This technique has been applied by one of the authors (P.K.P.) in mediastinal exploration after sternotomy with satisfactory results (Fig. 125-27). Despite uptake of sestamibi by myocardial tissue, background radioactivity within the mediastinum seems to be less than that of thyroid tissue, facilitating a focused dissection with minimal disturbance of surrounding mediastinal structures. Reoperation for multiple-gland disease in secondary and tertiary hyperparathyroidism has been aided with the use of the gamma probe when supernumerary glands are present. In one notable instance in this series, three additional parathyroid glands (two cervical and one mediastinal) were recovered in a patient with tertiary hyperparathyroidism who previously underwent documented four-gland parathyroidectomy during preparation for cadaveric renal transplantation. The gamma probe was instrumental in identifying one of the cervical glands and one mediastinal gland, which was the only parathyroid gland that was localized accurately on initial sestamibi imaging. The gamma probe may also be applied for removal of hyperfunctional parathyroid tissue autotransplanted to the forearm in the setting of secondary or tertiary hyperparathyroidism.

Parathyroid Carcinoma

Parathyroid carcinoma is reported to be the cause of primary hyperparathyroidism in only 0.1% to 4% of individuals affected.[404-407] Parathyroid carcinoma occurs with equal frequency in male and female patients; in contrast, parathyroid adenomas occur more frequently in female patients.[408] The epidemiology of parathyroid carcinoma offers few clues about its etiology and pathogenesis. The development of cancer of the parathyroid glands has been linked to chronic renal failure and dialysis,[409-411] and familial hyperparathyroidism syndromes including MEN-I and MEN-IIA and the hereditary hyperparathyroidism–jaw tumor syndrome.[412] The hyperparathyroidism–jaw tumor syndrome is

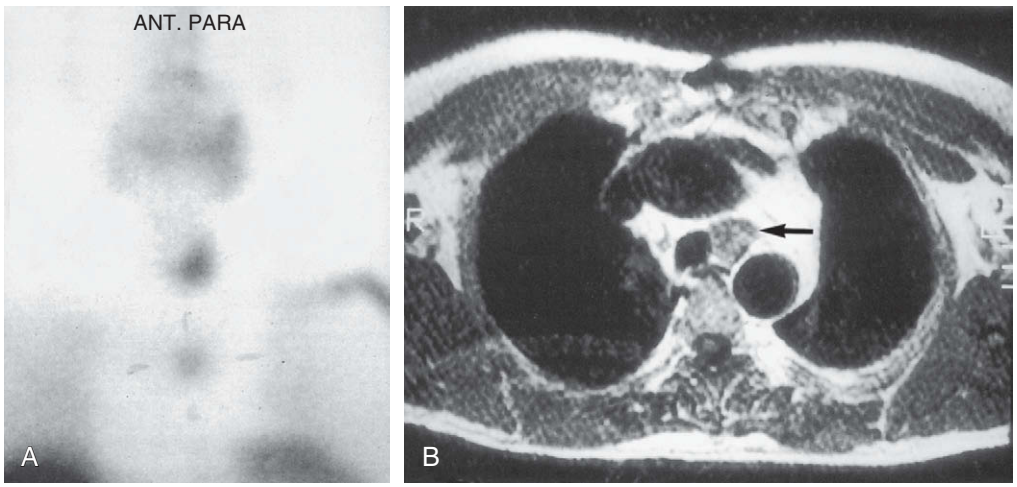

Figure 125-26. Tc 99m sestamibi scan **(A)** and MRI scan **(B)** in a patient with a mediastinal parathyroid adenoma. The area of nuclear uptake noted on the sestamibi scan correlates anatomically with the nodule shown in the aortopulmonary window on MRI. Adenoma was removed via left lateral thoracotomy.

