious shadow and be easily noticed. The best technique for everting the edges of a wound is to use vertical mattress sutures. Properly placed, these sutures elevate the incision just enough to counteract scar contracture. The distal pass of the needle should be placed perpendicular to the surface of the skin and should be placed one half the chord-length of the needle from the incision. The chord-length is the distance from the tip of the needle to the swage. The proximal pass of the needle should only include enough of the epidermis to align the edges and reapproximate them. It is a common technical error to place the distal pass too close to the laceration and the proximal pass too far away. This has several negative effects. First, there is very little skin supporting the suture and, as the wound swells, the tension causes the suture to act as a seton, creating suture tracks. The second is that the epidermal edges will not be in apposition, which results in a gap that granulates and reepithelializes, creating a red, shiny scar (Fig. 22-4).

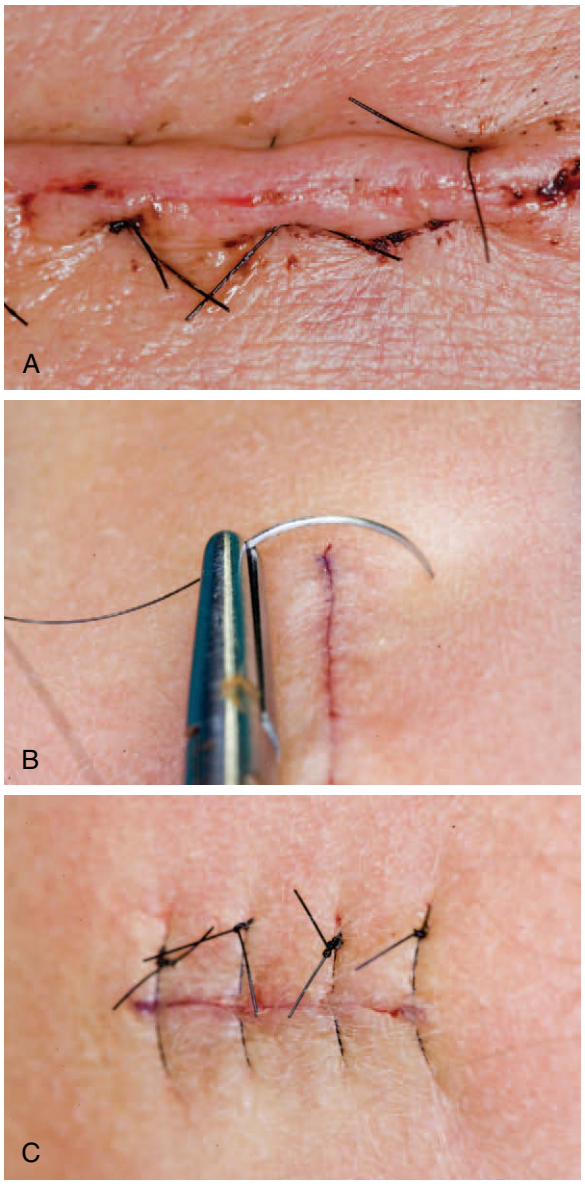

Figure 22-4. **A,** Improperly placed vertical-mattress sutures will cause separation of the wound edge and suture-track marks. This happens when the far bite is too close to the wound and the near bite is too far. **B,** Properly placed vertical-mattress sutures have the far bite bisecting the chord-length of the needle and enter the skin at a 90-degree angle. **C,** This results in an everted wound with good approximation of the edges and lots of skin supporting the sutures.

Types of Injuries

Abrasions

Abrasions are defined as a superficial soft tissue wound caused by contact with a hard, irregular surface, resulting in skin loss not extending to the subcutaneous layer. In the multiply injured patient, these wounds are often neglected and can ultimately result in significant color and contour irregularities. Even with appropriate initial treatment consisting of meticulous cleaning, débriding devitalized tissue, dirt, or debris, these wounds require ongoing care for optimal healing. Once clean, a moist environment conducive to reepithelialization can be achieved with a variety of media including antibiotic ointment, hydrogel, or hydrocolloid dressings.[35] Because these wounds tend to weep and collect fibrinous debris, especially in the setting of increased interstitial fluid, ongoing gentle cleaning is essential. This allows a maximum degree of epithelialization with a minimum degree of fibrosis and scar. Pigmentation abnormalities are nearly universal; however, significant changes are usually temporary and based partially on the depth of injury. Abrasions deep to the papillary dermis cause a greater degree of scarring than more superficial injuries. As with any other scar, protection from sun exposure decreases the likelihood of postinflammatory hyperpigmentation.

Lacerations

Although the technical aspects of treating lacerations demand varied approaches to repair based on the complexity of the wound, some principles and techniques are nearly universal. The goals of treating any laceration should be the same as those for closure of a surgical incision: appropriate reapproximation of deep tissue, reapproximation of dermis with a tension-free closure, precise apposition of epidermal edges, and an everted skin closure.

The excellent blood supply in the face allows for conservative débridement; however, obviously devitalized tissue and significantly irregular wound edges must be excised. When an experienced surgeon recognizes that a wound edge will result in a wide, irregular scar likely needing later revision, that wound may be approached with conservative, beveled excision to optimize closure. This is especially true in areas of soft tissue laxity or in lacerations along relaxed skin tension lines. Judicious undermining in subcutaneous or subfascial planes may be performed to decrease tension. This should be performed with proper attention to how redistributing tension may affect surrounding structures. For example, a periorbital laceration excessively undermined toward rather than away from the eye may result in excessive lid tension with eventual distortion of the palpebral fissure.

Lacerations occurring as a result of a severe contusion are caused by a ripping, rather than cutting of the tissues. Force is transmitted through the skin and soft tissues to the underlying bony prominences of the facial skeleton resulting in a full-thickness crush injury, splitting open the skin, and often, the underlying soft tissue as well. In these cases, the laceration is frequently centered in a periphery of crush injury and diffuse soft tissue hematoma. Closure of these lacerations where the surrounding tissue is partially compromised is best accomplished with the least amount of suture material capable of achieving adequate closure. Such lacerations commonly result in depressed, widened scars requiring later revision for optimal cosmesis. Stellate lacerations often occur in this setting. Small stellate lacerations can be excised in an elliptical fashion, converting the injury to a simple laceration that may then be closed primarily within a relaxed skin-tension line. Larger stellate lacerations should be closed under as little tension as possible, recognizing that there may need to be a balance between optimal tension and optimal approximation. Although the characteristics of some complex lacerations may appear to lend themselves to additional manipulation and rearrangement with local flaps, such endeavors in a contaminated wound bed with extensively injured tissue are rarely indicated. Patients or family members should be counseled regarding the anticipated outcome and potential for improvement with scar revision in the future. This strategy allows for appropriate initial management with the creation of a clean, safe wound without exhausting future resources for local reconstruction or scar revision.

Lacerations rarely divide the skin at a 90-degree angle to the surface. Nearly all are tangential to some degree and consideration should be given to converting a thin, beveled flap to a square edge while undermining the opposing side, such that deep and superficial sutures can be placed with equal eversion of skin edges. A good general rule is that any laceration with an angle too tangential to successfully evert both skin edges with simple sutures should be revised. This problem becomes more apparent in cases of a partial avulsion where a U-shaped flap is elevated. If such a flap is sutured to the surrounding tissues without appropriate eversion of the excessively beveled component, a pincushion or trapdoor deformity often ensues with a bulky, raised appearance to the flap skin. However, it should be noted that, even under ideal circumstances, lymphedema and scar contracture of a U-shaped laceration will also contribute to a pincushioned flap. Steroid injections in the postoperative period may make these contour irregularities less noticeable.

Soft Tissue Avulsions

Many partial avulsions with an apparently well-preserved pedicle can be treated as a complex laceration followed by close observation (Fig. 22-5). Any resultant wounds from ischemia, venous congestion, or suture-line dehiscence may be treated as a secondary rather than primary defect. There is no evidence that various interventions such as topical nitroglycerin paste, anticoagulants, or vasodilatory agents improve the outcome of partially devitalized or ischemic avulsion injuries and soft tissue flaps. Medicinal leeches may have a role in alleviating venous congestion in avulsion injuries with an intact arterial supply.[36]

Partial avulsions with devitalized tissue and complete avulsions with full-thickness tissue loss represent some of the greatest challenges in managing facial trauma. Full-thickness loss of soft tissue in an area amenable to wide undermining may be suitable for primary closure if surrounding structures are not distorted in the process. Otherwise, resultant wounds may be managed with débridement and local wound care, allowing healing by secondary intention if no critical structures are exposed and a wound bed suitable for developing granulation tissue is observed. Depending on location, this process can be aided with negative pressure wound therapy by placement of a wound VAC (vacuum-assisted closure) device. Application of subatmospheric pressure to a wound has been shown to decrease bacterial counts and aid in the formation of granulation tissue and increase the rate of wound contraction.[37] Sequential management with conversion of a larger, contaminated wound to a smaller, clean wound followed by undermining or local flap closure may circumvent the need for more extensive reconstruction upon presentation. In areas such as the forehead or non–hair-bearing scalp, such wounds may even be left to heal by secondary intention with results superior to split-thickness skin grafting or local flap reconstruction. In general, there are few areas in the face where split-thickness skin grafting is indicated as the optimal technique for final reconstruction. Usually surrounding or even distant tissue is available for an aesthetically superior repair.

Perhaps the greatest dilemma comes from avulsion of specific structures with distinct anatomic features such as the nose, ears, lips, eyelids, and scalp where the avulsed portion appears relatively clean and viable. Small, composite segments from the ear or nose may be sutured in place as a graft. Depending on the nature of the defect, this strategy adds little to no additional morbidity and preserves future reconstructive options if necessary. In this situation, there is little adjunctive care, outside of routine suture line care, that has been demonstrated to be beneficial. Patients are typically appreciative of the effort made to salvage a particular structure and no additional reconstructive efforts have been compromised.[38]

When an avulsed segment appears viable and has identifiable vessels suitable for microvascular anastomosis, free-flap replantation of the avulsed segment under a microscope or 4.5× loupe magnification may be possible. The level of technical difficulty involved with such an endeavor obviously requires some degree of experience in microvascular surgical technique. Microvascular replantation of all or portions of distinct structures such as the nose, ear, lip and scalp have all been described with varying degrees of success.[39-42] Most replants are at least partially successful, allowing the reconstruction of a portion of the defect with original tissue. This has been demonstrated to be particularly beneficial in the nose where preservation of even the mucosal layer alone allows for a simpler treatment plan for further reconstruction. Perioperative management usually includes anticoagulation with heparin and/or aspirin. In many cases when the venous anastomosis fails or when no suitable veins can be found for anastomosis, leech therapy has been reported to alleviate venous congestion.[43] Hyperbaric oxygen therapy (HBO) has also been described as an adjunctive measure for improving the viability of hypoxic replanted tissue. No controlled trials have been performed in humans but animal studies demonstrate a clear benefit to HBO, and a failing flap is an accepted indication for initiating treatment.[44] Even in experienced hands, both patient and physician should be prepared for flap failure and ongoing wound management.

Special Considerations in Repair of Specific Structures

Lacrimal Apparatus and Eyelids

Injuries to the eyelids and lacrimal apparatus require exceptional attention to detail in evaluation and treatment in order to obtain the best possible functional and aesthetic outcome. First, a thorough examina-

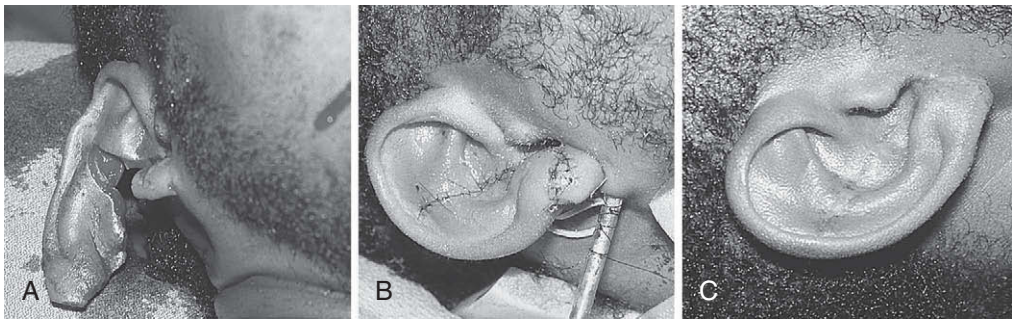

Figure 22-5. **A,** Knife injury resulting in a complex auricular avulsion. The vascularity is preserved by a small superior pedicle. **B,** After three-layer closure. **C,** Follow-up at 6 months showing normal auricular contour.

tion includes evaluation by an ophthalmologist to rule out injury to the globe. After assessment and treatment of the globe, repair of the lids may be performed with special attention to key structures. Lacerations of eyelid skin penetrating no deeper than the preseptal fat may be closed with 6-0 or 7-0 monofilament sutures, which should be removed in 5 days. The use of tissue adhesives for closure of blepharoplasty incisions has been described and may be an acceptable alternative in experienced hands.[45] Full-thickness lacerations of the lids, especially those involving the margin, must be closed in layers. In such injuries to the upper lid, involvement of the tarsal plate, orbicularis muscle, levator muscles (levator palpebrae superioris and Müller's muscle) and conjunctiva should be identified. The pretarsal component of the orbicularis muscle is crucial to the blink reflex and failure to adequately repair a levator injury will likely result in ptosis. If the margin is involved, this landmark is aligned first by approximating the edges of the gray line and lash margin with a 5-0 absorbable suture. The tarsal plate is incorporated into this suture to improve the strength of closure. The conjunctival component may be closed loosely with buried 5-0 or 6-0 absorbable suture such as chromic gut if the material is not likely to abrade the cornea. Alternatively, leave the conjunctiva open if the edges sit in relatively close approximation. With the wound edges properly aligned, close the muscular or tarsal layer with 5-0 absorbable suture, followed by skin closure as described previously. The temptation to débride troublesome orbital fat herniating into the wound should be tempered by the fact that lacrimal glands can closely mimic fat and inadvertent overresection of orbital fat may result in an asymmetric hollowed-out appearance.

Traumatic loss of a lid segment with resultant tissue deficit is rare. When this does occur, however, corneal protection and ophthalmologic consultation to rule out other globe injuries are primary concerns. Up to one fourth of the lid may be lost before primary closure is likely to result in entropion.[46] A lateral canthotomy and cantholysis may add some laxity to the lateral segment, facilitating primary closure without undue tension. This can be extended onto the face to become a cheek rotation advancement flap if necessary. Additional techniques of lid reconstruction (e.g., lid transposition) or cartilage, skin, or mucosal grafts generally require advanced training and skill.[47]

Injuries in the medial canthal region should be evaluated for injury to the lacrimal system and traumatic telecanthus from disruption of the canthal tendon. Normal intercanthal distances are approximately 30 to 35 mm. After underlying bony injury has been ruled out, lacerations of the medial canthal tendon are repaired with permanent suture such as 5-0 polypropylene. Canalicular injuries are best assessed with lacrimal probes, which in cases of canalicular transection are visible in the wound bed when advanced through the punctum (Fig. 22-6). Irrigation of the ducts may also be performed but is less reliable in ruling out an injury. All lacerations of the canalicular system are repaired over silicone stents to prevent stenosis. The introducer is first advanced and the stent attached through the punctum and into the wound bed. The distal segment is located and the stent advanced through the lacrimal sac and into the nose. These steps are repeated for the other limb of the system even if uninjured because it allows the free ends of the stents to be tied together and left in the nose. Repair under a microscope or

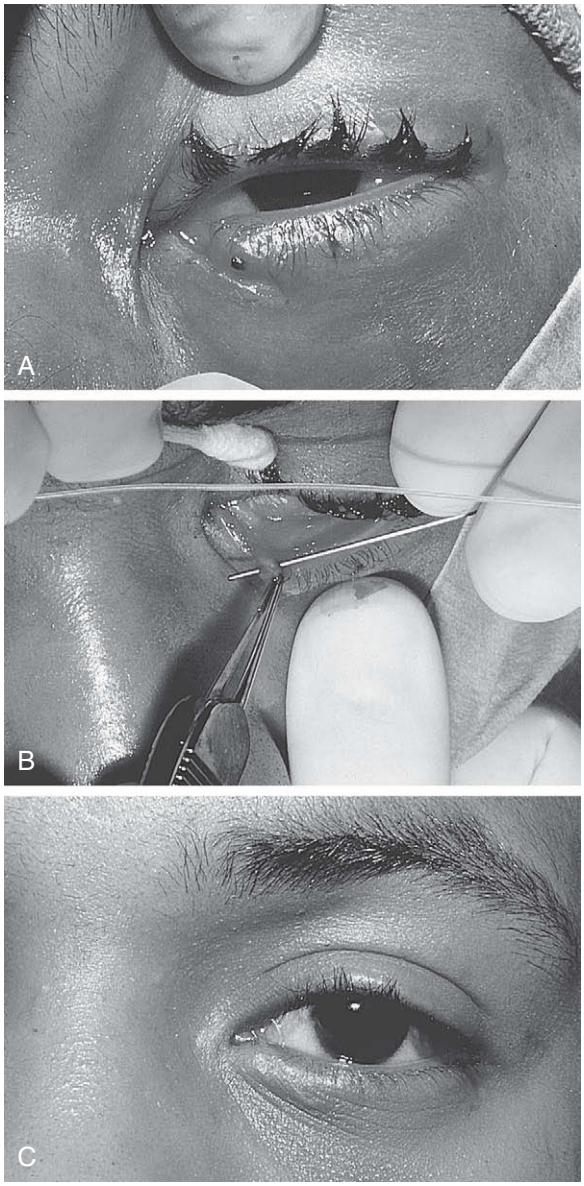

Figure 22-6. **A,** Laceration of the medial lid, suspicious for lacrimal duct injury. **B,** Confirmation of duct injury with lacrimal probe; the duct is repaired over a lacrimal stent with fine monofilament suture. **C,** No epiphora present at 6 months postoperatively; note the stent, visible medially, coursing into both puncta.

loupe magnification allows the placement of 7-0 or 8-0 absorbable sutures to reapproximate the edges of the canaliculus. Excessive effort should not be directed at placing sutures exactly through the lumen of the canaliculus because the low-pressure lacrimal system does not require a water-tight seal when closed over a stent.[48] Stents are usually left in place for several weeks. After removal, the clinician assesses the patency of the system with a Jones test.

Facial Nerve

Facial nerve function should be routinely evaluated and documented early in the course of assessing and treating patients with facial trauma. In every case, this is done before wound exploration, anesthetic application, and repair, because each intervention has the potential for additional nerve compromise. Delayed identification of a deficit can result in significant confusion regarding the mechanism of injury or location of the damaged segment. This is especially true when multiple possible sites of injury exist, as is the case with skull base fractures, cheek lacerations, or severe mastoid trauma. Injury to any of these areas should significantly raise the index of suspicion for damage to the facial nerve in patients otherwise unable to cooperate with a neurologic examination. Penetrating injuries or lacerations to the facial soft tissues between the tragus and a line drawn vertically through the lateral canthus must be carefully examined to rule out facial nerve injury unless a convincingly normal examination has been obtained. Injuries medial to the lateral canthus are unlikely to result in significant deficits. Transections to the main trunk or major branches should ideally be repaired as soon as the injury is recognized.[49] Distal segments will maintain excitability and may be identified with a nerve stimulator for up to 72 hours. Proximal segments not identified in the wound bed can be located by retrograde dissection of adjacent, intact branches, or by parotid dissection or even transmastoid approaches if necessary.

In the rare but devastating case of a missing segment of nerve, a cable graft from the great auricular or sural nerve can be performed. Primary anastomosis or interposition graft neurorrhaphy is performed under the microscope or with loupe magnification using 9-0 or 10-0 monofilament suture. Alternative methods of nerve repair have been described including sutureless techniques with fibrin glue and CO_2 laser welding in both end-to-end anastomosis and interposition grafting. Proponents of fibrin glue neurorrhaphy cite ease of repair and favorable outcomes on a par with microsuture techniques as advantages.[50] CO_2 laser-assisted techniques with a protein solder such as bovine albumin have shown results similar to microsuture and fibrin glue techniques in a rat model.[51] However, epineurial repair with fine monofilament suture remains the gold standard, particularly for extratemporal injuries, and is probably a more accessible technique to the majority of surgeons treating traumatic nerve injuries.[52] Routine facial paralysis precautions, including vigilant eye care, must be emphasized to patients and caregivers even after a technically successful nerve repair. Patients should be counseled regarding the usual return of function, occurring over the course of months rather than days or weeks. When the injury is proximal, it is important to explain the limitations of repair and the implications of synkinesis.

Lips

The function of the lips in articulation of speech and maintaining oral competence depends largely upon an intact oral sphincter. Deep lacerations and avulsions involving the lips can cause significant disruption of the orbicularis oris muscle, which must be addressed in the repair. Complex, full-thickness lacerations should be closed by approximating mucosal, muscular, and cutaneous layers individually (Fig. 22-7). In lacerations involving the vermilion border, the surgeon first places a key-stitch to accurately align the vermilion-cutaneous junction of the opposing wound edges. Depending on the degree of injury to the surrounding skin, defining this landmark can be difficult and may be aided with magnification. In some cases, the white roll can be a more visibly defined marker just below the vermilion border. Avulsions of the lower lip are more common and are usually more forgiving than full-thickness tissue loss in the upper lip. Loss of up to one third of the lower lip may be managed with primary closure without significant distortion or resultant microstomia, whereas similar defects in the upper lip would cause significant deformity.[53] As with other areas of the face, many avulsion injuries of the lip should be ultimately treated with local flap reconstruction not suited to acute repair. Large-segment avulsions with a salvageable amputated segment may be replanted with microvascular reconstruction.[41] Unlike the ear or nose, replantation without micro-

vascular anastomosis is unlikely to be even partially successful and should be avoided.

Ears

The prominent position of the ears over a firm underlying bony surface leaves them particularly susceptible to lacerations, avulsions, and blunt trauma (see Fig. 22-4). The unique and intricate detail of the ear's cartilaginous skeleton is virtually irreplaceable, making it a fairly unforgiving structure with regard to revision of an unacceptable scar. Full-thickness lacerations require accurate reapproximation of the cartilage to maintain the original orientation, although the cartilage itself does not necessarily need to be sutured. Perichondrial sutures and skin sutures are usually sufficient to close simple and complex lacerations involving cartilage. Occasionally, anchoring sutures through cartilage must be placed sparingly to bring wound edges together while maintaining the original shape and prominence. In older patients, the cartilage is more brittle and it is difficult to place sutures solely in the cartilage that do not pull through.

Traumatic loss of auricular tissue can be problematic. Small segments of denuded cartilage can be reliably covered with split or full-thickness skin grafts, as long as perichondrium is still present. Small or moderately sized complex or composite defects that cannot be closed without distorting the ear, especially those involving the helical rim, can be dealt with in a staged manner. Various techniques for composite grafting and local flap reconstruction have been described and are performed in a delayed manner after adequate cleaning, débridement, and local wound care.[54]

Larger segments of composite defects require a different set of treatment options. A robust vascular supply frequently allows partially avulsed auricular segments to survive, even large segments on a relatively small pedicle. In the case of near-total avulsion injuries it is therefore reasonable to replant the avulsed portion, leaving the pedicle intact. Management may then proceed as described earlier for other avulsions. There is some debate, however, regarding the management of total and near-total avulsion injuries as it relates to the cartilaginous framework of the ear. Some authors advocate deepithelialization of the avulsed segment followed by burial in a postauricular subcutaneous pocket (Fig. 22-8), while others believe that the final result of a reconstructed auricle is more reliable with an autograft than with banked cartilage, which often resorbs to some degree and is ultimately distorted.[55] A variation of the "pocket principle" described by Baudet involves deepithelialization of only the posterior aspect of the avulsed segment followed by fenestration of the exposed cartilage at 1-cm intervals.[56] The anterior skin edge of the avulsed segment may then be sutured to a modest postauricular scalp flap elevated over the mastoid to provide a vascular supply. The flap should be divided several weeks later and a skin graft applied posteriorly on the auricle. Advocates of this technique cite preservation of the original cartilaginous framework and overlying skin with reliable results.[57] A temporoparietal fascia flap followed by split-thickness skin grafting also serves to salvage an amputated auricle in an acute setting. In experienced hands, microvascular replantation of an avulsed segment generally yields the best final outcome, even in cases of venous insufficiency or inability to perform a venous anastomosis. Leech therapy and anticoagulation protocols are acceptable adjuncts in these cases and often have favorable results.[43]

Auricular hematomas typically present as a sports-related injury, particularly in wrestlers. Simultaneous application of blunt and shearing forces to the pinna results in disruption of perichondrial attachments to the underlying cartilage with subsequent accumulation of blood in the subperichondrial space. The separation of cartilage from its blood supply will lead to resorption or necrosis if left untreated, leaving potentially severe scarring and a "cauliflower deformity." Prompt needle aspiration or incision and drainage followed by application of a splint or bolster is the treatment of choice. No difference has been shown between various methods of treatment such as casting or bolstering.[58] A recent publication, however, describes the successful use of mattress sutures in 18 ears with only one recurrence.[59] Whatever the method, the splinting must be secure to ensure complete obliteration of the subperichondrial space. Recurrent hematoma or seroma that fails to respond to seemingly appropriate evacuation and bolstering can also be treated with wider incision and drainage followed by packing with thin iodoform gauze until healing of the pocket by secondary intention has occurred. If this method is used, it is usually possible to place the incision just under the helical rim so that the final scar is less noticeable. Keep in mind that, for many athletes, especially wrestlers, a misshapen ear is a desirable outcome. It is not unusual for the patient to remove bolsters, sutures, or packing after going home, thwarting every effort to treat the hematoma.

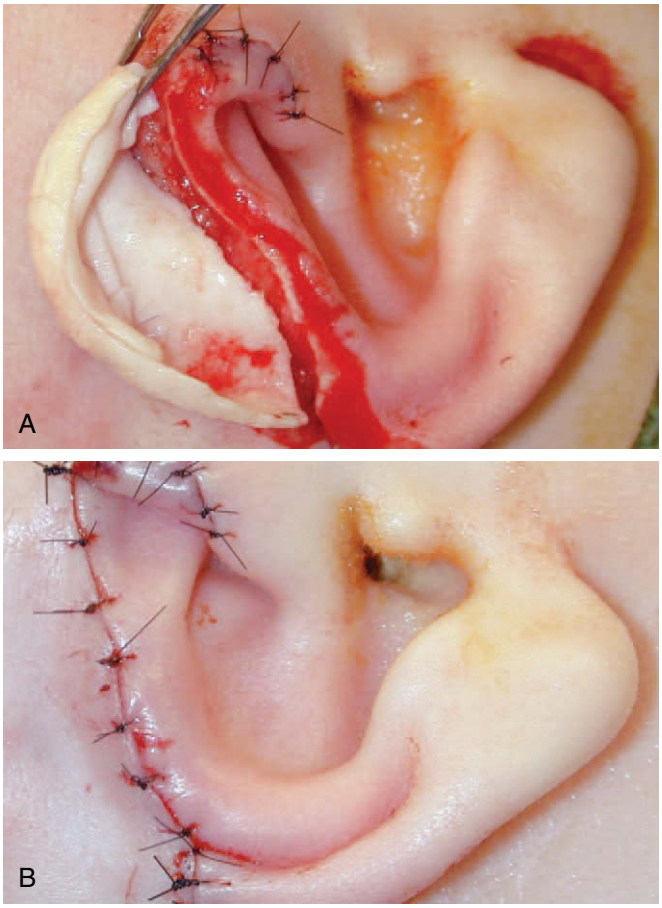

Figure 22-8. **A,** Dog-bite injury resulting in composite defect of superior auricle. Devitalized skin has been removed, revealing well-preserved cartilaginous framework suitable for reconstruction. **B,** Avulsed cartilage anatomically aligned with intact inferior framework and banked in a postauricular scalp pocket.

Antibiotic therapy with a fluoroquinolone is prudent for injuries involving cartilage. In the ear, the rationale for fluoroquinolone use is related to the presence of *Pseudomonas aeruginosa* and the excellent skin and soft tissue penetration with oral administration rather than some distinct cartilage-protecting characteristic of the drug. Contaminated wounds may benefit from at least a single dose of levofloxacin or ciprofloxacin, although there is no evidence for a full treatment course in an uninfected wound.

Nose

The prominent position of the nose on the face makes nasal trauma especially noticeable. The additional functional component of nasal airway compromise, both acutely and as an adverse long-term outcome, poses a significant challenge as well. As with any three-dimensional structure with an internal and external lining, all layers of the nose must be repaired in complex lacerations and avulsions. Although these injuries may look confusing at first, the best course of action is to simply put the pieces back together again. A thorough understanding of nasal anatomy is a prerequisite, however.

Significant underlying nasal injuries such as a septal hematoma or nasal fracture should be ruled out or identified and treated before soft tissue work. In complex, full-thickness, or marginal lacerations, the nasal mucosa and vestibular skin are closed first, with close attention given to the resultant position of the free edge of the alar rim. If this closure distorts the position of the rim, a deep anchoring suture is placed close to the margin first to prevent an irregular step-off or notching (Fig. 22-9). Vertical mattress sutures ensure enough eversion to minimize the risk of alar notching. Undue effort to perform a watertight internal closure is rarely necessary because simple approximation of internal wound edges usually heals with proper wound care. Judicious placement of deep sutures through perichondrium or cartilage should be used to reestablish the cartilaginous framework of the nose. Deep lacerations through the soft triangle and columella almost always involve the lower lateral cartilage, and repair with fine, clear monofilament suture helps prevent distortion of the tip and vestibule resulting

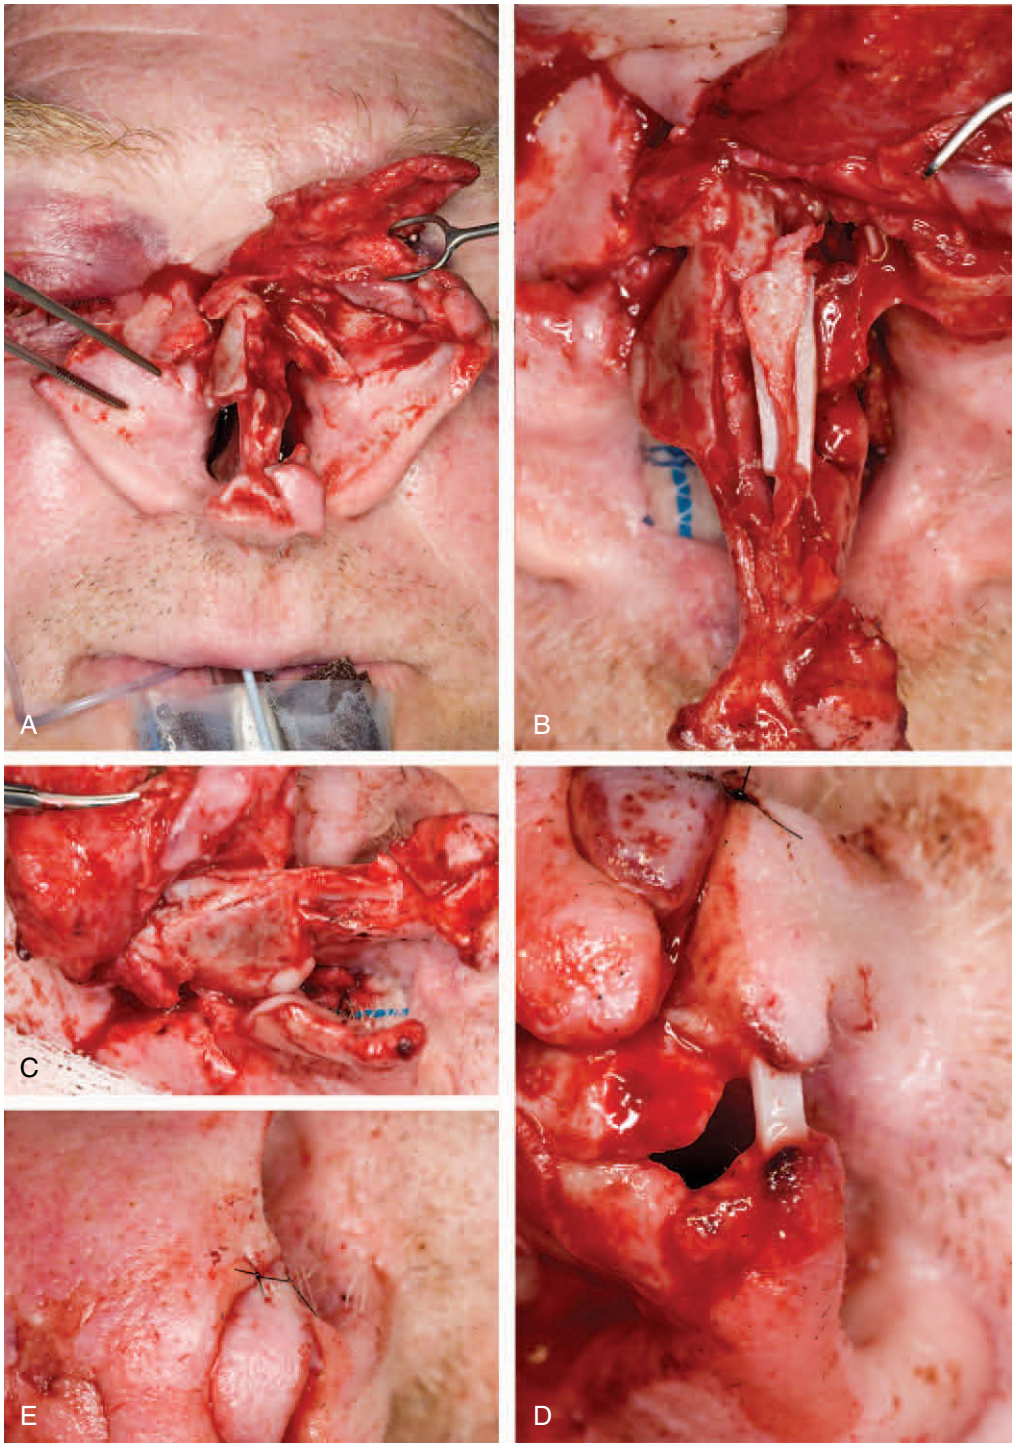

Figure 22-9. **A,** This man was injured when his single-engine airplane crashed. He sustained complex lacerations to the soft-tissue and cartilage. **B,** His dorsal septum was also fractured, necessitating spreader graft placement for reinforcement. **C,** Systematic reapproximation of the upper lateral cartilages provides structure for the internal nasal valve. **D,** An alar rim graft was also placed to make alar notching less likely. **E,** Vertical-mattress sutures along the alar margin also help prevent notching.

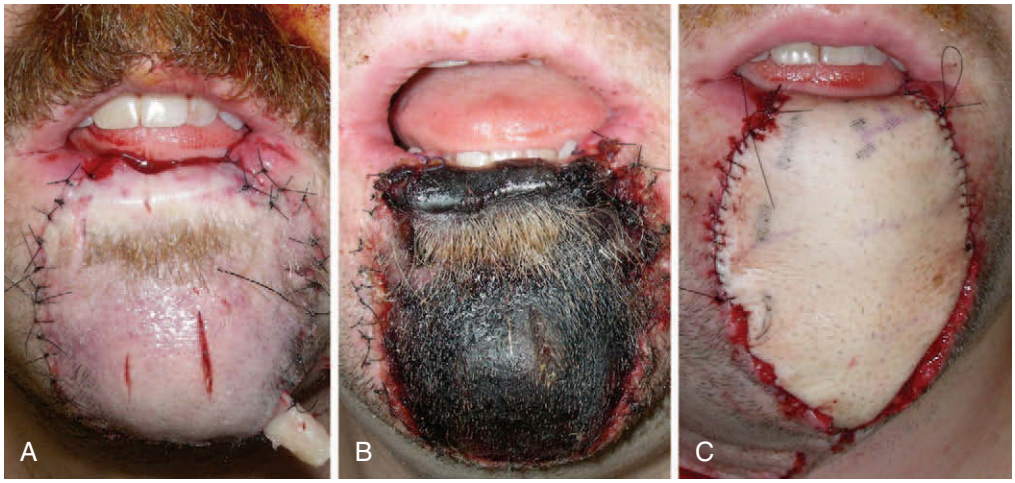

Figure 22-10. A, A replanted lower lip and chin that had a tenuous blood supply. **B,** Several days later, the replanted tissue was necrotic. **C,** Reconstruction was ultimately completed with a forearm free-flap.

from contracture and scarring. The clinician should have a low threshold for removing and revising any sutures that seem to distort the tip, ala, or columella.

Composite defects should be managed according to size and severity. Small defects may be successfully repaired with careful mobilization and reapproximation of all layers. An avulsed segment may be replanted as a composite graft, although with increasing size, the likelihood of graft survival decreases. As initial interventions, these techniques may fail and often result in the need for scar revision; however, they may also provide an adequate result and do not immediately exhaust any other reconstructive options. Local or regional flap reconstruction is rarely indicated in the acute setting. In the nose, even apparently minor defects are often best managed with local or regional flaps combined with cartilage or mucosal grafts. These repairs require careful counseling, planning, and execution and are best postponed until after the acute injury has healed. Healing by secondary intention is remarkably well tolerated on the dorsum and in concavities. These defects may not need further revision.

Large-segment, composite avulsions or amputations are best managed with microvascular replantation if possible.[40] If no suitable vessels for anastomosis can be identified, the patient may still benefit from simple replantation and aggressive wound care with the potential for preservation of at least some of the original structure (Fig. 22-10).

Salivary Gland Trauma

Salivary gland trauma is uncommon and is often more significant with regard to implications for adjacent structures than for any injury to the submandibular or parotid glands themselves. Submandibular gland trauma may be accompanied by injury to the marginal mandibular branch of the facial nerve or the facial artery. Parotid gland injury may also present with facial nerve injury, parotid duct injury, or damage to the carotid sheath. Penetrating injuries to the parotid region must be managed carefully to rule out more serious injuries to these structures. Workup of salivary gland injuries requires an appropriate degree of suspicion and a carefully executed physical examination, whereas radiographic studies play a lesser role. Sialography can be useful in assessing the integrity of the parotid duct, although in most centers this is an infrequently performed examination, potentially limiting the reliability of the results. Cannulating the duct for dye injection can be the most technically challenging part of the study and, if necessary, the surgeon should offer assistance with this. The utility of sialography is limited in cases in which the wound can be easily explored but may be useful in the rare circumstance of deep penetrating trauma or puncture wounds with an intact facial nerve. Adequately exploring a narrow but deeply penetrating injury with potential for parotid duct injury can be difficult and may subject branches of the facial nerve to unnecessary trauma. Sialography may help rule out a ductal injury in such a circumstance. Imaging of the salivary glands with CT or MRI is rarely helpful in the acute setting, whereas other studies such as CT angiography, MR angiography, or Doppler ultrasound may be beneficial in instances of penetrating salivary gland trauma to rule out vascular injuries. Sialoendoscopy is an emerging technique that, in the future, may play a greater role in the exploration of parotid duct injuries.[60] Fig. 22-11 is an overview of the management of parotid injuries.

Parotid Duct

Whereas facial nerve injuries are often detected on a basic head and neck examination, parotid duct injuries are less evident and require a high index of suspicion. They should be considered in any deep laceration or penetrating injury of the cheek. If the possibility of an injury is being considered, then detecting a transection of the duct is relatively straightforward. Like injuries to the lacrimal system, integrity of the parotid duct is assessed by cannulating the papilla intraorally, while searching both visually and with palpation in the wound bed for the probe. Lacrimal probes work well in this setting but should never be forced into the duct because they may cause additional trauma. Alternatively, an angiocatheter may advance into the duct without additional trauma. The papilla of Stensen's duct has a reliable position in the buccal mucosa, opposite the second upper molar. Clear saliva from the papilla does not necessarily rule out injury to the duct proximally. Conversely, a lack of saliva from the papilla, especially in a multiply injured, sedated, or obtunded patient, is not a reliable sign of injury. The parotid gland does not normally produce saliva at a basal rate, rather it acts as an on-demand source of saliva in response to parasympathetic stimulation. The duct exits the parotid gland at approximately the level of the tragus where the parotid abuts the masseter muscle. It then travels in a line toward the upper lip over the belly of the masseter, curling medially to enter the oral cavity as it crosses the anterior border of the muscle. The buccal branch of the facial nerve typically lies inferolaterally to the duct or crosses over it.[61] Because of the close proximity of these two structures, ductal injuries are frequently accompanied by transection of the buccal branch. Loss of upper lip elevation and saliva pooling in the wound are hallmarks of this type of injury. A missed diagnosis and subsequent repair of overlying soft tissues results in significant inflammation within the wound, leading to dehiscence, abscess formation, or parotitis. One should suspect an unrecognized injury with any increasing pain, erythema, or edema after an otherwise uncomplicated soft tissue repair. Identification of the duct at this point is more difficult because the surrounding inflammation and friable tissue complicate efforts to identify the proximal portion of the duct and any exposed facial nerve branches.[62]

Although different techniques for repair have been described, in most injuries where both ends of the severed duct can be identified and mobilized, primary anastomosis over a stent is the preferred method

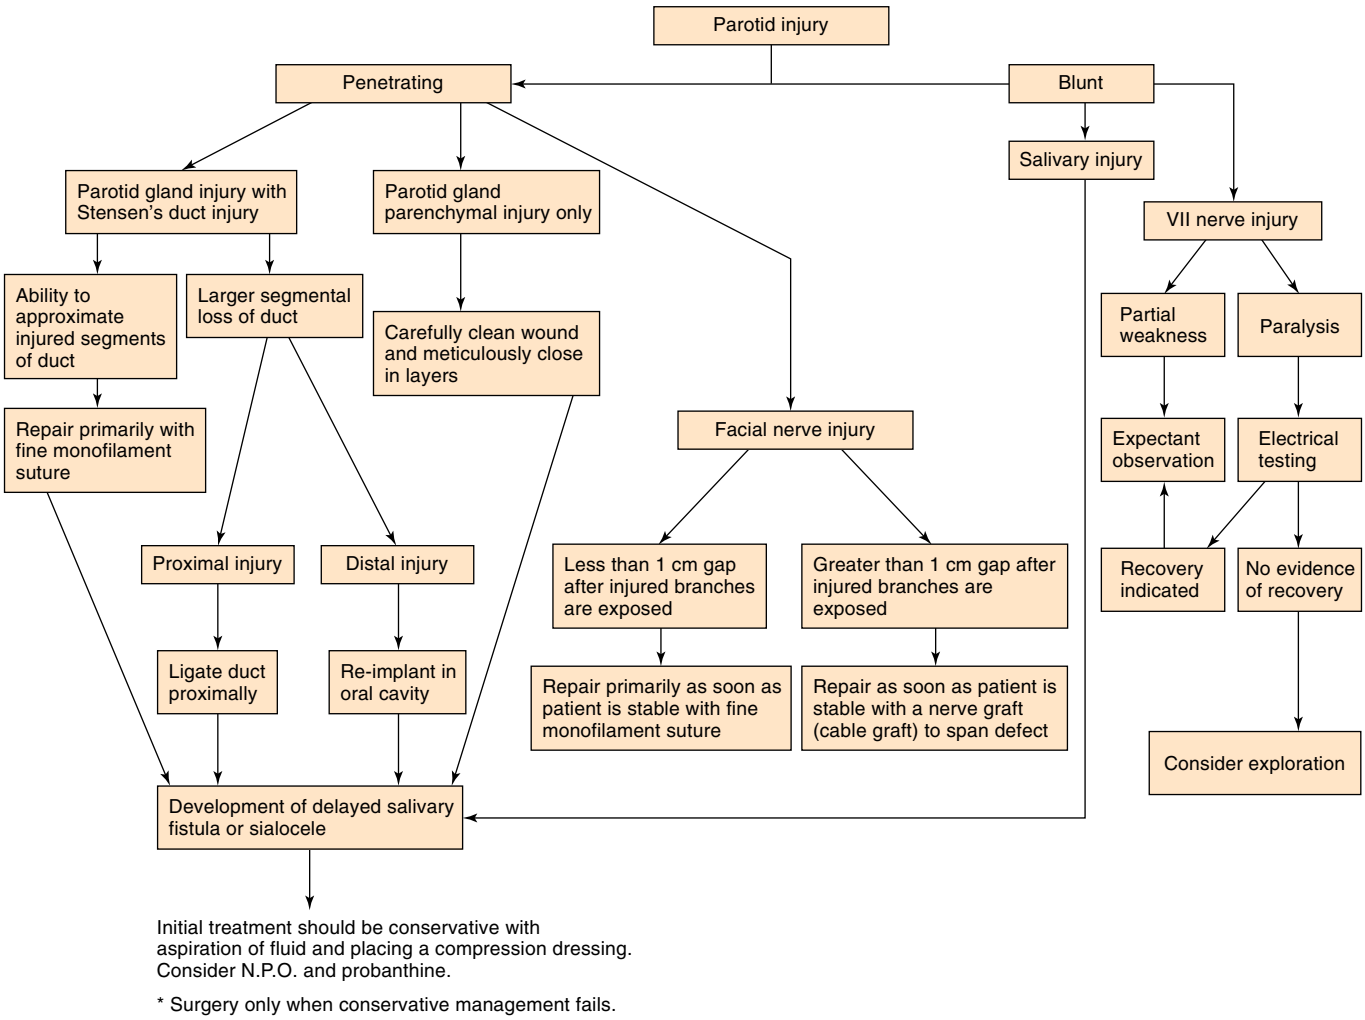

Figure 22-11. Algorithm for the management of parotid injuries.