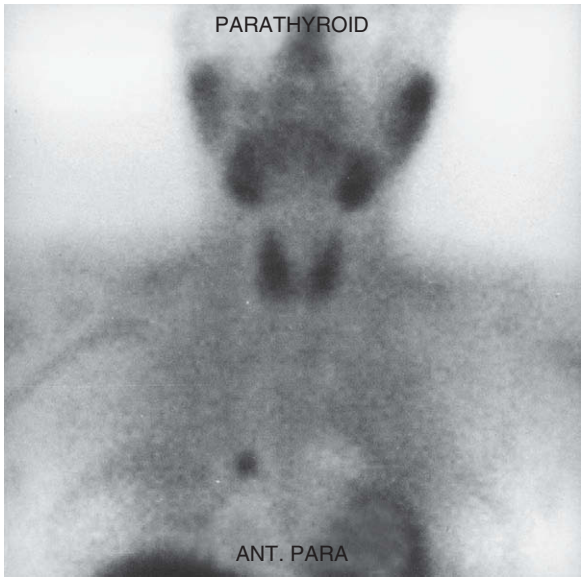

Figure 125-27. Tc 99m sestamibi imaging showing mediastinal parathyroid that represented a fifth hyperplastic gland missed at initial surgery, at which time four hyperplastic glands were removed.

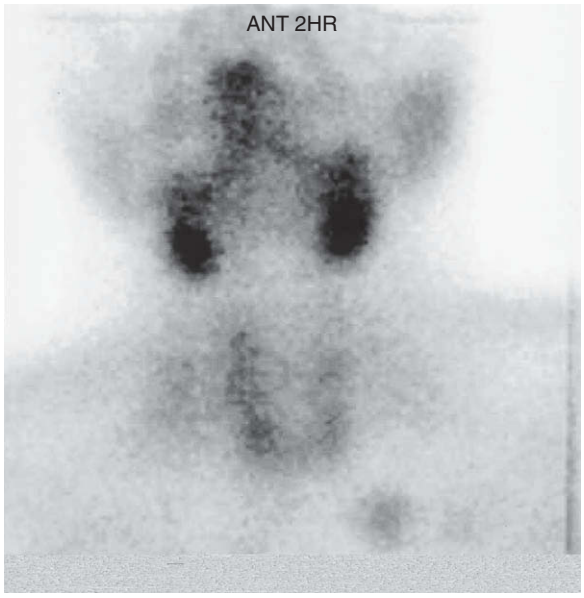

Figure 125-28. Tc 99m sestamibi image showing delayed uptake in the left superior mediastinum in a patient with recurrent parathyroid carcinoma.

characterized by recurrent parathyroid adenomas, fibroosseous tumors of the mandible, and Wilms' tumors.[412]

Generally, patients with parathyroid cancer have higher serum calcium levels, higher levels of intact PTH, and more profound metabolic abnormalities than patients with parathyroid adenoma or hyperplasia. Approximately 70% of patients with parathyroid carcinoma have serum calcium levels greater than 14 mg/dL and intact PTH levels at least five times the upper limit of normal.[413-417] Approximately 80% of patients with parathyroid cancer are either symptomatic or have some metabolic abnormality associated with their disease, and 40% were found to have a palpable neck mass.[413,415] This finding contrasts with the presentation in patients with benign causes of hyperparathyroidism; 50% of that cohort are asymptomatic in diagnosis, and the presence of a neck mass is rare.

A definitive preoperative diagnosis of parathyroid carcinoma is impossible to make; metabolic manifestations of parathyroid cancer overlap with the manifestations of parathyroid adenoma. A high index of suspicion of parathyroid carcinoma should be maintained especially in patients with serum calcium levels greater than 14 mg/dL and a palpable neck mass.[413,415,417] Recurrent laryngeal nerve palsy manifesting in a patient with hyperparathyroidism is also highly suggestive of parathyroid cancer.[418]

The definitive treatment of parathyroid cancer is en bloc resection of the tumor and areas of potential local invasion or regional metastasis or both. Parathyroid cancer frequently recurs in the central neck compartment, and typically exhibits a natural history marked by recurrent hypercalcemia. Performance of the appropriate surgical procedure during the initial operation is crucial, and is one of the most important prognostic factors in parathyroid cancer.[419] The integrity of the parathyroid capsule should be maintained during dissection using an en bloc resection of the ipsilateral central neck contents, including the thyroid lobe and tracheoesophageal soft tissues and lymphatics.[420] Structures such as the recurrent laryngeal nerve, esophageal wall, or strap muscles may require sacrifice if the tumor adheres to them; this reduces the risk of tumor spillage and local recurrence. The increased local control achieved with resection of the recurrent laryngeal nerve outweighs the complication of vocal cord paralysis, which may be managed by phonosurgical rehabilitative procedures.