(Fig. 22-12).[63] If necessary, the papilla is dilated with lacrimal dilators and the duct is probed through the mouth. A readily available and reliable stent can be easily fashioned from a 20- or 22-gauge Silastic catheter, which can be cut to length and advanced into the duct transorally. The catheter is identified in the wound and advanced into the proximal segment of the duct. This segment may also need to be dilated to accommodate the catheter. When both lacerated ends of the duct are safely positioned on the catheter, anastomosis under an operating microscope or loupe magnification is done with 7-0 or 8-0 monofilament suture. The catheter is sewn to the buccal mucosa adjacent to Stensen's duct and left in place for 2 to 3 weeks.

Microsurgical instruments including microvascular clamps for duct positioning encourage precise repair, reducing the risk of postoperative sialocele, fistula, or stricture.[64] The use of vein grafts has been described for cases of duct loss, precluding a tension-free approximation of the proximal and distal segments.[65] In cases of severe buccal trauma with an intact proximal duct and no identifiable distal duct or papilla, sialodochoplasty with rerouting of the duct proximally can be performed.[63] In this case, widely opening the duct with a longitudinal incision and a filleted inset into the surrounding buccal mucosa are essential to prevent stenosis. Even when initial rerouting is technically successful, ongoing patency is frequently difficult to maintain. Another option is to tie off the duct completely, although this is less than ideal. This invariably results in parotitis manifest as swelling and pain, which usually resolves with fibrosis and atrophy of the gland. Occasionally, it also results in infectious parotitis requiring treatment with antibiotics, although the final outcome is usually the same.

Parenchymal injuries of the major salivary glands with intact nerves and ducts still require thorough examination, cleaning, and débridement, followed by a layered, tension-free closure. Sialocele and fistula are less likely in this instance than in cases of ductal injury but are still possible, warranting placement of a gentle pressure dressing after repair to mitigate salivary leak into the wound.

Sialocele and Salivary Fistula

Posttraumatic salivary fistulas and sialoceles, although rare, can cause significant morbidity and discomfort related to impaired wound healing, infection, and irregular scarring. However, most cases resolve with conservative therapy.[66,67] Much of the available data on treatment of salivary fistulas and sialoceles come from series of postparotidectomy patients; however, the applicability of treatment options to the traumatic patient has also been demonstrated in a number of reports. An overlooked parotid duct injury usually first manifests as swelling, mimicking soft tissue edema, glandular swelling, or hematoma. If the missed diagnosis is identified early, before significant granulation tissue, inflammation, or fibrosis develops, the wound may be safely reopened and explored while the possibility of a successful anastomosis exists. Some authors recommend sialography to identify ductal injuries at this stage.[63] Injection of dilute methylene blue into the parotid duct transorally is another technique for assessing ductal integrity in the setting of a fistula.[68] Blue exudate from the fistula tract confirms the diagnosis, but tissue staining may complicate subsequent exploration and repair. Sialoendoscopy may be beneficial in these cases and may facilitate identification of the site of duct injury.

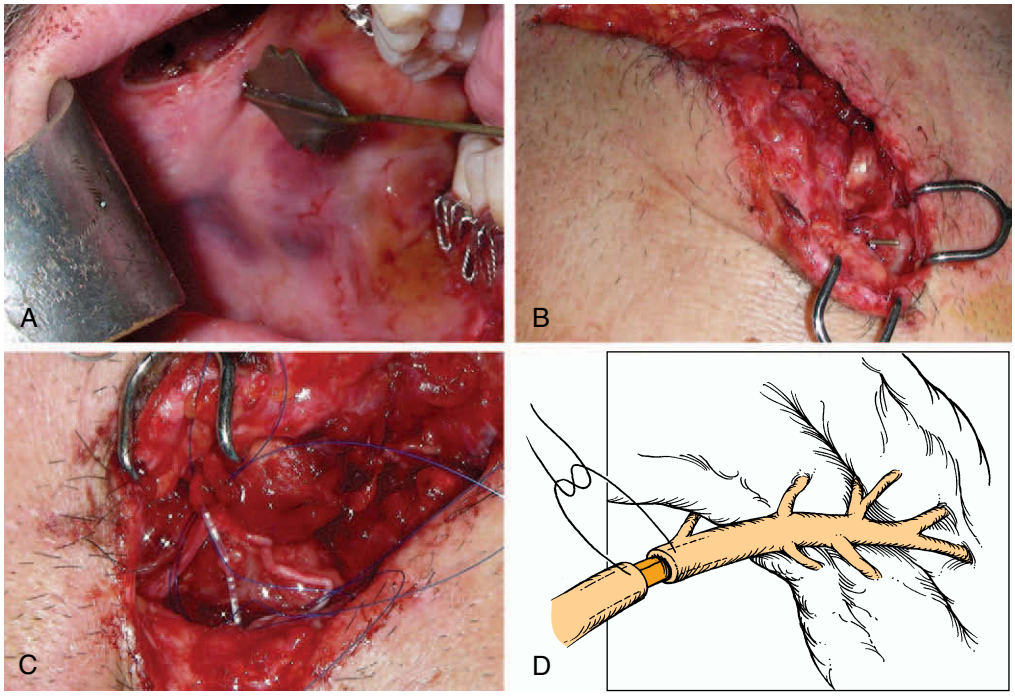

Figure 22-12. **A,** Lacrimal probe advanced intraorally into parotid duct to confirm suspected involvement of the duct associated with a through-and-through laceration of the right cheek. **B,** Tip of lacrimal probe visible in wound. **C,** Silastic stent is visible between the skin hooks, traversing the cut ends of the duct. Fine monofilament sutures have been placed and are positioned to bring the duct together over the stent. **D,** Demonstration of intraluminal placement of fine suture for repair over a stent. *(**D** from Olson NR. Traumatic lesions of the salivary glands.* Otolaryngol Clin North Am. *1977;10:345.)*

Sialoceles may be managed initially with needle aspiration and compression, which can be repeated if necessary.[63] Broad-spectrum antibiotic coverage is indicated because of the significant risk of infection in a contaminated wound bed. Aspirated fluid may be sent for amylase levels to confirm a salivary source. Parenchymal injuries respond best to this conservative treatment and do so in a shorter time period than ductal injuries.[69] Those tend to require longer periods of conservative treatment or are refractory. Anticholinergic pharmacotherapy in the form of propantheline, scopolamine, or glycopyrrolate may be added, diminishing saliva production and, perhaps, the risk of recurrence. Tricyclic antidepressants exhibit the side effect of cholinergic blockade and may also be helpful in diminishing salivary flow. No convincing evidence exists to indicate a clear benefit to adding these agents; however, they are well tolerated by most patients for a short period of time and have been included in case reports and small series as a component of conservative treatment regimens.[70]

Increasing numbers of reports describing the use of botulinum toxin in the treatment of sialoceles and salivary fistulas have emerged in the last several years with favorable outcomes, although no large series or controlled trials currently exist to support a clear benefit.[71] The limited data that exist support use of botulinum toxin A as an adjunct to conservative therapy by way of direct injection into the parenchyma of the involved gland. Ultrasound guidance may aid in the precision of injections, limiting side effects such as masticator or facial weakness, which may occur if injections are placed too far anteriorly.[72]

Other strategies advocated for conservative management include elimination of oral intake and parenteral nutrition, if necessary, in combination with needle aspiration and pressure dressings.[66] Although this strategy has been employed successfully in cases of known ductal injuries, surgical repair, if possible, is the preferred method of treatment.

Conservative management of delayed or chronic salivary fistula or sialocele may require exceptional patience and persistence; however, these measures are often more appealing when one considers the available alternatives. Parotidectomy alone would presumably remove the source of the problem and provide a definitive cure. However, the difficulty of such a procedure with the concomitant risk to the facial nerve in an inflamed surgical bed must be considered against the presumed benefit of resolution. Tympanic neurectomy has also been described although reports of efficacy in treating chronic parotitis demonstrate variable results.[73] Low-dose radiotherapy has been discussed by authors in the past although currently is more of a theoretical "last resort" option given the risks associated with irradiating nonmalignant tissue.

The previous discussion primarily centers on the parotid gland. Submandibular injuries are rare and are usually associated with penetrating trauma. Although these injuries are also reported to respond to the conservative measures described, surgical removal of the gland is accompanied by far less risk than parotidectomy.[74] Accordingly, some authors have advocated surgical excision as the preferred initial intervention.

Burns

Classification

Burns result in cellular damage due to heat, cold, chemical exposure, electrical current, and ionizing radiation. The depth of injury depends on the intensity and duration of the exposure, although electrical burns can have irregular patterns of damage. Broadly categorized as partial thickness or full thickness injuries, burns can be further classified as first-, second-, third-, or fourth-degree injuries based on depth.

First-degree burns are characterized by damage no deeper than the epidermis, resulting in pain and erythema but little or no permanent injury. The injured epidermis typically regenerates in a matter of days with no significant scarring. Second-degree or deep partial-thickness burns extend into the dermis to some extent and are accompanied by pain, erythema, and blistering. Early after initial exposure, second-degree burns may appear to be limited to the epidermis, demonstrating only erythema and pain. The true depth of injury may only become apparent as blistering occurs and the amount of pain increases, often becoming severe. Adnexal structures are generally preserved and serve as a source of epithelial regeneration. This occurs spontaneously,

Figure 22-13. Second- and third-degree burns. Note the gray, leather-like appearance of the third-degree burns in contrast to the erythema of the second-degree burns elsewhere.

resulting in healing with little scarring over the course of a few weeks depending on the depth of dermal injury.

Third-degree or full-thickness burns involve all of the epidermis and dermis, destroying adnexal structures, blood vessels, and nerve endings. The skin often appears leathery and gray, in contrast to the erythema and blistering of partial thickness injuries often seen around the periphery of a third-degree injury (Fig. 22-13). Because of the deep damage to nerve endings, the skin is insensate. Pain is usually due to accompanying partial thickness injuries, and pricking the affected skin with a needle typically does not elicit pain or bleeding. Full-thickness burns extending to the hypodermis form a dense eschar, which ultimately requires débridement because no source of epithelial regeneration is left. These injuries are conceptually similar to soft tissue avulsion injuries in that they result in a full-thickness tissue deficit which, when left to heal secondarily, results in significant hypertrophic scarring. Fourth-degree burns penetrate to deeper structures such as muscles, tendons, ligaments, and bone, resulting in composite defects that typically require débridement, wound care, and subsequent reconstruction.

Assessment and Treatment

Although the head and neck compose only 10% of total body surface area, severe third-degree burns in these areas can be life-threatening. Depending on the mechanism, initial evaluation mandates an appropriate degree of suspicion for a concomitant inhalation injury. Patients with both cutaneous and inhalation burn injuries, especially those with facial burns, are more likely to need airway intervention than those with inhalation injuries alone.[75] An upper airway examination includes flexible endoscopy of all nasal, oral, pharyngeal, and laryngeal mucosal surfaces to establish the immediately visible extent of injury. Airway intervention is generally subject to the same principles that apply in any traumatically injured patient, recognizing that it may take several hours for the full extent of mucosal injury, swelling, and resultant mechanical obstruction to occur. When there are burns on the anterior neck, orotracheal or nasotracheal intubation is preferable to an early tracheotomy due to adverse effects on healing and the potential for pulmonary sepsis from an infected burn eschar.[76]

The general approach to a burn patient follows an orderly progression from initial assessment, stabilization, and resuscitation to definitive measures for healing and reconstruction.[77] Major fluid shifts, with the potential for significant hemodynamic instability, should be treated according to the amount of total body surface area affected. This can be estimated using the Parkland formula or other protocols for fluid resuscitation. Pain control, tetanus prophylaxis, nutritional support, vigilant wound care, and close monitoring are all performed in the acute phase. Systemic antibiotics have a role in treatment only on an episodic basis such as at initial presentation, eschar excision, and skin graft placement.[78] Routine, ongoing administration of systemic antibiotics for prophylaxis alone should be avoided to reduce the risk of selecting for resistant organisms. A burn eschar at significant risk for superinfection has exceptionally poor blood supply, decreasing the likelihood that any significant amount of systemically delivered antibiotic will actually penetrate the wound bed. Instead, topical antibiotic wound preparations such as silver sulfadiazine, mafenide acetate, and bacitracin are all administered to burn wounds and eschars in the acute phase to prevent infection and promote healing.[78] Biobrane is a bilaminar temporary skin substitute and has been shown to decrease pain.[79]

The best functional and aesthetic outcomes in facial burns occur with early reepithelialization (within 14 days), whether spontaneous or by eschar excision and skin grafting. Because of this, it has become standard care in most burn centers to determine early which burns will heal well with ongoing wound care and which will require débridement and reconstruction.[80] After 7 to 14 days of wound care, including gentle mechanical débridement of grossly necrotic or infected tissue and topical antibiotics, burn wounds should be assessed for improvement and likelihood of spontaneous epithelial coverage.[80] In the face, this is facilitated by robust blood supply and high density of epithelial appendages. Beyond 7 to 14 days, secondary healing is associated with a higher degree of contracture, hypertrophic scarring, and poor appearance. Wounds that have not reepithelialized or that were obviously third degree at initial presentation are appropriate for tangential excision and reconstruction. Eschars should be excised tangentially down to healthy, bleeding tissue rather than to some predetermined depth to ensure preservation of as much viable tissue as possible. Delaying grafting for 48 to 72 hours after excision allows time for the recipient wound bed to display adequate vascularity for graft take, following a "no bridges burned" policy of reconstruction.

Operative intervention for wound closure and reconstruction should be based on optimizing function first and appearance second. Some structures, such as the eyelids, perioral region, and nasal aperture, have particularly critical roles in that they provide corneal protection, oral competence, and airway patency. Skin grafting and other reconstructive efforts should also be based on the principle of aesthetic units.[81] Replacing facial units as a whole and placing scar lines along the borders of adjacent units or parallel to relaxed skin tension lines diminishes the visual impact of flaps and grafts with distinctly different characteristics from surrounding skin. Postoperative care is equally important in optimizing aesthetic and functional outcome. Physical therapy can help avoid contracture; placement of pressure garments, silicone sheeting, and splints may diminish the likelihood of hypertrophic scarring.[82]

Skin grafting remains the mainstay of reconstruction for deep partial-thickness and full-thickness burns. Although full-thickness skin grafts often provide the best match for texture and color, size limitations often preclude their use. Common sites for full-thickness skin graft harvest include the upper eyelids, supraclavicular fossae, preauricular and postauricular skin, and nasolabial folds. If the initial defect is too large for full-thickness grafting, donor sites can be saved for secondary procedures aimed at scar revision or contracture release.

Split-thickness grafts are the most commonly employed technique of burn coverage because of the simplicity of the technique and the wide availability of donor sites. Secondary contraction is inevitable but is inversely proportional to the amount of dermis included with harvest. Grafts from 0.018 to 0.035 inch in thickness may be reliably used to cover large defects, depending upon the recipient bed. Even with extensive facial burns, split-thickness grafts applied to this area should never be meshed. Bolstering grafts to the face is usually impractical, necessitating vigilant wound care and regular rolling of the graft to express fluid from the undersurface until graft take.

Other reconstructive options, including regional flaps and free tissue transfer, are often best used as secondary, staged procedures.[83] However, wounds demanding immediate coverage with a large volume of well-vascularized tissue, such as deep full-thickness burns extending to underlying bone or critical structures, may warrant flap reconstruction acutely. Tissue expansion of adjacent or distant donor sites can increase the surface area of regional flaps or distant full thickness skin grafts and is best used as a secondary technique after initial treatment with split-thickness grafting. In this way, an open burn wound at risk

for infection and contracture is first converted to a safe, epithelialized surface that is then replaced with tissue more similar to surrounding skin.

Special Considerations

Eyelids

Eyelid injuries have special priority in treatment because of their role in corneal protection. Many severe periorbital burns do not actually involve the globe, and corneal exposure occurs as a secondary event after resolution of edema, eschar formation, and wound contraction. The globe may actually be protected acutely by significant periorbital edema; however, early eschar excision and grafting should be performed as soon as swelling subsides. Reconstruction of the anterior lamella with skin grafts is frequently complicated by graft contracture and late cicatricial ectropion. Split-thickness grafts are theoretically well suited to replicate the thin, pliable skin of the upper lid, although some authors advocate using full-thickness grafts from the contralateral lid because they contract less than split-thickness grafts.[84] Full-thickness grafts match the lower lid characteristics best and reduce the risk of ectropion.

Nasal and Auricular Cartilage

Burns of the nose and ears are common because of their location and prominence. Before the routine use of topical antimicrobials, nasal and auricular cartilage were at high risk for severe progressive chondritis.[85] With proper wound care currently, the need for radical débridement or excision is relatively rare. However, suppurative chondritis of the ear may still develop despite adequate wound care. This requires incision and drainage to save cartilage not otherwise injured. Conservative débridement and eschar excision followed by split-thickness grafting may be performed if a suitable wound bed develops over the underlying cartilage. Exposed cartilage must be excised or covered with a flap. Otherwise, nasal or auricular reconstruction as previously described may be performed on a secondary basis with local, regional, or free flaps.[86]

Lips and Oral Commissure

Thermal injuries of the lips and perioral region can cause severe functional impairment by limiting oral competence, hygiene, speech, eating, and airway access. These injuries also often pose significant challenges in accomplishing an aesthetically pleasing reconstruction. Microstomia is a common complication, both in patients in whom reepithelialization occurs spontaneously and in patients who undergo reconstruction secondarily. Consequently, most authors recommend initial conservative treatment with wound care and pressure application, waiting to intervene surgically until scars are fully mature.[82] Furthermore, fitting the patient with an oral appliance designed to splint the commissure or labial margin keeps the tissue under constant tension and may help prevent microstomia. Multiple types of devices exist and no single protocol has been established; however, this approach has gained acceptance for improving outcomes. Patients should be fitted with a device approximately 3 weeks after injury and should continue to wear it for 4 to 6 months.[87]

Isolated oral commissure burns are a unique class of burns and are seen almost exclusively in young children who have bitten an electrical cord. Because of the irregular depth of penetration of the electrical current, the initial appearance of the injury is an unreliable indicator of severity. The extent of tissue injury and necrosis often takes up to 48 hours to become evident. Therefore excision and reconstruction for most oral commissure burns is generally not recommended; rather, conservative treatment with wound care and limited débridement are standard of care.[88] Topical antibiotics should be applied until the wound spontaneously reepithelializes or until the eschar clearly demarcates itself from surrounding tissue and begins to come off. Early experiences with oral commissure eschars demonstrated a 25% rate of significant hemorrhage from labial artery exposure at the time of eschar breakdown and separation; more recent series have not reported this complication.[89]

The priority in the treatment of oral commissure burns should be prevention of microstomia. Severe burns involving the oral commissure, lips, and adjacent facial structures with early, obvious development of microstomia and associated difficulties with oral competence often benefit from early excision and reconstruction, similar to other facial burns. Oral commissure burns not associated with electrical injury and clearly superficial in nature will generally respond well to local wound care with or without splinting. The difficulties in management, therefore, primarily involve deep partial-thickness, localized full-thickness, and electrical burns. In such cases, satisfactory results have consistently been obtained with conservative management as described above, often combined with application of a splint device, which typically applies a stretching force in the horizontal direction. Whereas one series managed patients successfully without splinting, others were able to show a benefit and some authors recommend regular use of a splint during the maturation of scars.[88,89]

Frostbite

The nose, cheeks and ears are commonly exposed to cold and are frequent sites for frostbite. Despite the rich blood supply to the face, cold exposure results in peripheral vasoconstriction as blood is shunted to the core. A relative hypothermia develops in exposed areas, which is tolerated by local tissue until the skin temperature drops toward freezing. As tissue freezes, ice crystals form in the interstitium, drawing water out of cells and resulting in cell death. Cells are also killed directly by intracellular freezing and indirectly by ischemia from vascular stasis. A significant component of tissue damage in the form of progressive dermal ischemia continues after the initial temperature insult and appears to be related to inflammatory mediators such as prostaglandins, thromboxanes, bradykinin, and histamine, rather than the coagulation cascade alone.[90]

The initial examination of frozen tissue before rewarming yields little diagnostic information about the degree of injury. Even after rewarming, many seemingly superficial injuries demonstrating a margin of erythema around a numb, white central plaque may go on to show more ominous signs of deep involvement with hemorrhagic blisters or a hard, black eschar in the ensuing 2 to 3 weeks. Favorable findings include return of pinprick sensation, normal skin color, and blisters that fill with clear, not milky fluid.[91]

The single greatest factor in improving outcomes is rapid rewarming of the affected tissue as soon as possible. Avoid partial rewarming or slow rewarming through exposure to a warm ambient temperature. Immerse or continuously bathe the affected area in a solution of warm water with a mild antibacterial agent. The water temperature should be maintained at 40°C to 42°C (104°F to 108°F). Rapid rewarming continues for 15 to 30 minutes until thawing is complete. As tissue thaws it becomes redder or purple in color and more pliable in texture, indicating the end of vasoconstriction. Avoid mechanical manipulation of the tissue or any immediate débridement, except in cases of clear blisters, and apply aloe vera every 6 hours. Aloe vera is an antithromboxane agent and has been shown to reduce ischemia when used alone or in combination with pentoxifylline.[92] Rewarming can be painful and often requires narcotic analgesia. Tetanus prophylaxis is also indicated and many authors recommend prophylactic treatment with systemic antibiotics such as penicillin. Post-thaw care aimed at diminishing the severity of progressive dermal ischemia should include ibuprofen 400 mg orally every 12 hours, ongoing application of aloe vera every 6 hours, and daily hydrotherapy at 40°C for 30 to 45 minutes until wounds appear stable. Other adjunctive measures include treatment with rheologic agents such as dextran, vasodilators such as reserpine, thrombolytic agents, and anticoagulants. These strategies have a theoretical benefit, but there is no convincing evidence for routine use.[93]

Surgical treatment is primarily a reconstructive endeavor. In the absence of an uncontrolled subeschar infection, early débridement is rarely necessary. An uninfected injury typically mummifies over the course of several weeks, and elective débridement with immediate or staged reconstruction may be performed when the demarcation between normal and devitalized tissue is clear.

Conclusion

Traumatic facial injuries have a broad scope of etiologies. Necessarily, their treatment also comprises a wide variety of treatment strategies. As

a rule, an aggressive examination is usually coupled with conservative management. Initial treatment should emphasize reapproximating lacerations or creating an environment conducive to reepithelialization. Scar revision or reconstruction with flaps is usually best postponed until a time when the full extent of the injury can be appreciated.

CHAPTER TWENTY-THREE

Maxillofacial Trauma

Robert M. Kellman

Key Points

- Proper repair of craniomaxillofacial fractures requires accurate diagnosis and a plan for repair. Diagnosis requires a good physical examination and high-resolution computed tomography (CT) scanning, with evaluation of at least axial and coronal scans.
- Associated injuries must be recognized and addressed.
- The mandible is often evaluated using panoramic tomography, but CT scans pick up missed fractures and better demonstrate condylar head malpositions.
- Fractures must be classified: frontal, skull base, naso-orbital-ethmoid, orbital wall, zygomatic, maxillary, and mandible.
- Familiarity with the Le Fort classification is mandatory.
- Familiarity with surgical access is important. Attempts are made to minimize violation of the facial skin; for example, the upper third is often accessed via a coronal incision and the mandible is approached transmucosally whenever possible.
- The middle third bones are accessed from above via a coronal incision, centrally through orbital incisions, and from below transorally via sublabial transmucosal approaches to whatever extent is possible, minimizing use of transcutaneous approaches.
- Endoscopic approaches help minimize surgical access.
- Repair requires understanding of biomechanical principles: The upper third requires repair for cosmesis and separation of the cranial vault from the nose and sinuses. Naso-orbital-ethmoid fractures require repositioning of the medial canthal tendons. The middle third is supported by vertical and horizontal buttresses. Repair of these buttress areas restores facial dimension and functional support.
- The mandible sustains large forces during mastication, and repair must overcome tension forces in function. Proper restoration of occlusion is key to reduction of tooth-bearing bones.
- Panfacial fractures are most difficult and require a comprehensive plan for repair.
- Rigid fixation allows for anatomic repair and early restoration of function, but requires precise repositioning and adherence to technical principles.

The term *maxillofacial trauma* is generally used to refer to the injuries of the facial skeleton, and the management of these injuries is sometimes thought of as "facial orthopedics." (*Craniomaxillofacial trauma* might be a better term because the anterior wall and floor of the anterior cranial fossa are included in these injuries.) As in this text, soft tissue injuries are often discussed separately. However, accurate repositioning of fractured skeletal fragments has major implications for facial aesthetics and soft tissue redraping as well as a significant impact on critical functions such as vision and mastication. Positioning of incisions and the extent of various surgical exposures can influence the final appearance of the face and the function of facial structures such as the eyelids, lips, and nose. Therefore the proper management of maxillofacial trauma requires a comprehensive approach. These injuries should be addressed by practitioners who are familiar with the various ramifications of skull base, orbital, facial, sinus, dentoalveolar, and airway injuries and, most importantly, by those willing to collaborate when necessary with other specialists who may have overlapping areas of expertise. For example, combined facial and anterior skull base injuries are frequently best approached jointly by the neurosurgeon and the craniomaxillofacial surgeon rather than by the use of separate, independent, and even staged management. Even though this chapter only scratches the surface of many complex and controversial aspects of craniomaxillofacial trauma management, it always assumes a comprehensive approach to these often complex and challenging injuries.

The management of facial injuries has evolved significantly during the past 2 decades. Evaluation of craniomaxillofacial injuries has changed significantly with the advent of computed tomography (CT), which has improved dramatically during this interval. Modern CT scanners are exceptionally fast and offer high enough resolution to allow dependable and accurate reconstruction in multiple planes and in three-dimensional imaging. These advances have added greatly to the surgeon's preoperative understanding of the nature of the injuries.

Borrowing from the revolutionary techniques of congenital craniofacial surgery pioneered by Paul Tessier, wider exposures have been possible, while visible scars have been minimized. Wider access has led to better understanding of common fracture patterns and their management, and, as might be expected, taking advantage of the experience gained from extended access approaches, surgeons are now trying to perform the same complex surgeries using less invasive techniques.[1] Recently, these have been improved by taking advantage of the additional visualization made possibly by endoscopy.[2-10]

Bone repair techniques have evolved as well from the frequent use of interosseous wire repairs and Adams suspension wiring[11] to the common use of rigid fixation with plates and screws. Many early mandibular fixations used large plates with large-diameter screws,[12-15] and these repairs have progressed more recently to the frequent use of smaller ("miniplating") techniques as advocated by Michelet and colleagues,[16] Champy and associates,[17-19] and more recently, Ellis.[20] Micro-

plates and even absorbable plates have been advocated for the repair of mid and upper facial as well as cranial fractures and osteotomies. Progress in understanding the biomechanical principles involved in facial fracture repair has resulted in more dependable repairs, both from the standpoint of the technology and in its application. Although not yet widely available, advanced intraoperative imaging techniques allow for more dependable and accurate restoration of the complex three-dimensional facial skeletal architecture.[21,22]

Advances in implant technology, particularly the wide use of titanium mesh, plates, and screws have led to better biocompatibility.[23] Porous polyethylene implants so far seem to be well tolerated in the orbit, and such implants along with hydroxyapatite cements have provided a wider variety of options for craniofacial reconstruction. Finally, secondary (late) repair of unsatisfactory results has progressed as well, providing more options for the unfortunate patient with a poor outcome due to either an untreated injury or a suboptimal initial repair. This chapter focuses primarily on management, including evaluation and primary repair, with mention of complications and the treatment of unsatisfactory late outcomes.

Anatomy, Physiology, and Pathophysiology

General

While form and function are the underpinnings of facial anatomy, and generally speaking form is important for function, the facial architecture is also critically important aesthetically. Knowledge of facial skeletal anatomy is necessary for understanding the mechanisms and patterns of facial injuries as well as the approaches to their repair. Anatomic depictions are available in many anatomy texts and atlases; the focus herein is on aspects relevant to injury and repair.

The face can be arbitrarily divided into sections, each including bony anatomic structures and associated visceral and soft tissue entities. From superior to inferior, the frontal bones are generally considered the upper third of the face. The maxillae, zygomas, and orbits comprise the middle third, or midface, which may include the nose. Or, the nose and nasoethmoid complex may be separately considered as the central face. The mandible is generally considered the lower third, although the vertical (posterior) portions of the mandible extend superiorly to the skull base, which is well above the lower third.

Upper Third

The frontal bone forms the contour of the forehead. Displaced fractures can create various deformities, the most common of which is a central forehead depression (Fig. 23-1). The frontal bone forms the junction between the cranium and the face, and it relates to several visceral structures, the most critical of which is the brain. The typically paired frontal sinuses, when present (approximately 85% of the time), are housed completely within the frontal bones (Fig. 23-2). Frontal bone fractures may involve only the anterior sinus walls, in which case the fractures are significant only for sinus function and cosmesis; or they may involve the posterior wall of the sinus or extend beyond the sinus, in which case they are true skull fractures and become neurosurgical concerns as well. The supraorbital rims and roofs are also part of the frontal bones, which are therefore also related to the orbits, and fractures can thus affect orbital and ocular functions. Inferiorly in the midline, the glabella portion of the frontal bone relates to the superior extent of the nasal bones. This thick glabellar bone protects the underlying frontal outflow tracts and the cribriform plates, which house the branches of the olfactory nerves. The supraorbital and supratrochlear nerves pass through notches or foramina in the supraorbital rims and can be injured from trauma or, more commonly, from surgical manipulation.

Middle Third

The middle third includes the zygomas, orbits, and maxillae, as well as the nose, which together with the anterior medial orbits form the central face. The anterior projection of the zygomas, the malar eminence, or "cheekbone prominences," are important determinants of facial projection and contour. The posterolateral projections, the zygomatic arches, abut the temporal bones posteriorly and provide the attachments for the masseter muscles superiorly. The superior and

Figure 23-1. Lateral view of a patient with a depressed central frontal fracture.

medial projections of the zygoma contribute to the lateral and inferior orbital rims and the inferolateral orbital walls. Displacement of this portion of the zygoma can significantly alter the position of the globe in the orbit. The inferomedial extension of the zygoma extends from the inferior orbital rim and broadly contacts the maxilla, forming the important lateral buttress of the midface (Fig. 23-3). While the superior, medial, and inferior orbital rims extend anterior to the globe, the lateral rim, which is comprised primarily of the zygoma, is situated near the equator of the globe (Fig. 23-4).[24] Therefore minor changes in the position of the zygoma can have a significant impact on the anteroposterior position of the globe. Enophthalmos is a common complication of inadequately repaired or unrepaired zygomatic fractures.

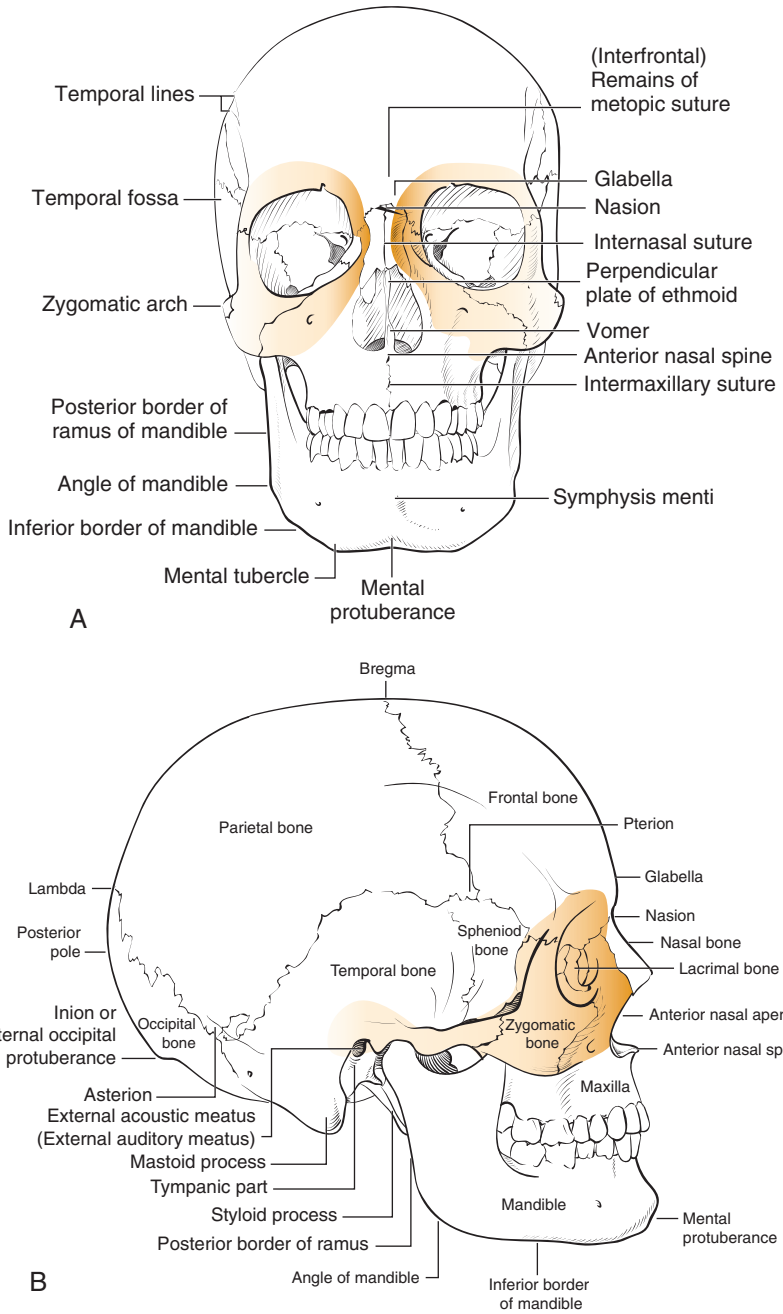

Figure 23-3. Frontal **(A)** and lateral **(B)** view of the craniofacial skeleton demonstrating the broad attachment of the zygomatic bone to the maxilla extending from the infraorbital rim inferolaterally. *(Redrawn from Grant JCP.* Grant's Atlas of Anatomy. *Baltimore: Williams & Wilkins; 1972, with permission.)*

The maxillae extend from the zygomas laterally to the nasal bones medially, forming the medial portions of the infraorbital rims and anterior orbital floors and support for the nasal bones. They also form the piriform apertures and house the nasolacrimal ducts. The maxillary dentition is important for mastication, and proper repositioning of the maxilla after trauma is critical to the recreation of a functional occlusion between the maxillary and mandibular teeth. Superomedially, the anterior lacrimal crest is formed by the maxillary bone. Fractures of this area often lead to malpositions of the medial canthal ligaments, which can result in telecanthus, an unsightly cosmetic deformity.

The maxilla also contains the infraorbital nerve, the terminal branch of V2, which provides sensation to the medial cheek, lateral nose, upper lip, and upper gingiva and teeth (Fig. 23-5). Fractures can compromise this nerve, and care must be taken to both preserve it and, if necessary, decompress it when repairing these fractures. The maxillae also house the maxillary sinuses, which drain into the middle meatus of the nose, lateral to the middle turbinates. Injury to the outflow tracts is uncommon, but preexisting obstruction may contribute to infection.

The nasal bones form the bony nasal projection and support the upper lateral cartilages, which form the internal nasal valves. Because of their prominent position in the middle of the face, the nasal bones are the most frequently fractured bones in the human body. Restoration of nasal function is important for breathing and olfaction, which also may have a significant impact on taste. The nasal bones are also cosmetically important, and suboptimal restoration of nasal contour is usually quite apparent. The nasal bones are supported by the frontal processes of the maxillae, which are anterior projections of the maxillae superomedially. Failure to identify fractures in this area can lead to unsatisfactory results of nasal fracture reductions.

The orbits are complex bony structures with structural contributions from multiple facial and skull bones. In addition to the frontal, zygomatic and maxillary contributions discussed earlier, the lacrimal

bone sits behind the maxillary bone medially (Fig. 23-6). The maxillary bone and the lacrimal bone together form the lacrimal fossa, which houses the lacrimal sac. The strong anterior (maxillary bone) and posterior (lacrimal bone) lacrimal crests provide the sites of attachment of the components of the medial canthal ligaments. Note that the medial canthal ligaments have three components, an anterior, a posterior, and a superior attachment (Fig. 23-7). The thin lamina papyracea of the ethmoid bone completes the medial orbital wall. The palatine bone makes a small contribution posteroinferiorly. The posterior lateral orbit is provided by the greater wing of the sphenoid and the solid optic canal bone is contributed by the lesser wing of the sphenoid. The optic canal sits posteromedially behind the medial wall where it is generally protected from all but the severest injury. The optic foramen is actually directed toward the lateral orbital rim rather than directly anteroposterior. The important "orbital apex" includes the area lateral to the optic canal through which cranial nerves III, IV, V, and VI pass to enter the orbit, which is considered part of the superior orbital fissure. When pressure from an injury (or tumor, abscess, hematoma) causes dysfunction in these nerves, it is called *superior orbital fissure syndrome,* which requires urgent surgical intervention.[25,26]

Familiarity with the complex shape of the orbital walls is important for repair. The position of the globe is determined by the orbital shape and contents. The best way to prevent globe malpositions is to restore the natural shape of the orbit and ensure that orbital fat that has escaped through fractures is returned to the orbit. While the orbital floor is gently concave inferolaterally, it tends to be more convex medially and becomes significantly convex posteriorly behind the equator of the globe (see Fig. 23-6). Familiarity with this anatomy increases the likelihood of proper repair after injury.

It is also important to understand the proper terminology associated with injuries. The term *blowout fracture* implies that the orbital rims have remained intact, while one or more walls of the orbit, typically the floor, though the medial wall are also commonly affected or have fractured. It also has implications for the mechanism of injury: a force transmitted by a blunt impact through the globe to the surrounding walls. Floor fractures can damage the infraorbital nerve, which runs through the floor of the orbit.

Midfacial structures are paired and the central bones are joined in the midline. The nasal bones and maxillae are joined vertically, and the palate forms the inferior horizontal bridge between the two maxillae. The upper horizontal bridge is formed by the anterior cranial base. There are horizontal connections across the nasal bones, but these are not straight across, because the nasal bones are situated on a line superior to the infraorbital rims, and posteriorly across the sphenoid. The relationships between the various bones are important not only when considering normal anatomy and its reconstitution, but also for understanding how facial architecture distributes biomechanical forces, which is important for the repair of fractured structures.

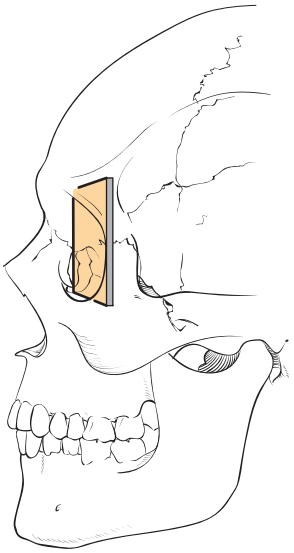

Figure 23-4. Schematic representation of axis of the globe extending from the lateral orbital wall to the lacrimal bone. The entire lateral wall is behind the axis of the globe, whereas only a portion of the floor is so situated. *(Redrawn from Pearl RM. Treatment of enophthalmos.* Clin Plast Surg. *1992;19:99.)*

Table 23-1

"Survival Protection" Anatomic Structures

Facial Crumple Zone	Area Protected
Medial orbital wall	Optic nerve, globe
Orbital floor	Globe
Maxillary sinus	Globe, middle cranial fossa
Ethmoid sinus	Globe, optic nerve, anterior cranial fossa, middle cranial fossa
Frontal sinus	Anterior cranial fossa
Sphenoid sinus	Carotid arteries, cavernous sinuses
Face as a whole	Cranial cavity
Condylar necks of mandible	Middle cranial fossae

The concept of the "central face" comes into play only in the presence of injury and refers to injury in which the trauma to the solid nasal root is transmitted posteriorly resulting in a telescoping injury. This has variously been called *naso-orbital fractures, fracture of the ethmoids,*[27] *nasoethmoid complex (NEC) fractures,* and more recently *naso-orbital-ethmoid (NOE) fractures.* It is an important fracture clinically, but it takes on even greater significance when used as a paradigm for the understanding of how facial fractures occur and how the face is designed to provide maximum protection for structures important for the survival of the human organism.

The nose is important for airway, smell, and cosmesis, but it is less critical to human survival than vision or cerebral function. The solid glabellar and nasal root bones not only protect the underlying cribriform plate, but also take the first impact to the central face. Because the nasal bones and frontal processes of the maxillae are backed up by the thin laminae papyracea of the ethmoid bones, these latter provide little support and crumple, thereby allowing the nasal bones to "telescope" posteriorly while dissipating the shockwave into the ethmoid sinuses. The optic nerves are suspended in cushioning orbital fat anterior to the optic foramen and more posteriorly are protected by the thick bone of the lesser sphenoid wings once they enter the bony canal. Thus the medial orbits form a "crumple zone" to protect the globes and optic nerves in most central facial traumas.

This same concept can be applied to other aspects of facial skeletal anatomy. The globes tend to be protected in direct blunt trauma by the thin bones of both the orbital floors and medial walls. The globes are relatively round and suspended in fat so that most blunt traumas are transmitted to the thin orbital floors and medial walls, accounting for why "blowout fractures" are much more common than globe ruptures.[27a] Similarly, the face itself functions as a "shock absorber" for the cranial cavity, so that the frequency and severity of brain injury can be limited. Finally, this theory provides an explanation for the presence of the paranasal sinuses that offers a survival advantage: that is, the sinuses serve as a crumple zone for the face,[27a] allowing the energy to be dissipated before it reaches the eyes and brain. Thus the entire facial architecture has evolved by design to provide survival protection for critical organs (Table 23-1).