A central compartment (level 6 and possibly level 7) neck dissection together with resection of soft tissues within the superior anterior mediastinum is important to stage appropriately any lymph node involvement that is not directly palpable during the initial surgery. Lymph node metastasis lateral to the jugular vein is rare in parathyroid cancer during the initial presentation.[413] Prophylactic modified radical or selective dissection of levels 1 through 5 is not generally recommended. Neck dissection is reserved for patients with lymph node metastasis detected radiographically or by clinical examination in the jugular distribution, or for patients with massive soft tissue invasion of lateral neck structures.

Although cure after resection of recurrent parathyroid carcinoma is rare, aggressive resection of local recurrence is recommended to control severe hypercalcemia. Selected patients achieve prolonged disease-free intervals after one or more surgical procedures for recurrence in the neck or anterior superior mediastinum.[421]

In addition to the approach for initial surgery of parathyroid carcinoma and local recurrence, an aggressive surgical approach to metastatic parathyroid cancer has been advocated to control marked hypercalcemia. Obara and colleagues[420] reported on lung resection for metastasis from parathyroid cancer in which 32% of patients resected achieved a significant reduction in total serum calcium levels, and 14% achieved long-term survival ranging from 9 to 30 years. Surgery for locally recurrent parathyroid cancer may be guided by preoperative localization studies to define better the extent and location of recurrent parathyroid cancer (Fig. 125-28). Localization studies should be interpreted with caution, however, because not all tumor foci may be detected, and in patients with very high intact PTH levels, benign lesions of bone (brown tumors) may mimic metastases.[422-426]

The low incidence of parathyroid cancer has made it difficult to study the roles of radiation and chemotherapy. A report issued by the National Cancer Database described the use of radiation therapy in combination with surgery in less than 7% of the 286 cases included.[408] Some reports have advocated the importance of complete en bloc resection followed by radiation therapy to increase local control.[427,428] The results of these reports must be tempered, however, by the finding that patients in these series may not have had advanced poorly resectable disease, a finding that characterized investigations in which radiation therapy was believed to be a factor that worsened prognosis for parathyroid cancer.

Chemotherapy has a very limited role in the management of parathyroid cancer. Some response to therapy has been noted with a combination of fluorouracil, cyclophosphamide, and dacarbazine, and the combination of methotrexate, doxorubicin, cyclophosphamide, and

lomustine. These agents were not administered in a controlled study environment, and patient numbers were exceedingly few.[429,430]

Hyperparathyroidism during Pregnancy

Hyperparathyroidism during pregnancy is rare, and pregnant women usually represent a very small fraction of the total number of patients treated for this disease.[431] As in nonpregnant patients, a single parathyroid adenoma is the most likely to be the cause of hyperparathyroidism, although hyperplasia and carcinoma have been reported.[432-434]

During pregnancy, there is a degree of protection in the mother against hypercalcemia provided by calcium transport across the placenta.[432] Large amounts of calcium depress the fetal parathyroid function and result in fetal hypoparathyroidism. After delivery, when maternal calcium is no longer available, neonatal tetany develops as a consequence of hypercalcemia; this is the most common presenting sign for maternal hyperparathyroidism in pregnancy.[434] Additional fetal complications described in mothers with hyperparathyroidism include spontaneous abortion, prematurity, intrauterine growth restriction, and stillbirth.[431] Although many pregnant women are asymptomatic, presenting symptoms of hyperparathyroidism during pregnancy may include muscle weakness, abdominal symptoms, disorientation, coma, and death.[433]