Lower Third

The mandible is generally considered the lower third of the facial structure. It contains the mandibular dentition, which interfaces with

the maxillary dentition for mastication. Unlike the middle third, which is fixed to the skull, the mandible is mobile and swings, hinged to the skull base in two, bilaterally symmetric attachments. The hinges occur at the temporomandibular joints (TMJs), which are true arthrodial joints that both swing and slide. The conformation of the mandible, a somewhat horseshoe-shaped bone hinged in two places to the same solid entity, the skull, makes it well designed to absorb impact forces rather than transmit them to the solid middle fossa floor, and therefore multiple mandible fractures due to a single impact force are not uncommon. (Mandibular trauma causing injury to the skull base can occur, and the condylar head of the mandible has even rarely traversed the glenoid fossa, which houses the articular cartilage of the joint and entered the middle fossa, but such injuries remain rare.)[28] The condylar head of the mandible is housed within the TMJ and is connected to the vertical ramus by the relatively thin and weak condylar neck. This weak area of the bone seems to give easily when a contralateral impact is applied, and fractures of this neck area are generally called *subcondylar fractures*, indicating that they occur below the TMJ. A central impact to the mentum does not uncommonly result in bilateral subcondylar fractures. The condylar neck extends inferiorly into the vertical ramus, which is also relatively thin compared to the tooth-bearing body and symphyseal regions of the bone. However, fractures of the vertical ramus (other than extensions of subcondylar fractures) are relatively uncommon, presumably due to the protective effects of the muscular sling provided by the muscles of mastication, all of which attach to aspects of the vertical rami. The powerful masseter muscle attaches broadly to the inferolateral surface of the ramus, whereas the pterygoids attach to the medial surface. The temporalis attaches to the coronoid process, a superior extension of the anterior ramus. The angle region of the mandible occurs at the posterior extent of the tooth-bearing region and is a common area for fracture. Fractures here extend from the thick, tooth-bearing area in the third molar region posteroinferiorly into the much thinner bone of the ramus. The presence of the third molar tends to thin the bone superiorly, and tension of the muscle sling may also splint the area, creating a natural break point. Fractures in this region are particularly difficult to stabilize, and repairs have traditionally resulted in the highest rates of complications (see later). As might be predicted, the mandible is thickest in the tooth-bearing areas. The anterior portion from canine to canine is referred to as the *symphyseal region* or *symphysis* (sometimes arbitrarily divided into symphysis in the midline and parasymphyseal regions on either side of the midline). From canine to the angle of the body of the mandible contains the two premolar (bicuspid) and three molar teeth. Another unique aspect of mandibular anatomy is the presence of the inferior alveolar nerve. A branch of the third division of the trigeminal nerve, the inferior alveolar nerve enters the mandible at the lingula and travels beneath the tooth roots that it supplies, exiting the mental foramen as the mental nerve, generally in the region of the first bicuspid tooth. It is important to keep in mind when repairing mandibular fractures that the mental foramen does not generally represent the most inferior position of the nerve, and this must be considered when placing hardware on the mandible in the body region behind the mental foramen.

A common classification scheme for mandible fractures uses the terms *favorable* and *unfavorable*.[29] However, this scheme has no impact on management and is not addressed here. It is also important to be familiar with the changes that take place in the mandible with age and tooth loss. When people lose teeth, the normal stresses on the bone are significantly altered, and bone remodeling tends to result in atrophy of the alveolar portion of the bone. The tooth-bearing portions of the mandible atrophy from the top down, bringing the inferior alveolar nerve closer and closer to the oral surface; in extreme cases, it can even rest on top of the bone. In addition, atherosclerosis of the inferior alveolar artery occurs, limiting the blood supply to the thin atrophic bone.[30] This has significant implications for repair of these fractures.

Fractures of alveolar segments, tooth fractures, and tooth avulsions are beyond the scope of this chapter.

A knowledge of basic dental anatomy and familiarity with normal and common abnormal occlusal relationships is important for anyone treating fractures in the tooth-bearing facial bones. The normal adult complement of teeth is 32, with eight in each quadrant of the maxilla and mandible. Common numbering in adults in the United States is from 1 to 32, starting from the right maxillary third molar (number 1) counting toward the left with the left maxillary third molar being number 16, the left mandibular third molar being number 17, and ending with the right mandibular third molar being number 32. The dental surfaces contain cusps for chewing and grooves between these cusps, and in multicusp teeth these are identified by their positions as mesial (toward the incisors), distal (toward the posterior mandible or maxilla), buccal (toward the cheek), and lingual (toward the tongue). Occlusion is complex and has many aspects, but a normal molar relationship has been defined by Angle as the "mesiobuccal cusp of the maxillary first molar sitting within the mesiobuccal groove of the mandibular first molar."[31] This is Angle's class I. When the maxillary molar is more anterior (chin generally relatively retruded), it is class II, and when the maxillary molar is more posterior (chin relatively prognathic), it is Angle's class III. The maxillary arch should be wider than the mandibular, and when the maxillary buccal cusps fall lingual to the mandibular buccal cusps, there is a crossbite on that side. Similarly, anteriorly, the maxillary teeth should extend anterior to the mandibular teeth, which is defined as a normal overjet. The maxillary incisors should overlap the mandibular incisors vertically, which is defined as a normal overbite (Fig. 23-8).[32]

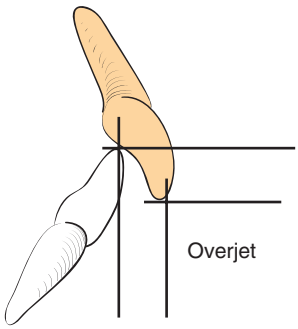

Figure 23-8. Overbite is the vertical overlap of the maxillary incisors over the mandibular incisors. Overjet indicates the horizontal extension anteriorly of the maxillary incisors forward of the mandibular incisors. *(Redrawn from Bailey BJ.* Head & Neck Surgery—Otolaryngology. *2nd ed. Philadelphia: Lippincott-Raven; 1998.)*

Evaluation and Diagnosis

Physical Examination

While the CT scan has become the workhorse of maxillofacial trauma diagnosis, there are still important aspects of facial injuries that are best assessed by performing a good physical examination. The importance of this sometimes lost art must be emphasized.

First and foremost, the initial assessment must address the ABCs and any other potentially life-threatening injuries. Facial trauma may be associated with primary airway injuries to the larynx or trachea, or the airway may be secondarily obstructed by swelling of the oral cavity and/or pharynx or by blood. Establishing a safe airway may require intubation or tracheotomy, and the status of the cervical spine must always be considered. When bleeding is not severe, use of a fiberoptic endoscope may allow intubation without manipulation (extension) of the neck. Other options include use of the lighted stylet and retrograde intubation, or temporary airway stabilization using the laryngeal mask airway. When necessary, a cricothyroidotomy may be performed, although if possible, a tracheotomy is preferred.

Most severe bleeding is from the nose and sinuses and can be managed by tamponade with packing. However, laceration of the internal carotid artery in the skull base may require immediate angiography and balloon occlusion above and below the tear, although these injuries

are rarely compatible with survival. Of course, neurologic injuries should be evaluated by the neurosurgeons, because these may be life threatening as well.

Although the injury may not be not be life threatening, visual status should be evaluated as soon as possible, because progressive loss of vision usually indicates increasing intraorbital pressure or optic nerve injury, and early intervention is needed to salvage vision.

The quality of the physical examination of the facial structures varies depending on the amount of time that has transpired since the injury, the amount of swelling that has developed, the presence of hematoma, and the presence of treatment-related devices such as packing, tubes, and cervical collars. The general facial appearance should be assessed first, looking for penetrating injuries and lacerations as well as the possibility of foreign bodies. Facial nerve function should be evaluated in each division, and the possibility of cerebrospinal fluid (CSF) leakage, otorrhea, and/or rhinorrhea, should be considered if there is any fluid discharge. If the patient can cooperate, a thorough evaluation of cranial nerve function should be performed. When lacerations are present, sterile examination of the wound may yield information about the status of the underlying bone. In particularly severe injuries, for example, brain herniation through the wound, this should be deferred to surgery.

Upper Third

In the upper third of the face, the forehead is evaluated for sensation and motor function. In some cases, fractures may be visible as depressions (see Fig. 23-1) or palpable as step-offs, although typically these fractures are more readily seen on CT scans.

Middle Third

As noted earlier, the middle third of the face houses numerous structures. Of these structures, the eyes are the most important functionally. Vision should be assessed as soon as possible, because progressive visual loss demands emergency management. A light shined in the eye will evaluate pupillary response, even in the unresponsive patient. Failure of the pupil to respond can indicate injury to the afferent system (optic nerve) or efferent system (third cranial nerve and/or ciliary ganglion), or it could indicate a more serious intracranial condition. This must be immediately evaluated by both the neurosurgeon and the ophthalmologist. A CT scan is imperative to assess the nature and extent of injuries. Other significant but less serious dysfunctions include gaze limitation with or without diplopia. Forced duction testing is performed by anesthetizing the conjunctiva and then manually manipulating the globe in all directions with forceps. An applantation tonometer can also be used to determine whether there is an increase in pressure when the patient looks in the direction of gaze limitation (an increase in pressure of 4 mm Hg or more is indicative of entrapment).[33] The position of the globe should be assessed both in its anteroposterior position (enophthalmos vs. proptosis) and its vertical position. The Hertel exophthalmometer is a good tool for measuring globe position when the lateral orbital rims are not displaced. Otherwise, devices that measure relative to the external auditory canal should be used (e.g., Naugle device).[34] Enophthalmos may also be identified clinically, either by recognizing the more posterior position of the globe or sometimes by the deepening of the upper lid crease and elongation of the upper lid. Schubert recommends measuring the anteroposterior distance from the globe to the upper brow with the patient in the supine position, because the distance increases in the presence of enophthalmos.[35] Chemosis and subconjunctival hemorrhage as well as periorbital ecchymosis are telltale signs of orbital injury. Although not universally accepted, regardless of the findings, if a periorbital fracture is identified, I believe that ophthalmologic evaluation should be performed before repair, because subtle injuries such as retinal tears may be a contraindication for surgery.

Zygomatic malposition may be visible or palpable, although if there is a large amount of swelling present, it may be obscured. The same is true of nasal fractures. The nasal septum must be visualized, because septal hematomas must be drained before they result in necrosis of the septal cartilage. A careful nasal examination may also reveal trauma to the upper lateral cartilage with resultant loss of nasal valve support. Cheek and lateral nasal numbness (V2 injury) may be the only indication of the zygomatic fracture and should alert the clinician to obtain a CT scan.

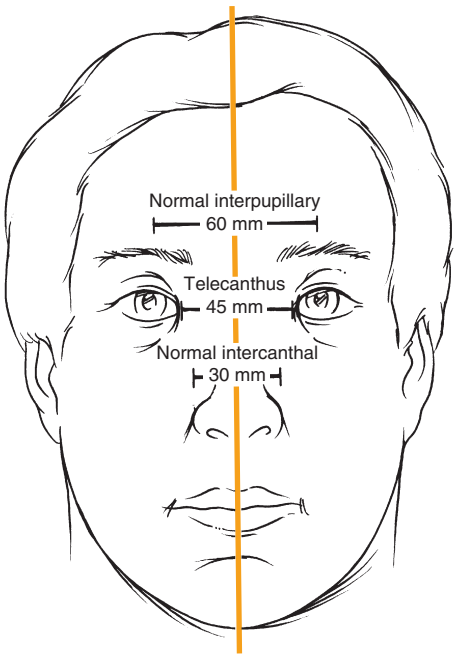

Figure 23-9. Metric relationship of normal and abnormal intercanthal distances to interpupillary distance in traumatic telecanthus. *(Redrawn from Holt JE, Holt GR.* Ocular and Orbital Trauma. *Washington, DC: American Academy of Otolaryngology-Head and Neck Surgery Foundation, Inc., 1983.)*

Telescoping fractures of the nasal, lacrimal, and ethmoid bones (so-called NEC or NOE fractures) require careful evaluation of the medial canthal relationships, and even with close study, they can still be missed. When the canthal ligament is fully avulsed (which is uncommon) or when the bone to which it attaches is completely detached (more common), the medial canthal ligament gets slowly pulled away from its natural position. It tends to displace laterally, anteriorly, and inferiorly, although the displacement may take place gradually and be missed during the acute phase. Careful assessment includes measurement of the horizontal palpebral widths and the intercanthal distance, as well as the distance between the nasal dorsal midline and each medial canthus. The two sides should be equal, and the intercanthal distance should be approximately equal to each horizontal palpebral width, both of which should be equal. It has also been described as one-half the interpupillary distance (Fig. 23-9).[36] A loss of nasal dorsal height and development of epicanthal folds are other telltale signs. Finally, direct traction on the medial canthi should be performed to test the firmness of the attachment. A bimanual examination performed with an instrument in the nose and a finger over the medial canthal area as advocated by Paskert and Manson[37] may also be attempted. Evaluation of the lacrimal collecting system is generally reserved for surgery.

Displaced or mobile fractures of the maxillae are generally assessed at the level of the dentition. A change in the patient's preinjury occlusion is indicative of a fracture in one or more of the tooth-bearing bones. Of course, evaluation starts at the teeth themselves, which if displaced will alter the occlusion. Excluding loose teeth, the teeth are carefully evaluated for mobility of the alveolar segments to which they are attached. Motion of an entire midfacial segment indicates midfacial fracture, most of which occurs at the maxillary level, even when more superior fractures are present. Pure craniofacial separation at the Le Fort III level in the absence of lower midfacial (maxillary) fractures is an extremely rare occurrence. More important than identifying the level of a midfacial fracture on clinical examination is finding evidence of its presence, which indicates the need for repair as well as careful study of the CT scan to identify all levels involved. Generally, if the teeth and

alveoli are intact, grasping the maxilla at or above the incisors and gently rocking back and forth will identify motion relative to either the nasal root or the skull above it. Note that the absence of motion does not assure that the bones are not fractured, because impacted segments may not be mobile. The presence of an anterior open bite is also suspicious, even though subcondylar mandible fractures may produce the same finding. Examination of the palate may also reveal evidence of fracture, and it is not uncommon to find mucosal tears along the paths of palatal fractures.

Lower Third

The mandible should be evaluated for sensitive areas, mucosal tears along the gingiva, and mobility of fragments. Foreshortening of a vertical ramus, deviation to that side, premature contact of the molars, and an anterior open bite may all be indications of a subcondylar fracture. Bilateral subcondylar fractures may show only the anterior open bite and bilateral premature molar contact when they are present. It is important to assess sensation in the mental nerve distribution, because postoperative numbness is not uncommon, and unless it is documented preoperatively, it would be difficult to determine whether it was due to the injury or the surgery. The patient's teeth should be assessed for fractures and other injuries such as intrusions, subluxations, and avulsions. Unless the facial plastic/head and neck surgeon is comfortable managing these, a dental consultation should be obtained.

Radiographic Evaluation

With some exceptions, the CT scan has replaced other forms of radiographic imaging for the assessment of craniomaxillofacial injuries. With the high availability of modern high-speed, high-resolution CT scanners, most maxillofacial trauma surgeons have abandoned plain radiographic imaging of middle and upper third facial bones, even as a screening tool. The numerous overlapping shadows make it easy to miss fractures that would be found on a CT scan, and the presence of a fracture would necessitate a CT scan. The exception here is for simple nasal fractures (*simple* meaning without evidence of involvement of other facial bones) that are routinely assessed using plain radiographic study (although even these may be unnecessary, in that they have little impact on management). Another exception is the use of the 6-foot AP Caldwell view for creation of a template for use in creating an osteoplastic frontal sinus bone flap.

In general, the plane of the CT (axial vs. coronal) does make a difference in how effectively selected fractures are visualized.[38,39] In a series of studies, fractures were created in fresh cadaveric heads, and these were scanned using various protocols. Dissections were then carried out to correlate the CT findings and to determine which planes of orientation yielded not only the best primary CT data but also the best three-dimensional reconstructions. It was found that axial orientation was best for visualizing most frontal fractures as well as NOE fractures and the zygomatic arches and vertical orbital walls. Coronal orientation was better for the orbital roofs and floors and the pterygoid plates. In general, as would be predicted, vertical structures were better seen on axial scans and horizontal structures were better seen on coronal scans. It was also found that scans performed at a resolution of less than 1.5 mm should not be used to make three-dimensional reconstructions, because the "fill-in" algorithms used by the computer programs created too many misrepresentations. In general, three-dimensional reconstructions create an overview picture that may help the surgeon visualize the overall facial architecture; however, they contain potential inaccuracies that are not present in directly obtained scans.

Upper Third

For frontal fractures, a high-resolution axial CT gives good information about the anterior and posterior walls (Fig. 23-10). However, in the presence of posterior wall fractures, it is impossible to determine the significance of soft tissue density inside the sinuses. When the posterior wall is displaced (regardless of the degree of displacement), and there is soft tissue density within the sinus, I recommend that the inside of the sinus be visualized (either directly or endoscopically). (We have had more than one experience in which placement of an endoscope in a sinus with minimal displacement of the posterior wall and no CSF leakage revealed brain tissue herniating into the sinus.) Displaced anterior wall fractures that require repair are commonly found on CT, even when there is no clinical evidence of cosmetic deformity. Fractures extending into the floor of the anterior fossa are best evaluated with a high-resolution CT scan.

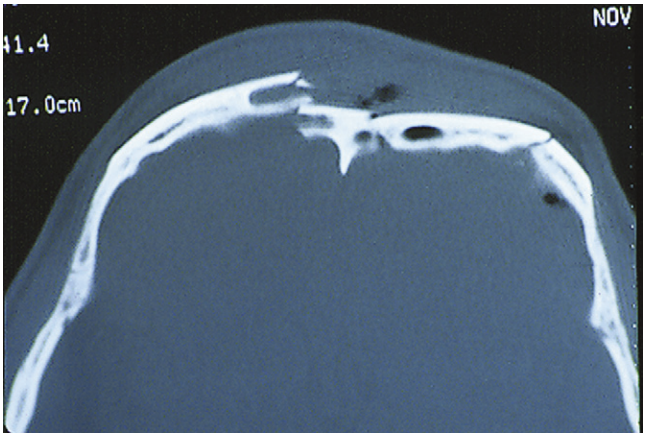

Figure 23-10. Axial computed tomography scan demonstrates markedly displaced anterior and posterior walls of the frontal sinus.

Middle Third

Simple orbital floor blowout fractures are best assessed via coronal CT scanning. However, if there is suggestion of extension into the medial wall, an axial scan (or a high-quality reconstruction from a 1.0 or 1.5 mm coronal) should be obtained as well (Fig. 23-11). In addition, for accurate orbital assessment, Schubert[35] has recommended creating a parasagittal reconstruction in the plane of the optic nerve (which actually traverses the orbit from posteromedial to anterolateral, so it is not in a true sagittal plane).

Accurate assessment of orbital wall displacement allows the surgeon to anticipate the amount of enophthalmos that is likely to result if the fractures are not repaired.[40-42] This not only helps determine the extent of orbital repair that will be necessary but also whether repair is required at all. CT evaluation of the optic canal and orbital apex take on critical significance in the presence of cranial neuropathies related to these areas. Visual loss due to trauma necessitates immediate analysis of orbital CT scans when possible, because a reversible injury causing constriction of the orbital apex may be identified.[25,26]

Whereas zygomatic fractures can be visualized on plain films, accurate assessment of displacement is best analyzed on CT scans. The status of the arch can be evaluated on plain films (so-called bucket-handle views). Although this may be adequate for simple zygomatic arch fractures (without involvement of the malar portion of the zygoma), most zygomatic fractures involve complex three-dimensional alterations in position as well as involvement of the lateral and inferior orbital walls and are best assessed with CT scans. The axial CT demonstrates shifts in the position of the zygomatic arch that may be otherwise missed in high-impact trauma in the anteroposterior direction. Careful comparison with the contralateral arch is important, as is a familiarity with the normal shape of the zygomatic arch, which is more flattened anteriorly and does not therefore represent a true convex arch.

Displacement of maxillary fractures is typically well demonstrated on axial scans. These scans also show fractures through the pterygoid plates, which help define the presence of Le Fort type fractures. However, the horizontal components of these fractures are best displayed on coronal scans (and as might be expected on three-dimensional reconstructions from the coronal scans).[43]

Lower Third

For the mandible, unlike the middle and upper thirds of the face, most surgeons prefer plain radiographs, or more commonly panoramic tomography, and often both are the imaging techniques of choice.

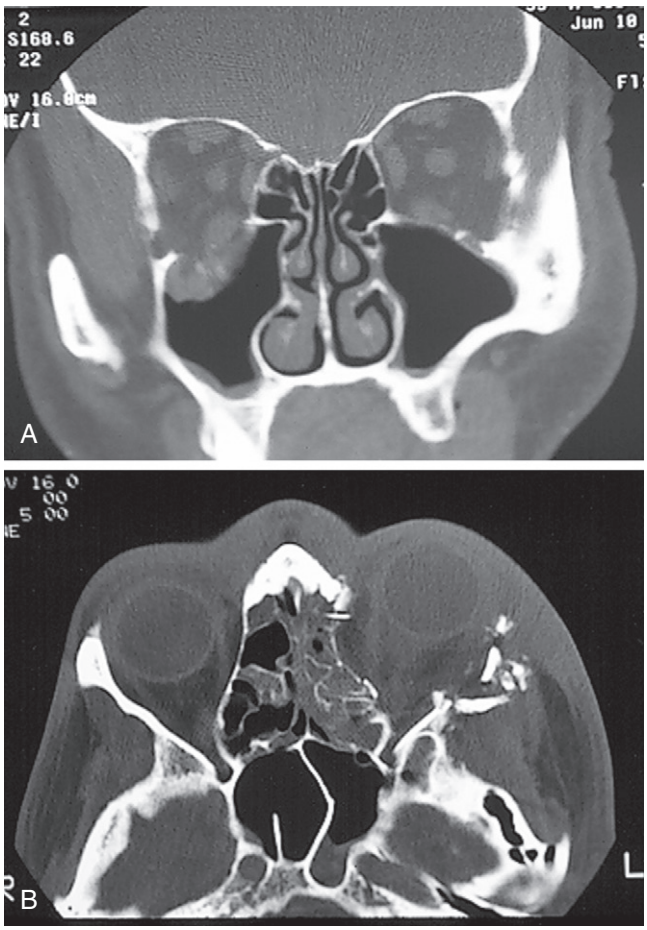

Figure 23-11. A, A coronal scan clearly demonstrating a complete blowout fracture of the right orbital floor. **B,** An axial scan demonstrating a medial orbital blowout fracture.

Several studies[44,45] have found radiographic films to be better than CT scans, although 3-mm slice resolution was used in these studies. Wilson and colleagues,[46] suggested that the addition of axial CT in 39 patients with mandible fractures revealed two parasymphyseal fractures and 15 cases of comminution or displacement that had been missed on panoramic tomography. However, the CT also missed posterior mandibular fractures, so that both were required to maximize information. However, 3- to 5-mm slice resolution was used, and this might account for the poor sensitivity of the CT scans in their series. In a subsequent study using high-resolution helical CT (1-mm slice resolution), the sensitivity for the CT scans was 100% while that for panoramic tomography was 86% (seven fractures missed in 6 of 12 patients).[47] Considering the cost disparity between panoramic tomography and CT scanning, it is unclear whether the standard of care for mandibular evaluation will change. Lee has suggested that coronal CT scanning with three-dimensional reconstruction is the procedure of choice for assessing the position of the proximal fragment in subcondylar fractures of the mandible.[6] Furthermore, he recommends a postoperative scan to assure that the reduction is accurate after endoscopic repair. This is certainly a more expensive approach than the Towne's view radiographic study, which is typically used to view the position of the condylar fragment. Additional experience will ultimately determine the most appropriate studies.

Classification Schema

Numerous classification systems have been developed and reported for the various fractures that occur in the facial skeleton. Such systems are useful for communication between physicians and are valuable for documentation purposes, particularly statistical analyses, but they should also be useful for treatment planning. However, many classification schemes fail to meet one or more of these criteria. A brief summary of some of the more widely used systems is given.

Upper Face

In the frontal area, classification schemes have focused on the involvement of the frontal sinuses, and these systems have been treatment oriented. The most useful classification, which predicts the likelihood of disruption of the frontal sinus drainage passages, was presented by Stanley and Becker.[48] They separated frontal sinus fractures into linear horizontal and linear vertical and comminuted anterior and posterior walls, with and without NEC or supraorbital rim fractures. Of interest was the finding that whenever an NEC or a supraorbital rim fracture occurred in combination with comminuted fractures of either the anterior or posterior frontal sinus walls, a ductal injury was predicted. This scheme has been modified by Gonty and colleagues,[49] but interestingly, in the commentary on this paper written by Stanley,[50] he suggests that even his own classification system is not all that useful clinically. Numerous other classification systems have been suggested, but they offer little to the planning of the treatment approach.

There are also classification schema designed to predict the incidence of CSF rhinorrhea after anterior skull base trauma. The most useful of these, which is also somewhat intuitively predictable, was reported by Sakas and colleagues,[51] who found that the more centrally located the fracture in the skull base and the more severe the fracture, the greater the likelihood of CSF leakage.

Middle Third

Numerous classification systems have been created for addressing the multiple fractures that occur in this area. Although not always applicable, the most important system is that developed more than 100 years ago by Rene Le Fort.[52] It was developed artificially by analyzing the facial fracture patterns that were seen in cadavers that were traumatized by being dropped from a height. The Le Fort I fracture, or horizontal maxillary fracture, occurs above the level of the maxillary dentition, separating the alveoli and teeth from the remaining craniofacial skeleton. It crosses the nasal septum, and posteriorly it completes the fractures through the posterior maxillary walls and pterygoid plates. The Le Fort II fracture, or pyramidal fracture, starts on one side at the zygomaticomaxillary buttress, crosses the face in a superomedial direction, fracturing the inferior orbital rim and orbital floor, traverses the medial orbit, crosses the midline at the nasal root or through the nasal bones, and then travels inferolaterally across the contralateral side of the facial skeleton, creating a pyramidal shaped inferior facial segment that is separated from the remaining craniofacial skeleton. Like the Le Fort I, it fractures the nasal septum, the posterior maxillary walls, and the pterygoid plates. The Le Fort III fracture, or complete craniofacial separation, occurs at the level of the skull base, separating the zygomas from the temporal bones and frontal bones, crossing the lateral orbits and medial orbits, and reaching the midline at the nasofrontal junction, also violating the nasal septum and pterygoid plates (Fig. 23-12). Even though many fractures seen clinically do not fit precisely into this classification scheme, it has stood the test of time, and it does prove useful for communication and treatment planning. In order to use it for documentation purposes, it is helpful to more specifically describe the nature of the particular fractures in each case. For example, the pure Le Fort III fracture is probably a rare occurrence, yet many surgeons will describe an injury by the most severe level encountered and then describe the additional components.

Numerous classification schemes have been used to describe NOE fractures. The system that is probably the most useful for treatment planning is that described by Markowitz and colleagues (Fig. 23-13).[53] In this scheme, a type I fracture occurs when a large central fragment containing the medial canthal ligament is freed from the surrounding bone. It is repaired by rigidly fixing this central fragment in place. In a type II fracture, there is significant comminution, but the fragment containing the medial canthal ligament is still repairable. However, transnasal fixation of this fragment and/or the tendon is still necessary. In type III injuries, the tendon is either detached or attached to an unusable fragment. It must be freed and directly repaired with transnasal fixation. This description shows how a useful classifica-

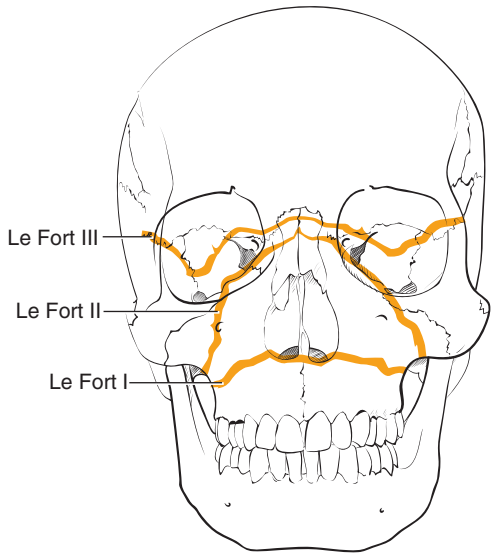

Figure 23-12. Le Fort I fracture is a horizontal fracture that separates the bone containing the maxillary dentition from the remainder of the craniofacial skeleton. The Le Fort II fracture is a "parametal" fracture, which extends across the maxilla through the infraorbital rim and orbital floor up through the medial orbital wall and across the nasal root area and then across similarly the other side. The Le Fort III fracture is the true craniofacial separation, which includes fractures of the zygomatic arches and frontozygomatic areas, then crosses the lateral inferior and medial orbits, and is completed across the nasal root. Note that all Le Fort fractures cross the nasal septum and pterygoid plates.

tion not only describes the injury but also helps in the planning of the repair.

Lower Third

Mandibular fractures are for the most part classified by the anatomic region in which they occur and by their severity. Severity typically includes simple, comminuted, or avulsive (bone loss). The mandible is also categorized as dentulous, edentulous, or atrophic edentulous. Historically, a common classification has separated so-called favorable from unfavorable fractures. In fact, these descriptions are no longer considered helpful in determining the treatment plan, and they certainly offer no documentation or communication advantages. They are thus of historical significance only.

Management

General

Once the injuries have been identified, a management plan should be developed. As noted earlier, appropriate consultations should be made, and, when necessary, the consultants should be included in the process so that the management plan is comprehensive. A piecemeal approach increases the likelihood of a less than ideal outcome and should therefore be avoided.

It is generally accepted that because most maxillofacial injuries are considered contaminated due to communication with the nose, sinuses, and/or oral cavity, antibiotic treatment should be initiated at the time the patient initially presents. A prospective study by Chole and Yee demonstrated some benefit of this approach.[54] Typically, antibiotics that cover oral organisms such as penicillins, cephalosporins, or clindamycin are selected. It is unclear how long they should be continued, but they are generally administered until at least 24 hours after surgery, although they are sometimes given for longer periods.

An issue that has generated strong opinions is that of the timing of surgery. Early reviews of mandible fractures suggested that delay in treatment increased the likelihood of infection.[55] However, since the advent of routine prophylactic antibiotic therapy, this does not seem to be true. Many surgeons have suggested that surgery should be delayed until swelling resolves so that facial asymmetries can be better assessed. However, because fractures are assessed using CT scans, this is probably not a relevant concern either, particularly because extensive soft tissue exposures recreate the soft tissue swelling anyway. More recent and cogent arguments have suggested that re-insulting the soft tissues after the acute inflammatory phase has resolved may result in a less pliable and resilient soft tissue envelope and less satisfactory healing and outcomes, although this remains more theoretical than proven. Certainly, logic seems to suggest that early intervention to restore the hard and soft tissues to their normal anatomic positions would be beneficial. However, it is not uncommon for other considerations to intervene, particularly in severe trauma in which the stabilization of the

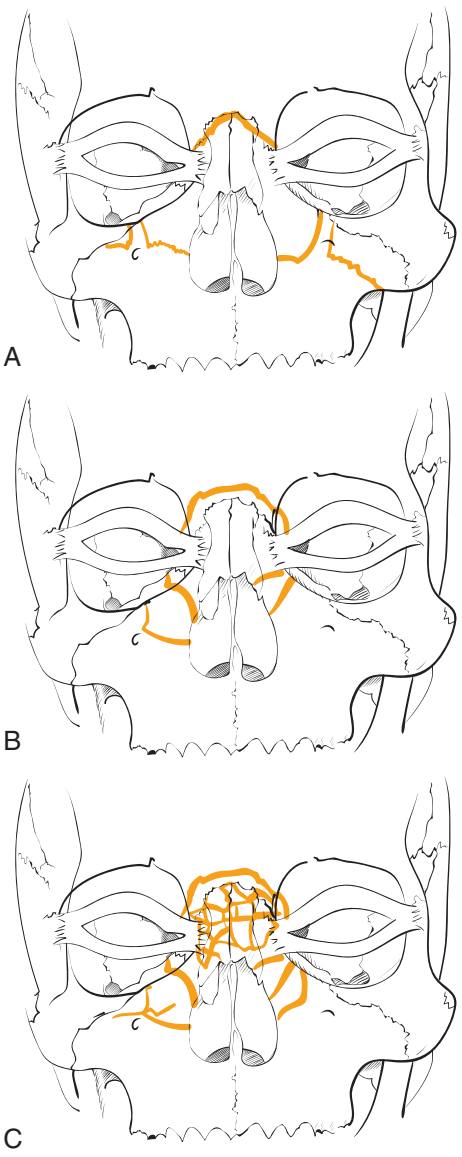

Figure 23-13. Naso-orbital ethmoid fractures have been classified as type I, type II, and type III by Markowitz and colleagues.[53] The type I fractures **(A)** include a solid central segment to which the medial canthus is attached. Type II injuries **(B)** are more comminuted than type I but still leave a central segment to which the medial canthus is intact. In type III injuries **(C)**, the bone is shattered and there is no solid bone to which the medial canthal tendon is attached. *(Redrawn from Markowitz BL, Manson PN, Sargent L, et al. Management of the medial canthal tendon in nasoethmoid orbital fractures: the importance of the central fragment in classification and treatment.* Plast Reconstr Surg. *1991;87:843.)*

patient with life-threatening injuries takes priority. Thus the level of urgency remains an individual decision.

Surgical Access

The frequent use of extended access approaches[56,57] has led to a better understanding of fracture patterns and the complexities of reduction and fixation. Combined with the use of rigid fixation techniques and the liberal use of bone grafts,[58] repair of the facial skeleton has become more dependable, and the need for postsurgical maxillomandibular fixation (MMF) and tracheotomy has been minimized.[59] However, there are also disadvantages to these wide exposures, and facial asymmetries may be seen in the presence of excellent skeletal reduction. These have been attributed to problems with soft tissue healing and redraping, leading surgeons to look for more limited access approaches that will still allow for correct bony repositioning.[60]

There is also an additional challenge in craniomaxillofacial surgery, which is the inability to make incisions directly over most fractures, because unacceptable scars and facial nerve injuries would result. Incisions are carefully planned to take advantage of sites that are either well hidden, transmucosal, or in which the scar can be adequately camouflaged. Frequently, however, this requires extensive undermining and elevation as well as significant intraoperative retraction, all of which can lead to soft tissue changes that result in a less than ideal outcome. These issues must be carefully considered when planning surgery, keeping in mind that it is sometimes wiser to extend an incision than to damage the soft tissues with overzealous retraction.

Upper Third

The workhorse of frontal and supraorbital rim exposure is the coronal incision. (Generally speaking, this incision is less obtrusive even in the bald or balding man than the bilateral brow, so-called butterfly or gullwing incision. The exception might be a unilateral brow incision in the patient with bushy eyebrows, or in the presence of a significant laceration.) In the patient with hair, irregularizing the incision with a running W or a wavy line[61] prevents the scar from parting the hair, making the scar virtually unnoticeable. However, a straight incision seems to be less visible on the bald scalp (Fig. 23-14).

Shaving the hair is not required, although creating a hairless strip makes it easier to keep hair out of the wound during surgery and wound closure (Some neurosurgeons favor a complete shave when an intracranial injury is present.) When full exposure of the zygomas is required, the incision typically begins in the preauricular crease and extends superiorly above the auricle and over the top of the head to the contralateral auricle. The incision may curve anteriorly over the central scalp to shorten the skin flap, which allows the flap to flip more easily. When zygomatic exposure is not needed, the incision starts above the auricle. When a long pericranial flap is needed (for anterior fossa repair and/or frontal sinus obliteration), the incision should not violate the pericranium. The skin can then be elevated posteriorly over the pericranium, which is then incised more posteriorly and elevated with the anterior skin flap, thus creating a long, anteriorly based pericranial flap for later use (Fig. 23-15).

As the flap is elevated anteriorly, care must be used to avoid injury to the temporal (frontalis) branches of the facial nerve. This can be accomplished by either elevating directly against the temporalis fascia or incising the superficial layer of the deep temporal fascia at the temporal line of fusion so that elevation can be continued beneath this layer. If this is done, it is critical that the fascia be resuspended at the time of closure to prevent desuspension of the midfacial soft tissues. The supraorbital and supratrochlear nerves are encountered as the flap is elevated to the supraorbital rims. When the supraorbital nerve passes through a notch, it is easily elevated inferiorly with the flap, although care must be used to avoid injuring it. When the nerve passes through a true foramen, the inferior lip of the foramen must be fractured (using an osteotome, curet, or other bone-biting instrument) to allow the nerve to move inferiorly with the flap. Orbital fat may herniate around the nerve. Elevation of the superior orbital periosteum from the orbital roof requires elevating first in a superior direction once over the rim, because there is typically an overhang of 3 to 7 mm. (Failure to recognize this may result in elevation directly into the orbital tissues.) The periosteum tends to be adherent at the nasofrontal suture, and sharp elevation may be needed here. Elevation to this level provides wide access to the upper third of the face. Elevation of this flap can also be continued inferiorly in the midline for exposure of the nasal bones, medial orbital walls, and frontal processes of the maxillas; elevation laterally provides exposure of the zygomatic arches and most of the zygomatic bones and lateral orbital walls.

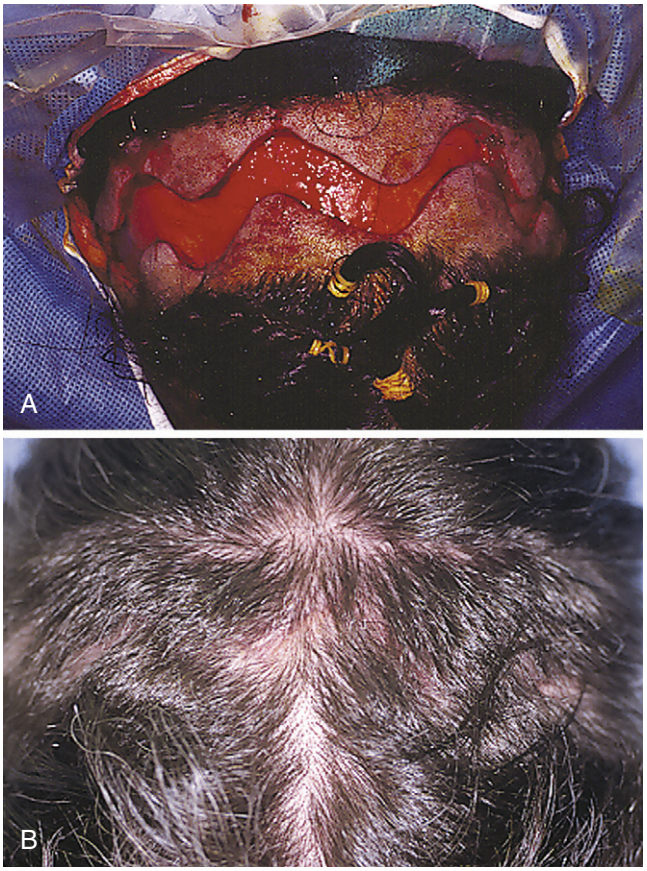

Figure 23-14. A, A coronal incision broken up by irregularization. **B,** Even when the hair is relatively short, the irregularization of the incision allows it be well hidden beneath the hair.

Middle Third

There are numerous options available to the surgeon for approaching the middle third of the facial skeleton, and the surgeon should select incisions based on the access needed to properly repair a particular injury, the ability to camouflage scars, and the surgeon's experience. Zygomatic fractures are generally repaired at more than one site, often necessitating more than one surgical exposure. As noted earlier, the zygomatic arches are well exposed via the coronal incision. A simple arch fracture, however, may be accessed via a Gillies' incision, which is made within the temporal hairline and elevated beneath the temporalis fascia (over the temporalis muscle, because the fascia inserts on the arch, while the muscle passes beneath the arch), allowing an instrument to be passed with assurance beneath the arch for elevation. Or it may be similarly approached using a transmucosal incision in the gingivobuccal sulcus intraorally. The frontozygomatic area (lateral orbital rim) may be accessed in several ways, and the facial plastic surgeon must select the most appropriate incision for the individual situation. The lateral upper lid incision (sometimes described as the "upper lid blepharoplasty incision") is commonly used (Fig. 23-16), because it tends to hide well in the upper lid crease, and it is replacing the lateral brow incision, which, though still considered acceptable by many, not infrequently leaves a noticeable scar. The lateral rim can also be reached through a lower lid conjunctival incision, when the incision is extended laterally

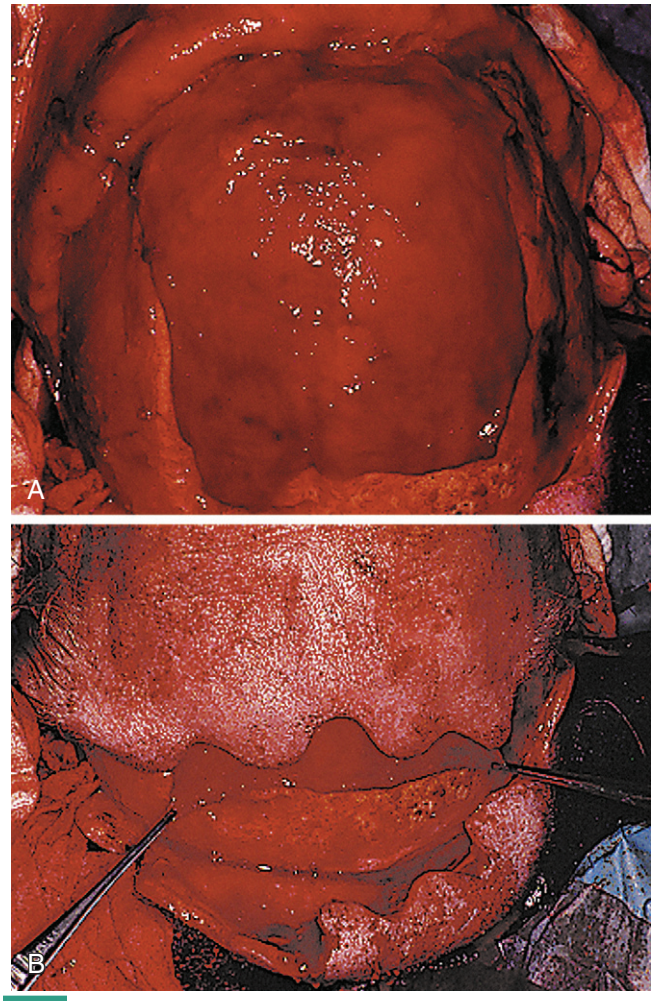

Figure 23-15. **A,** Note that the pericranium is cut posterior to the skin by elevating the posterior skin flap over the pericranium and then incising the pericranium more posteriorly. **B,** Demonstrates the longer pericranial flap made possible by this approach.

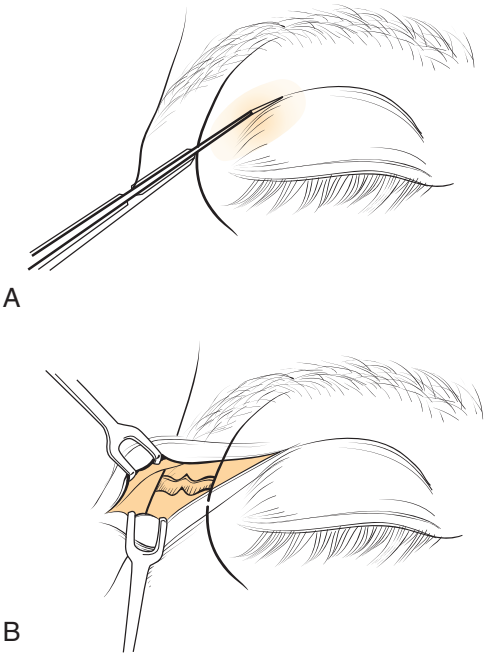

Figure 23-16. The upper lid blepharoplasty incision provides excellent access to the lateral orbital rim and lateral orbit. *(Redrawn from Bailey BJ, Calhoun KH.* Atlas of Head & Neck Surgery—Otolaryngology, *Philadelphia: Lippincott Williams & Wilkins; 2001.)*

Figure 23-17. Photograph demonstrates the fixation of a "Frost stitch." The suture is placed through the lower lid and then pulled under gentle tension over the forehead with the upper lid closed. A Steri-Strip is placed over the suture. The suture is folded back, a second Steri-Strip is placed, and then the suture is folded back upward and a third Steri-Strip is placed. This holds the lower lid under tension.

and a canthotomy is performed. However, an unacceptable amount of retraction may sometimes be required using this approach. The orbital floor, on the other hand, is well exposed via the transconjunctival incision through the lower lid. This can be performed using either a preseptal or a postseptal approach, and each has its advantages and disadvantages. Whichever approach is used, care must be taken to avoid injury to the orbital septum, because scarring in this layer tends to lead to postoperative lower lid malpositions. Extending these incisions to include a lateral canthotomy and skin incision allows wider exposure, particularly for placement of large grafts and for exposure of the medial and lateral orbits. The orbital floor can also be explored via transcutaneous incisions through the lower lid, including the subciliary and the lower lid crease incisions. The infraorbital incision has for the most part been abandoned due to limited access and excessive, prolonged lower lid swelling (except when there is already a significant laceration present). The medial orbit can be explored via a coronal incision, a transconjunctival incision (transcaruncular or retrocaruncular) or a cutaneous incision similar to an external ethmoidectomy approach. Note that whenever a lower lid incision is used, it is wise to place a Frost stitch at the end of the procedure and leave it in place for 24 to 48 hours. It is placed through the lower lid and taped to the forehead; it stretches the lower lid and may decrease the likelihood of lower lid malposition (Fig. 23-17).