The risk of obstetric complications has been shown to be significantly greater in women who do not undergo surgery for hyperparathyroidism while pregnant.[433] Some investigators believe that neonatal hypocalcemia is transient and treatable, and maternal disease can be successfully controlled medically when the diagnosis is already known.[434,435] The opposing opinion is that regardless of symptom complex severity, all pregnant patients with hyperparathyroidism should undergo neck exploration to prevent the array of potential maternal and fetal complications.[436]

There seems to be uniform agreement that in severely symptomatic patients, surgery should not be postponed until after delivery. The ideal safe period for parathyroidectomy is the second trimester, when chances of pregnancy loss or premature labor as a consequence of surgical intervention are minimal.[436] If the diagnosis is made during the third trimester, parathyroid exploration usually can be postponed until after labor and delivery. Preoperative hypercalcemia may be successfully controlled with fluids, diuretics, and orally administered phosphate. Plicamycin, an antineoplastic agent, should be avoided during pregnancy, however, because it is highly toxic to the fetal bone marrow, liver, and kidney. The most severe cases of hypercalcemia may require hemodialysis for appropriate control and stabilization.[432]

Medical Management of Hyperparathyroidism

It may be necessary in selected patients with hyperparathyroidism to consider medical therapy, including patients in whom significant comorbidity may render them at risk for significant complications as a consequence of surgical exploration or patients with unresectable parathyroid carcinoma and uncontrolled hypercalcemia. Consideration for medical therapy should be weighed in relation to the patient's symptom complex, age, and overall medical condition and health status.

A few general management schemes may be used to treat hypercalcemia. Expansion of intravascular volume by hydration together with the administration of loop diuretics should enhance urinary calcium excretion. Pharmaceuticals that reduce osteoclastic bone resorption, such as bisphosphonates, calcitonin, and plicamycin, may be used for various clinical settings.

The type of treatment employed generally depends on the severity of the hypercalcemia and resultant clinical setting. In patients not fulfilling any criteria for surgery and in the absence of any circumstances that would make the patient unsuitable for medical monitoring as currently accepted, no treatment is recommended except adequate hydration and avoidance of thiazide diuretics and immobilization. Estrogens have a theoretical advantage of potentially reducing serum calcium, while providing known beneficial effects on bone in the prevention of osteoporosis in postmenopausal women. The potential for the development of malignancies of the uterus and breast with estrogen use limits the practicality of this approach to reduce calcium levels. In addition, estrogen may increase levels of PTH. Considering these variables, estrogen should be used cautiously in these patients, and if estrogen is needed to control calcium levels, surgical exploration should be more strongly considered.

For patients in whom calcium levels are 12 mg/dL or less, enhancement of urinary calcium excretion should be the initial approach. Most patients in this category are volume depleted because of the loss of water resulting from hypercalciuria. Volume correction with appropriate oral intake of salt and fluids most often corrects the serum calcium level. Diuresis should be implemented carefully in these patients because the use of diuretics may worsen volume depletion and exacerbate hypercalcemia. If diuresis is warranted to enhance calciuria, loop diuretics such as furosemide may be used. Thiazide compounds, which may worsen hypercalcemia, should be avoided.

The use of oral phosphate salts has been advocated in the treatment of mild hypercalcemia in controlled situations.[437] This approach may reduce the serum calcium by 1 mg/dL through a series of complex mechanisms involving decreased calcium absorption from the gut, decrease in circulating 1,25-dihydroxyvitamin D, and reciprocal reduction of serum calcium by increasing serum levels of phosphorus. Bisphosphonates are among the most effective inhibitors of bone resorption, and are conceptually offered as an alternative in treatment for mild hypercalcemia caused by primary hyperparathyroidism, but so far they have not provided for a substantial reduction in serum calcium levels.[438] More recent clinical evidence has suggested, however, that the postmenopausal osteoporosis dose of alendronate (10 mg/day) effectively reversed bone loss in hyperparathyroidism.[439] Alendronate increased bone density within 1 year by more than 5% in the spine, similar to its effect in postmenopausal osteoporosis. It may be inferred that bone loss associated with hyperparathyroidism may be controlled by treatment with bisphosphonates, and this treatment could protect the bone in cases where surgery is contraindicated.