The lower portion of the middle third, that is, the anterior maxillary walls, including the piriform apertures, the frontal processes, and the zygomaticomaxillary junction are best approached transorally by incising the mucosa of the gingivobuccal sulcus. Care must be taken to avoid elevating bone fragments in the flap and to avoid injury to the infraorbital nerves. This incision allows elevation superiorly to the infraorbital rims. Additional exposure can be obtained by using the midfacial degloving approach, although this does add the risk of nasal stenosis, in that the mucosa of the nasal vestibule is incised circumferentially in this approach. Palatal exposure is generally obtained through lacerations that occur along fracture lines. A U-shaped palatal flap can also be elevated for wide palatal exposure.

Lower Third (Mandible)

The mandible can be exposed either transmucosally or transcutaneously. Early concerns that intraoral exposures would lead to higher

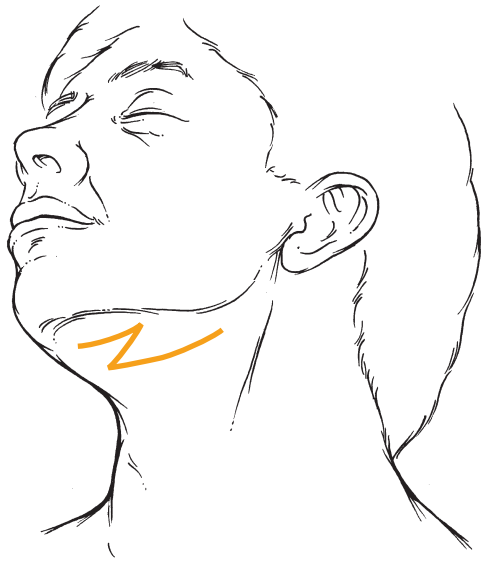

Figure 23-18. The mid body is difficult to reach through an external incision. The direction of the submental incision is different than the direction of the submandibular incision. Sometimes greater length can be obtained by combining these two incisions in a Z-plasty fashion.

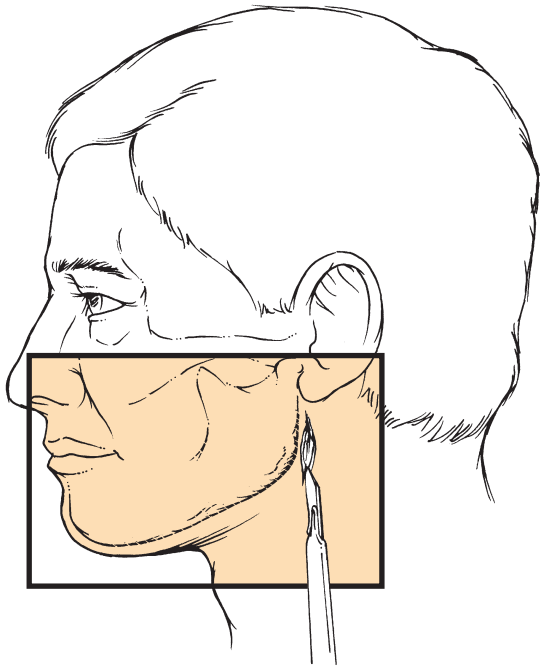

Figure 23-19. Vertical incision just posterior to the mandible through skin and subcutaneous tissue to the depth of the platysma muscle. *(Redrawn from Ellis E III, Zide MF.* Surgical Approaches to the Facial Skeleton. *Philadelphia: Lippincott Williams & Wilkins; 1994:143.)*

infection rates have not proved true in large experiences.[62] Virtually all areas of the mandible can be reached via transoral incisions. The symphyseal region is easily exposed using an incision that is placed 5 to 10 mm below the gingival margin, thereby leaving enough free mucosa for easy wound closure. Body fractures can be similarly exposed. Care must be used to avoid injury to the mental nerve as it exits the mandible and enters the soft tissues to supply sensation to the overlying skin. The angle region is best exposed using an incision that begins at the inferior portion of the anterior ramus of the mandible. This is extended over the oblique line and carried below the gingival margin of the posterior molars. Finally, the vertical ramus and subcondylar regions are exposed using the vertical portion of this last incision and extending it superiorly. Exposure of the subcondylar region is enhanced with the aid of endoscopes.[5-7]

Extraoral incisions add the risk of a visible scar as well as the possibility of injury to the mandibular ramus of the facial nerve. On the other hand, for anterior body fractures, the risk of injury to the mental nerve may be decreased. The symphysis is best approached using a submental incision. The posterior body, angle, and even the subcondylar regions are best approached using a submandibular incision. To aid bone exposure and minimize retraction, the incision may be made one fingerbreadth or less below the mandible and elevated inferiorly superficial to the platysma. The platysma is incised two fingerbreadths below the mandible to minimize the risk to the facial nerve (Fig. 23-18). The anterior body is more difficult to reach transcutaneously, because the relaxed skin tension lines cross the mandible and risk injury to the facial nerve. This area is probably best approached by combining a submental incision with an anterior submandibular incision and connecting them via a Z to minimize the scar. The ramus and subcondylar regions can be approached via the submandibular incision and elevating between the masseter muscle and the bone. Alternatively, a retromandibular incision may be used as advocated by Ellis (Fig. 23-19).[63] A preauricular incision may be used, but this may increase the risk of injuring the main trunk of the facial nerve, and if a preauricular approach is used, a facial nerve dissection should be considered for protection of the facial nerve.

Bone Healing

A cursory introduction to bone healing is included here from the standpoint of the interaction between repair techniques and the way that bone tends to heal. In general, like other injured tissue, bone tends to heal. The process begins almost immediately after injury with the development of a fracture hematoma. Subsequent ingrowth of vessels brings fibroblasts and other progenitor cells. There is a differentiation to chondroblasts, and these lay down fibrocartilage and chondroid matrix, which lead to early stabilization and provide the substrate for the development of osteoid. With differentiation into osteoblasts, osteoid is deposited, resulting in callus formation. It is helpful to think of callus as nature's fixation device, in that callus is deposited until motion ceases at the site of the fracture. Once motion ceases, delicate osteons, each with their own delicate vessels, can grow across the fracture, resulting in the bridging of the fracture by new bone and thus full stabilization and healing.[23,64] Once the fracture is bridged by bone, the bone form can then be remodeled to match its function according to Wolff's law, which says that bone remodels according to the forces acting on it. This results in a re-creation of proper form to match function. This process tends to be very effective for long bone healing.

Unfortunately for the craniomaxillofacial surgeon, Wolff's law fails to account for two key needs of the facial skeleton: aesthetics and dental function. Thus, allowing facial bones to heal on their own tends to result in both significant cosmetic deformities and compromised masticatory function, which can also have significant implications for nutrition. Even though the tooth-containing bones will indeed remodel in response to the forces that act on them, they will not remodel to re-create a proper and functional occlusal relationship between the maxillary and mandibular dentition. It is therefore critical that these fractures be managed in a way that will guide the healing process to re-create both satisfactory form and proper function.

There are two aspects to consider in performing these repairs. One is as noted the proper realignment of the bones to re-create aesthetic form and occlusal function. The other is methodologic and refers to the type of fixation accomplished, rigid fixation, which is designed to maximize the amount of stability created at the time of repair to minimize callus formation, infection, and any shifting in the surgical positioning. Rigid fixation refers to the use of devices (typically plates and screws) that fix the positions of the bones firmly enough to prevent motion of the fragments, even in the presence of functional loading. When properly accomplished, this type of fixation minimizes the development of callus (which may be cosmetically deforming), minimizes

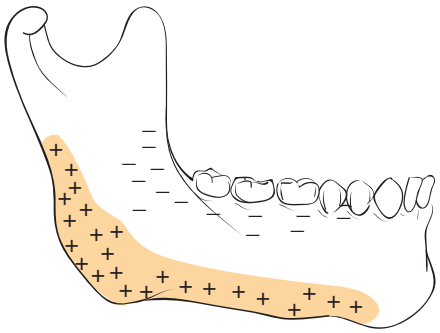

Figure 23-20. Oversimplified depiction of the tension and compression areas created in the mandibular body when force is directed along the anterior mandible by placement of a bolus between the anterior dentition of the mandible and maxilla.

infection, and allows for immediate function, thereby avoiding the need for MMF.

Bone healing via the differentiation cascade described earlier has been referred to as *indirect* or *secondary* bone healing to distinguish it from *direct* or *primary* bone healing, which only occurs when there is no motion across the fracture line.[23] It appears that the bridging of a bony gap by bone can only occur in the absence of motion across that gap. The more motion that is present, the greater the amount of callus needed to stabilize the fragments so that healing by bone can eventually occur. Conversely, the more stable a repair and thus the less motion, the less callus that will form and the greater the likelihood that bone will directly bridge the fracture and heal the injury. It follows that when callus is unable to stabilize a fracture, bone will never form; the fracture remains bridged by fibrous tissue, thus forming a fibrous union, alternatively known as a *nonunion, fibrous nonunion,* or *pseudoarthrosis* (see Complications). To accomplish a stable repair, it is necessary to understand the biomechanics of the facial skeleton, and even more important, it is critical to use this understanding when applying fixation. Otherwise, motion tends to occur when the repair is loaded in function, and complications are then more likely to occur.

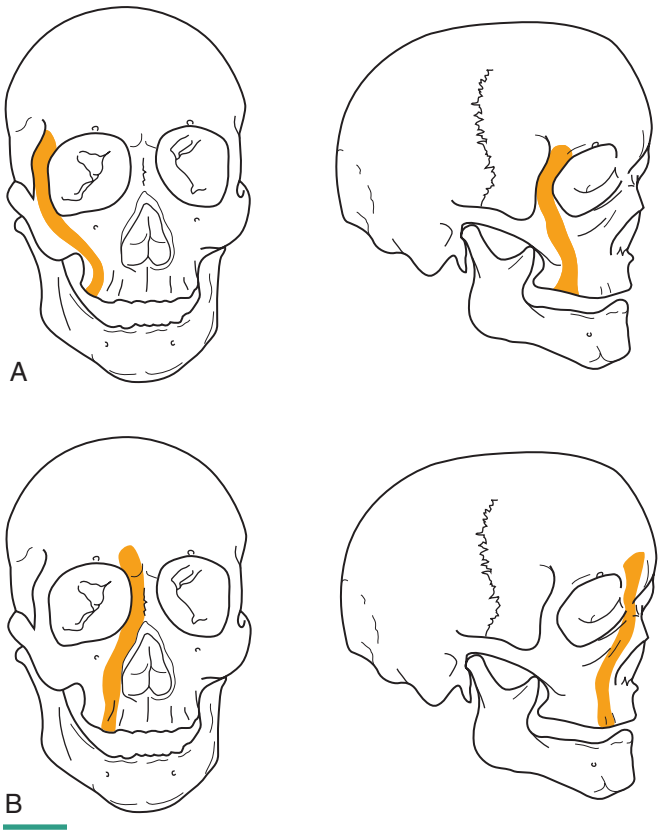

Figure 23-21. A, The lateral vertical buttress of the midface extends from the frontal bone along the frontozygomatic area down across the strong bone of the zygomaticomaxillary area. **B,** The medial vertical buttress extends from the frontal bone across the frontonasal region and down across the nasomaxillary junction encompassing the thick bone of the piriform aperture.

Biomechanics of the Facial Skeleton

The forces acting on the facial bones are complex and not yet fully elaborated.[65] However, the current level of understanding provides enough information to guide rigid repair techniques that can result in a high success rate. On the other hand, disregarding these principles will likely result in higher than acceptable complication rates.

As discussed, the facial form is designed to support its function and to serve as a buffer to protect more critical organs from traumatic injury. Areas that support function must have strength along the paths of force. In the midface, these have been variously called *pillars* and *buttresses*, and these areas support the facial architecture during the powerful acts of biting and chewing.[65-67] It is particularly important to reestablish these buttresses when they have been fractured. Furthermore, these buttresses are separated by areas of weakness, which seem to facilitate their acting as "crumple zones." The mandible provides support to the dentition during biting and chewing. Because this bone swings from the cranium, forces generated when a bolus of food is compressed between the teeth result in a fulcrum effect that generates tension and compression zones in various areas (Fig. 23-20). These must be considered when repairing fractures, because the repairs must overcome both the forces exerted by muscular contraction and the forces created by particular functions such as chewing.

Upper Third

In the upper third, the anterior wall of the frontal sinus is thin, in that it merely provides cover to the sinus itself, and there are no significant forces acting on this area. This can be considered when planning the repair. As long as the bones are held in position, a satisfactory outcome should result. The supraorbital rims, on the other hand, and the frontal bones lateral and superior to the frontal sinuses are thicker, providing protection for the orbital contents and the anterior fossa contents, respectively. It requires more force to fracture these bones, and they are therefore more likely to be impacted and difficult to reduce. Still, there are no significant functional forces acting on these bones.

Middle Third

The middle third is more complex. The so-called pillars or buttresses accept the high forces of mastication without fracturing. These "vertical" buttresses have been described as lateral and medial on each side, as well as posterior (Fig. 23-21). The lateral buttress passes from the molar regions superiorly along the zygomaticomaxillary suture, through the solid malar eminence, then up along the lateral orbital rim and the frontozygomatic suture into the frontal bone. The medial buttress passes from the canine region superiorly along the solid bone that borders the piriform aperture, then superiorly along the solid frontal process of the maxilla into the frontal bone. As Rudderman and Mullen[65] point out, the goal of repair is to reconstruct "load paths," so that the bone can once again support the loads for which it was designed. In the middle third, this requires reestablishment of these four vertical buttresses, which support the impact forces of mastication. There is an additional posterior vertical buttress that transmits forces via the pterygoid plates to the skull base, but little attention is paid to this buttress because there is no access to repair it.

The horizontal buttresses of the midface serve as the connectors across the vertical buttresses. These occur at the palate, incompletely across the central face from malar eminence to malar eminence along the infraorbital rims (incomplete because this horizontal strut is incomplete across the piriform aperture), and across the frontal bar. These buttresses are primarily important to the facial surgeon for reestablishing the correct facial architecture. There is also the third dimension

from anterior to posterior, and the only reconstructible buttress in this direction passes from the temporal root of the zygomatic arch anteriorly to the malar eminence on each side.

The zygoma forms an important attachment for the powerful masseter muscle. To support the function of this muscle, the bone needs to be solidly attached; yet in order to crumple, it also has to be able to give in response to a traumatic force. The multiple attachments of the so-called zygomatic "tripod" make this possible. Whether it is considered a tripod or quadrapod matters little; what is important is the nature of its attachments. The malar eminence is quite solid, but its attachments to the surrounding bone are less so. The zygomatic arch is quite thin, as is the inferior orbital rim. The lateral orbital rim is quite solid, and it is not uncommon for zygomatic fractures to be hinged from this attachment. The attachment to the remainder of the maxilla is broad (and continuous with the inferior orbital rim, thereby allowing the tripod nomenclature to make sense). Whereas the bone is relatively solid vertically to support the forces of mastication, it is actually thin bone that gives easily to a more horizontally or obliquely directed force. Repair requires stabilization of the zygoma in three dimensions. Traditional repairs focused on the most solid fixation point, and it was not uncommon for zygomatic fractures to be repaired with a single wire at the frontozygomatic fracture. The validity of this repair was called into question years ago,[68] and more recent data have suggested that multiple fixation points are required to maintain the three-dimensional position of the zygoma against the strong masseteric pull.[69] More recent repair techniques have focused on the zygomaticomaxillary buttress, because this is usually the mobile area, rather than on fixing the hinge point, which tends to be the frontozygomatic area.

The bony orbit serves as a support for the orbital contents. Thus for the orbit the only biomechanical concerns are the reconstitution of the orbital shape for proper positioning of the orbital contents. This assures proper globe position, which is necessary both cosmetically and functionally. The orbital reconstruction must be strong enough to support the orbital contents.

The central facial area includes the attachments for the medial eyelids and the projection of the nose. The medial eyelids are attached by the medial canthal ligaments to the solid lacrimal crests. When these are disrupted, the tendons are pulled laterally (as well as anteriorly and inferiorly), and the horizontal length of the eyelids is shortened. This needs to be reconstructed adequately to withstand the constant lateral tension of the lids. Otherwise, an unsightly appearance is likely, and poor function of the lacrimal collecting system may result as well. Reconstitution of the nasal bones is important both for nasal function and cosmesis.

Lower Third

As noted earlier, while the dental portions of the mandible occupy the lower third, the vertical rami of the mandible are included in this discussion as well. The normal adult mandible is a strong, solid bone that contains the mandibular dentition. Numerous muscles attach to the mandible, and forces are developed across the bone when these muscles contract, even in the absence of mastication. (This is important, in that forces continue to act across the mandible when a patient is in MMF.) The mandible supports the tongue and the hyoid, structures important for swallowing and airway function. However, the most significant forces across the mandible are developed during mastication, and the forces acting on a given area of the mandible vary depending upon the location of a food bolus between the teeth.

Early explanations of mandibular biomechanics assumed a simple beam with forces along the top of the beam always creating tension zones superiorly (toward the alveolar surface) and compression zones inferiorly. This concept was introduced in Europe almost simultaneously by Spiessl[14] in Switzerland and by Champy and colleagues[17,19] in France. Interestingly, however, these two maxillofacial surgeons developed two entirely different repair techniques to overcome these forces, and two competing schools of thought developed as a result. Those who followed Spiessl and the Arbeitsgemeinschaft fur Osteosynthesefragen (AO) used compression plating techniques to repair most mandible fractures, and those who followed Champy used so-called

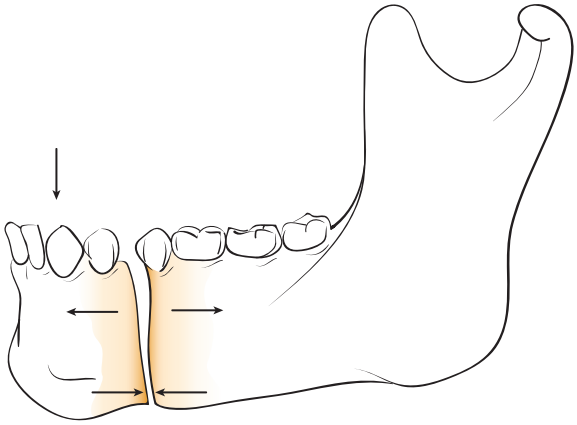

Figure 23-22. When force is applied anteriorly along the dental surface, the posterior portion of the mandible was held in place by the mandibular musculature. This results in a compressive force being generated along the inferior border while the superior border is distracted (an area of tension). *(Redrawn from Kellman RM, Marentette LJ.* Atlas of Craniomaxillofacial Fixation. *New York: Raven Press; 1995.)*

miniplating techniques. Today, it has become apparent that there is room for both of these concepts, and it is more important to understand the biomechanics of fracture repair and to select a particular technique that has the highest likelihood of success in a given situation.

In the simple beam model, a fracture of the mandibular body is distracted superiorly (the tension zone) and compressed inferiorly (compression zone) when a force is applied to the dental surfaces anteriorly (e.g., chewing a bolus between the incisors) (Fig. 23-22). In this situation, controlling the tension zone results in a maintenance of reduction. Furthermore, when a force is applied by chewing anteriorly with the tension zone controlled, the compressive force in function is distributed across the length of the fracture. Once this is clearly understood, a variety of repair options become available to the head and neck surgeon. However, certain limitations created by the unique aspects of mandibular anatomy must first be overcome. These are the presence of tooth roots within the bone and the presence of the inferior alveolar nerve within the bone. Because it is important to preserve these structures uninjured, certain areas of the mandibular bone become unavailable for the placement of fixation appliances. Both Champy and Spiessl came to the same conclusions regarding the need to control the tension zones without injuring vital structures, but they solved the problem of avoiding the teeth and nerves in different ways. Champy chose to control the tension zone with small ("mini") plates positioned carefully between the tooth roots and the inferior alveolar nerve using screws that pass through only one bony cortex, thereby minimizing the risk to the teeth and nerve in case the placement is imperfect. Spiessl shunned the use of these small plates with monocortical screws and instead used a well-placed arch bar across the dentition to control the tension zone and a larger compression plate using bicortical screws placed below the inferior alveolar nerve to maximize the amount of stabilization. The larger, compressive fixation was believed to be necessary in that it was being placed in a position that was actually biomechanically disadvantageous. However, using this approach, it is absolutely critical that the tension zone be controlled first; otherwise, the compression plate on the inferior mandible will distract the alveolar portion of the fracture. Ultimately, as it became clear that both of these techniques had high success rates, the battle between the schools of thought dissolved, and it is now clear that as long as biomechanical principles are properly followed, high success rates should be expected.[70]

Unfortunately, not all aspects of mandibular function follow this simple beam model. There are also irregularities of the mandibular bone that make some areas potentially more unstable than others. There appears to be greater potential for torque and rotational motion in the symphyseal region, so that when using miniplates, two are

required to obtain a stable fixation in this area. A single miniplate appears to be adequate along the mandibular body, as long as the patient does not chew on the side of the fracture during the healing period. The angle region presents some particular problems, and it is the region in which the highest number of complications has always been noted.[71,72] The angle region has thick bone superiorly and thin bone posteroinferiorly. There is often a tooth in the thick superior bone, and its presence may weaken the bone, but extracting this tooth (which may be unavoidable in some cases) tends to weaken the area even more. Furthermore, there is no dentition behind the fracture, so an arch bar lends no support to the repair. The complexity of forces acting on this area adds another challenge. It was first noted by Kroon and coworkers[73] that depending upon where a bolus of food was placed along the mandibular dentition, the location of the compression zones and tension zones at the angle actually varied so much that the inferior area could change from compression to tension and vice versa. (Rudderman and Mullen[65] confirmed this finding for other areas of the mandible as well.) The repair of the angle area remains controversial, but most authors agree that, although more difficult, time consuming, and demanding to apply, the larger, longer, mandibular reconstruction plates[71,74] offer the most dependable repairs and the highest overall success rates. On the other hand, the desire to use easier and simpler techniques has resulted in a pushing of the envelope, and Potter and Ellis have recently advocated the use of a single 1.3-mm miniplate placed intraorally along the oblique line of the mandible as adequate fixation for mandibular angle fractures.[75] A more recent report by Fox and Kellman[76] suggests that when using miniplating techniques to repair mandibular angle fractures, two miniplates are best (and they should probably be 2 mm), as has been previously suggested by Levy and colleagues,[72] as well as by Kroon and colleagues.[73] In a recent prospective study, Siddiqui and associates found no significant difference in complications when using one or two miniplates to repair mandibular angle fractures.[77]

Another important aspect of mandibular biomechanics is the role that the vertical ramus plays in establishing facial relationships. When the midface is shattered, the vertical rami of the mandible become the only determinant of the correct facial height. Therefore, it is critical that these buttresses of facial height be reestablished before attempting to reposition the crushed midfacial bones.