Long-term medical management of hypercalcemia in patients with mild hyperparathyroidism or patients in whom surgery may carry unacceptable risks remains problematic. Direct reduction of PTH levels by manipulating the calcium-sensing receptors on parathyroid cells has ushered in a new class of pharmaceuticals called calcimimetic agents.[440,441] These agents act at the level of the parathyroid cell calcium receptor as a G-protein, such that when coupled with the receptor, the receptor G-protein complex recognizes calcium as its ligand.[442] In the presence of increased extracellular calcium, the receptor complex is activated, which results in a signal to the cell via a G-protein–transducing pathway to increase intracellular calcium, inhibiting PTH secretion. One such calcimimetic agent under investigation is R-568, which was found to increase cytoplasmic calcium and reduce PTH secretion in vitro.[441] Further investigational experience was noted in postmenopausal women with primary hyperparathyroidism in whom administration of R-568 resulted in decreased PTH secretion and reduced serum calcium concentrations.[440] Larger clinical trials are expected to clarify further the therapeutic potential of these calcimimetic compounds, but it seems that they may offer a therapeutic alternative to parathyroidectomy in the long-term management of hypercalcemia, especially in patients with mild hyperparathyroidism, or patients in whom surgery is contraindicated or impossible (i.e., parathyroid carcinoma).

Summary

The management of hyperparathyroidism mandates a thorough, methodologic approach to diagnosis, patient evaluation and preparation, and development of a comprehensive therapeutic strategy. Advances in nuclear imaging and the ability to assess the serum level of PTH rapidly have allowed the fundamental surgical approach to become accurately directed, more refined, and less extensive, leading to improvements in outcome and reductions in treatment time, morbidity, and cost.

Although these changes have revolutionized the manner in which surgeons approach disorders of the parathyroid glands, they may not be universally applicable, and should not serve as a substitute for a well-founded and traditional knowledge base in surgical embryology, anatomy, and technique. Most patients with hyperparathyroidism who undergo surgical therapy benefit symptomatically and metabolically.

CHAPTER ONE HUNDRED AND TWENTY-SIX

Management of Thyroid Eye Disease (Graves' Ophthalmopathy)

Douglas A. Girod

Richard D. Wemer

Key Points

- Graves' disease is an autoimmune disorder that is associated with hypermetabolism, enlargement of the thyroid gland, and exophthalmos.
- In Graves' ophthalmopathy, retrobulbar fibroblasts secrete glycosaminoglycans, causing engorgement of extraocular muscles and orbital fat, resulting in increased volume of the orbital contents.
- Advanced Graves' ophthalmopathy can result in significant proptosis and optic neuropathy, with potential loss of vision.
- Conservative measures for Graves' ophthalmopathy include medical therapy, administration of steroids, and radiation therapy. Failure of conservative measures requires surgical decompression of the orbit.
- Orbital decompression can be performed via external, transantral, transconjunctival, endoscopic, or combined approaches. Two-wall and three-wall decompressions have been described with varying degrees of reduction in proptosis and improvement in vision.
- Ancillary procedures for Graves' ophthalmopathy include optic nerve decompression, extraocular muscle surgery, and eyelid surgery.

In 1835, Graves described a clinical syndrome that included symptoms such as hypermetabolism, diffuse enlargement of the thyroid gland, and exophthalmos. Although others also had recognized this entity, Graves defined the thyroid as playing a central role in the disease. Graves' disease is now recognized as a multisystem disorder characterized by one or more of the following: (1) hyperthyroidism associated with diffuse hyperplasia of the thyroid gland, (2) infiltrative ophthalmopathy (leading to exophthalmos), and (3) infiltrative dermopathy (localized pretibial myxedema). More recent work has helped to establish Graves' disease as an autoimmune process targeted at the thyroid-stimulating hormone (TSH) receptor in the thyroid.[1-3] In addition, retro-ocular fibroblasts have been found to play a key role in the development and progression of the ophthalmopathy seen in some patients with Graves' disease.[4,5]

Despite these advances in understanding of Graves' disease pathogenesis, only limited progress has been made in the management of the disease. Therapy is still primarily directed at the manifestations of the disease in a palliative fashion, rather than at preventing the underlying destructive autoimmune process. This chapter focuses on the evaluation and management of the ophthalmic manifestations of Graves' disease.