Fracture Repair

The key to fracture repair is an understanding of the biomechanical principles described, along with the various aspects of evaluation and access outlined earlier. Applying all of these principles should allow the surgeon to analyze the injuries, plan the repair, and execute it. The following description addresses some of the controversies and sequencing issues that the surgeon faces in managing these patients.

Most repairs are performed using titanium plates and screws, although a variety of absorbable plates and screws are used as well. These are generally polyester polymers containing polylactic acid (PLA), polyglycolic acid (PGA), or a variety of mixtures of these and a few other polymers. They degrade primarily via hydrolytic scission, and their byproducts are for the most part well tolerated by the human body. However, there is no contraindication to the use of stainless steel wires when needed, and repairs using such wires have stood the test of time.

Occlusion

In any maxillofacial trauma that involves tooth-bearing segments, it is essential that the proper occlusal relationship be reestablished. This is important for the restoration of normal masticatory function. The occlusal relationship between the maxillary and mandibular dentition also determines the relationship between the bones of the lower central face. Direct alignment of bone fragments virtually always takes second place to alignment of the occlusion. This is particularly true when the middle third of the face is collapsed, because the mandibular height is used to reestablish facial height, and the occlusion is a key component of the relationship between the mandible and the maxilla.

Occlusion is best reestablished using arch bars, which are pliable metal bands with hooks for wires or rubber bands that are wired directly to the teeth. The most common arch bar in the United States is the Errich arch bar. Other options include Ivy Loops, although these only stabilize a few teeth rather than the entire dental arch. They also do not provide tension banding across the mandibular dental arch. A variety of other options are available as well. A recent innovation has been the use of screws for MMF. Even though these can be placed quickly and easily, there are several disadvantages, the most common of which is the frequent penetration of tooth roots when placing them (Fig. 23-23).[78] All arch bars tend to pull the dentition lingually, but the more inferior and buccal positioning of the screws when screw-MMF is used tends to increase this tendency.

Figure 23-23. Orthopantomographic x-ray film of a mandible. Arch bars replace the IMF screws. Note the presence of multiple holes in mandibular tooth roots created by the placement of the IMF screws. *(Courtesy of Dr. Michael Ehrenfeld, Munich, Germany.)*

Once arch bars have been placed, they can be used to hold the patient in MMF. This is done by placing wires or rubber bands between the hooks on the upper arch bar and those on the lower arch bar. After rigid fixation of all facial fractures is completed, the MMF can be released, but the arch bars should be kept in place in case training elastics are needed during the healing period. MMF does not correct a malocclusion that is the result of rigid fixation of fragments in suboptimal positions; only replating the fragments corrects such malpositions. MMF may also be needed for management of unfixed fractures, such as subcondylar fractures of the mandible.

Upper Third

A number of algorithms have been published regarding the management of frontal, particularly frontal sinus, fractures. While each has its merits, they tend to be somewhat complicated. Instead, a more simplified approach is presented here. The key issues in frontal sinus trauma relate to two fundamental questions: (1) Is exploration necessary? (2) Is obliteration necessary? The answers require the use of surgical judgment, but certain guidelines are logical.

Keep in mind the purposes of the bone being repaired. The anterior wall needs to be repaired for cosmetic reasons. The posterior wall needs to be managed to protect the anterior cranial fossa. The sinus outflow tracts must function to drain the sinuses, or the sinuses must be obliterated; otherwise chronic infection will result. Thus pure anterior wall fractures that do not extend into the nasofrontal ducts are repaired for cosmetic purposes only. These should be explored if they are significantly depressed, because even in the absence of acute deformity, they are likely to lead to deformities when the swelling resolves. The smallest plates available are generally used, and absorbable plates may work well in this area as well, because there are little or no force demands on the repair. Comminuted fragments may be pieced together and "lagged" with single screws to a plate that bridges the defect, or small fragments can be pieced together with small plates and/or wires. Use of the endoscope may allow repair of selected anterior wall fractures with minimal incisions. These techniques are currently in their infancy, and they are likely to become more prevalent as new instruments are developed to simplify the procedures. When the ducts are involved but the posterior wall is intact, judgment allows more than one option. Frontal sinus obliteration is always acceptable, but it is also reasonable to allow the sinus to function to see what happens. If the sinus becomes

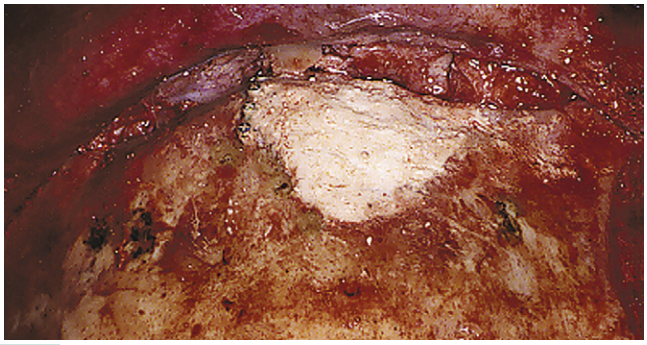

Figure 23-24. The anterior frontal sinus wall was unilaterally severely comminuted in this patient. The sinus was therefore obliterated using hydroxyapatite cement, which was simultaneously used to create a satisfactory contour.

obstructed and acute or chronic sinusitis develops, the sinus can be opened endoscopically, or obliteration can be carried out at a later date.[79] In the absence of posterior wall injury, nothing should be lost by this approach (as long as appropriate follow-up of the patient is assured).

The presence of posterior wall injury complicates the questions. A nondisplaced posterior wall fracture that does not demand exploration for ductal injury or for anterior wall displacement can be observed. However, if the posterior wall is displaced, it is difficult to determine the status of the dura and underlying brain. In the absence of apparent ductal injury, it is still wise to consider trephination and transcutaneous endoscopy, because unexpected herniation of brain into the sinus has been observed using this approach. (The dictum about a wall width of displacement has little meaning in this regard.) In the absence of posterior wall displacement and with no soft tissue abnormalities associated with such a nondisplaced fracture, it is unclear that obliteration is mandatory, even in the presence of ductal injuries. Careful follow-up including interval CT scans will demonstrate whether or not aeration of the sinus ensues. If chronic obstruction persists, then obliteration should be carried out. The choice of obliteration technique includes several options, and most seem to work. Fat has certainly withstood the test of time, as has bone and even leaving the sinus empty (after careful obstruction of the ducts with fascia) to allow for osteoneogenesis.[80-84] Numerous complications have been encountered using hydroxyapatite cements,[85,86] but in one series using it in combination with live pericranial flaps, no complications were seen.[87] The cements do offer the unique advantage of contourability, so they can be used to repair the frontal contour in the presence of severe comminution and/or bone loss of the anterior wall (Fig. 23-24).

Finally, the option of obliteration via cranialization, that is, the complete removal of the posterior sinus walls, is reserved for cases in which the posterior walls are severely comminuted. Donald and Bernstein[88,89] use this technique extensively whenever the posterior wall of the frontal sinus is involved in trauma. On the other hand, Schulz[90] believes that obliteration of the frontal sinuses is never necessary. If the sinus is to be obliterated anyway, it seems logical that the additional layer of the posterior wall adds another barrier between the contaminated nasal cavity and the anterior fossa and should be reconstructed and preserved if possible.

CSF Rhinorrhea

In the presence of severe trauma with fractures of the anterior fossa, CSF rhinorrhea is not rare and may occur via the frontal sinuses, or through the cribriform plate, ethmoid sinuses, and/or sphenoid sinuses. Large defects should be repaired at the time of facial fracture repair. Small defects should be identified endoscopically and can usually be repaired using this approach. Careful examination of defects is important, because a transient leak may have stopped as a result of herniated brain, and late complications such as meningitis or death may occur if these are left untreated.[91]

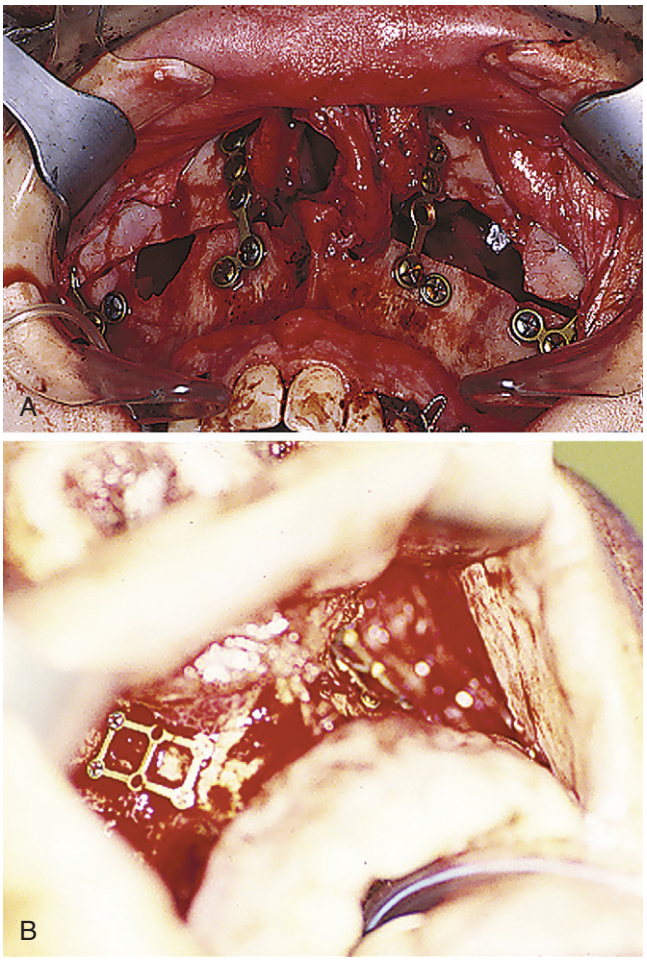

Figure 23-25. A, This is an example of a planned Le Fort I osteotomy repaired using L and J plates. **B,** An alternative repair using 1-mm box plates. The geometric shape of these plates adds additional strength to the repair.

Skull Base Disruption

In the presence of severe disruption of the anterior skull base, brain injury and CSF rhinorrhea are common. The best way to address these injuries is in collaboration with the neurosurgeons. The presence of brain injuries often lead to delays in management of the facial fractures and may actually increase the risk of meningitis. There is good evidence that the longer a CSF leak persists, the greater the risk of meningitis.[51,92] Therefore, earlier intervention may decrease the risk of such complications. The use of the transglabellar subcranial approach may allow for earlier intervention, in that it allows more direct access to the anterior fossa floor without the need for significant retraction of the frontal lobes.[93-96] It also allows direct visualization of the cribriform area without disarticulating it completely, so that many anterior fossa floor injuries may be repaired without completely sacrificing olfaction. The anterior fossa may be segregated from the nasal and sinus cavities, and the facial fractures may be repaired earlier, hopefully leading to better outcomes in these severely injured patients.[93]

Middle Third

Fractures that involve tooth-bearing segments are first stabilized at the level of the occlusion. Horizontal fractures above the occlusal level (Le Fort I) are repaired by reestablishing the four vertical buttresses, two medial and two lateral. Most surgeons repair these fractures using 1.5- to 2-mm L and J plates (Fig. 23-25), although other combinations and sizes may be used. It is important to ensure that two screws are placed on either side of each fracture plated, although more can be placed as long as tooth roots are not violated. The key is to fix these in the direc-

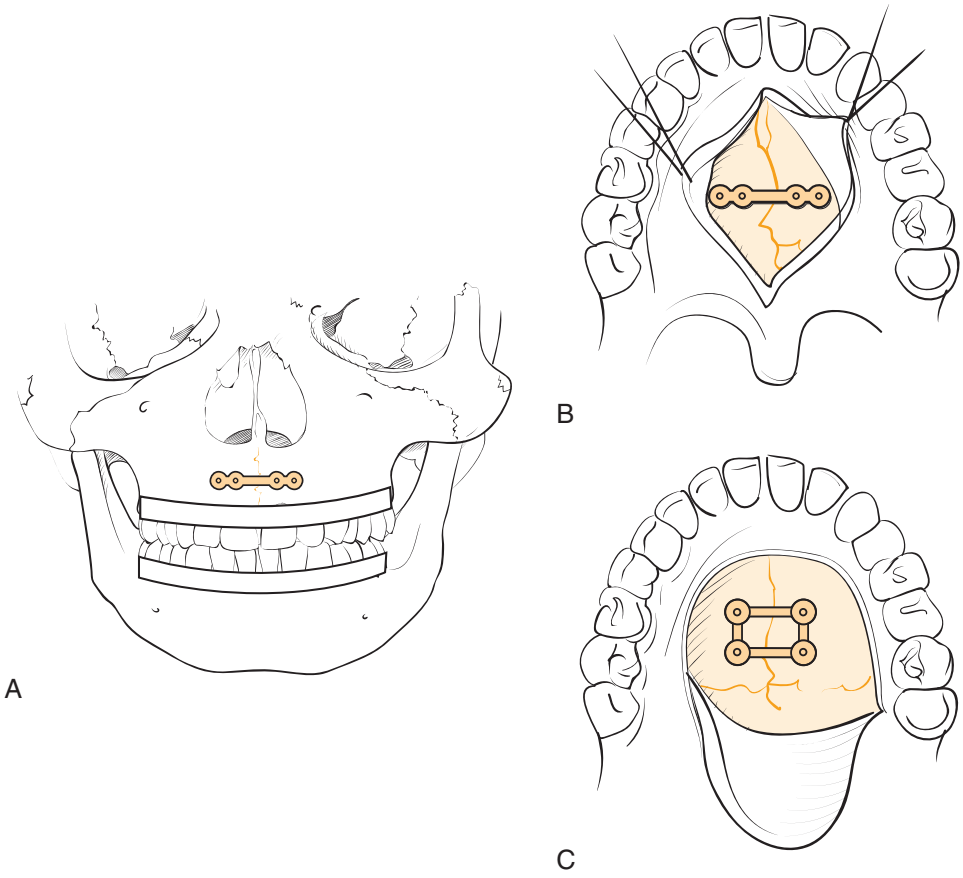

Figure 23-26. **A,** This demonstrates the repair of a split palate by the placement of a plate across the fracture in the anterior maxilla. **B,** This demonstrates direct placement of a plate along the palatal fracture. **C,** Similar to **B,** this demonstrates the use of a box plate to lend greater stability to the palatal fracture repair. *(Redrawn from Bailey BJ, Calhoun KH.* Atlas of Head & Neck Surgery—Otolaryngology. *Philadelphia: Lippincott William & Wilkins; 2001.)*

tion of the forces of mastication, so that chewing will not be likely to disrupt the repair.[65]

When the palate is fractured, it is important to ensure that the teeth have not rotated around the palatal fracture, which would result in lingual or buccal version of the teeth and a significant malposition of the bone fragments. In cases of severe disruption, particularly when alveolar segments are fractured and/or the mandible is similarly disrupted, a palatal splint may be needed to stabilize the dentition in the proper position. The palate may be repaired directly with a plate, or it may be stabilized along the premaxillary area if the occlusal stabilization is adequate to prevent rotation (Fig. 23-26).

Maxillary fractures at the Le Fort II level are similarly stabilized using 1.5- to 2-mm plates, again ensuring that at least two screws are placed on either side of each fracture plated (Fig. 23-27). A plate may be placed along the infraorbital rim to stabilize the upper portion of these fractures. Otherwise, when accessed, the nasal root should be rigidly fixated using very small plates (Fig. 23-28). It is critically important to be certain that the midface is not impacted and rotated superiorly before fixing the bones in place. Although MMF is applied first, it is actually possible to pull the patient into what appears to be good occlusion even though the midface is impacted; the mandibular teeth are pulled by the MMF toward the superiorly rotated maxilla, pulling the mandibular condyles out of the glenoid fossae. A patient may even remain in what appears to be good MMF for a full 6 weeks or longer, and when the MMF is released, the mandible returns to its neutral position revealing a significant anterior open bite. It is therefore important to recognize this at the time of surgery, so that the midface can be properly rotated downward into the correct position. If it is severely impacted, the Rowe midfacial disimpacters may be required to mobilize the midface and bring it down into its proper

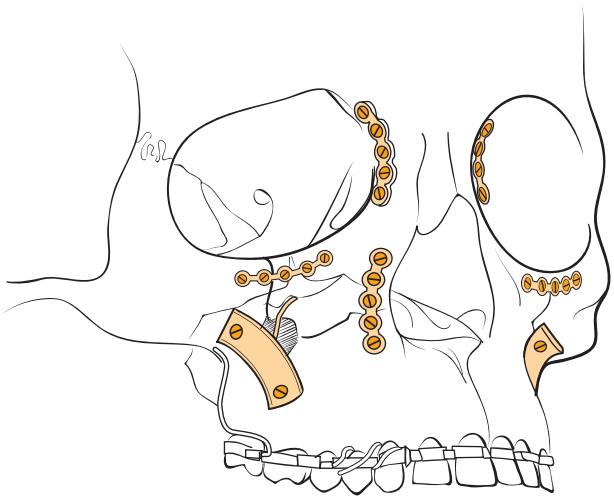

Figure 23-27. Diagrammatic representation of rigid fixation of Le Fort I and II level fractures with miniplates. Note that the right maxillary defect is repaired with a bone graft. The bone graft is lagged to the bone on either end so that the bone graft itself functions as the rigid fixation device. *(Redrawn from Kellman RM, Marentette LJ.* Atlas of Craniomaxillofacial Fixation. *New York: Raven Press; 1995.)*

position. For many years, surgeons were more concerned about the possibility of facial elongation due to MMF pulling on unfixed maxillary fractures than they were about midfacial rotation and foreshortening. Therefore, the mainstay of treatment was Adams suspension wiring, in which the upper arch bar was wired to the zygomatic arches (or frontal bones when the zygomas were fractured) to prevent facial elongation; such treatment probably aggravated midfacial rotation and led to foreshortening and anterior open bite formation in many patients. With the advent of extended access approaches and routine exposure and fixation of midfacial fractures, this problem was recognized and is now carefully avoided. Similarly, with the availability of rigid fixation techniques, the use of halos for external fixation of midfacial fractures has become extremely uncommon. Nonetheless, familiarity with such techniques is of value in understanding the variety of surgical options.

Whereas the areas between the buttresses are not particularly important for structural support, the buttresses themselves are. Therefore, when bone is deficient along these buttresses, it should be replaced. A defect less than 5 mm in a single buttress can probably be safely bridged with a plate. Otherwise, defects should be bridged using bone grafts from another site. Split calvarium is a common source of bone graft material. It can be stabilized under a plate, or it may be used as a biologic plate and fixed to the bone at each end using lag screws (see Fig. 23-27).

The amount of stabilization (and therefore the amount of surgical exposure) required for fixation of zygomatic fractures may vary depending on the amount of instability and comminution of the fractures. Manson[97] has suggested that the severity of the injury is determined by the amount of energy transmitted to the bone at the time of injury. This is implied by the injury, so it is the severity that is actually analyzed in planning the repair. However, for minimally displaced fractures, the zygoma tends to hinge at the frontozygomatic area and repair may require only percutaneous reduction, and it may pop into place and stay, or it may need only a sublabial exposure and fixation along the zygomaticomaxillary area. When greater force causes the injury, there tends to be comminution at the zygomaticomaxillary area, making this an inadequate point of reference for reduction. A lower lid exposure allows alignment of the infraorbital rim, as well as later exploration of the orbital floor if needed. Access to the lateral orbit is also particularly helpful, in that alignment of the zygoma with the greater wing of the sphenoid in the lateral orbit tends to be a dependable landmark for proper bony reduction. With more severe impacts, marked comminution may make it more difficult to be assured that the zygoma has been properly repositioned. A coronal incision allows full exposure of the entirety of the zygomatic arches. When the contralateral zygoma is intact, it serves as a good frame of reference. Otherwise, even wide exposure may not ensure accurate repositioning of the zygoma. Intraoperative radiography can be useful in this regard. The arch position can be checked using fluoroscopy.[21] However, while not commonly available, intraoperative CT scanning certainly provides the most accurate assessment of bone position. Otherwise, a postoperative scan may indicate the need for revision surgery. Finally, it is important to keep in mind that although most orbital floor defects can be evaluated on preoperative CT scans, a potential orbital floor defect may not be visible. This occurs when the zygoma is severely impacted into the orbital space. After disimpaction of the zygoma, a previously absent orbital floor defect that requires repair may be present. Failure to look for this may result in unanticipated enophthalmos postoperatively. An endoscope placed into the maxillary sinus provides a minimally invasive way to assess the orbital floor in this situation. It is also important to repair the orbital rims before addressing the orbital walls, because the rim position will affect the globe position and the overall shape of the orbit.