Pathophysiology

Extensive research in recent years has led to important insights into the pathologic mechanisms involved in Graves' disease and Graves' ophthalmopathy. As understanding progresses, so should the ability to deal with this challenging disorder.

Graves' Disease

Current theory describing the development of Graves' disease involves autoreactive T cells, which arise through an escape from clonal deletion, through failure of suppressor T-cell activity, or through molecular mimicry to become reactive to TSH receptors.[6,7] Most of the T cells responsible for the reaction are located in the thyroid gland itself. Subsequent thyroid damage from any etiology (e.g., chronic thyroiditis, radiotherapy, smoking, drugs) results in the release of the thyroid autoantigen (TSH receptors). As the autoimmune process amplifies, T lymphocytes are activated, and humoral immunity produces antibodies to the TSH receptor that are stimulatory, resulting in hyperthyroidism. In some patients, underlying chronic thyroiditis may dramatically reduce thyroid reserve, or TSH receptor–blocking antibodies may be present, resulting in "euthyroid" patients with Graves' disease.

Graves' Ophthalmopathy

The extraocular muscles are the site of the most clinically evident changes in patients with Graves' ophthalmopathy. Although the muscles are enlarged on computed tomography (CT) scan, the myocytes themselves appear fairly normal histopathologically.[8] There is an associated intense proliferation of perimysial fibroblasts and dense lymphocytic infiltration. Early reports of circulating autoantibodies against eye muscle antigen in sera from patients with Graves' ophthalmopathy led to the theory that the disease was a result of an autoimmune response directed against the extraocular eye muscle fibers.[9] This theory

began to lose favor as study of these autoantibodies proved them to be neither tissue-specific nor disease-specific. The lack of histologic evidence of cytotoxicity against eye muscle in vivo also argues against this theory.

Attention has now focused on the retrobulbar fibroblast as playing a key role in the pathogenesis of Graves' ophthalmopathy. These fibroblasts have several capabilities that place them at the center of the changes seen in the eye. They secrete a range of glycosaminoglycans (predominantly hyaluronate), the deposition of which is a hallmark of Graves' ophthalmopathy and causes interstitial edema as a result of their intensely hydrophilic nature. These cells can also produce major histocompatibility complex (MHC) class II molecules, heat shock proteins, and lymphocyte adhesion molecules, which allow them to act as target and effector cells in the ongoing immune process in patients with Graves' ophthalmopathy.[10] In addition, autoantibodies against fibroblast antigens have been found in most patients with Graves' ophthalmopathy. These antibodies share some characteristics with TSH receptor antibodies (TRAbs).[5] More recently, probes to TSH receptor messenger RNA (mRNA) have labeled mRNA within the retrobulbar fibroblasts of patients with Graves' ophthalmopathy.[6] The "fibroblast antigen" may be similar to all or part of the TSH receptor, and it represents a shared thyroid-eye antigen. Such an antigenic similarity would explain the immune cross-reactivity between these two seemingly unrelated tissue sites.

Lymphocytes also are active in the ongoing immune process of Graves' ophthalmopathy. Orbital lymphocyte infiltrates have been found to be primarily T cells, including $CD4^+$ (T helper cells) and $CD8^+$ (T suppressor and cytotoxic cells). Cytokines released by T cells have been shown to induce fibroblast proliferation and collagen and glycosaminoglycan deposition. Grubeck-Loebenstein and colleagues[11] cultured retrobulbar suppressor and cytotoxic T cells out of tissues removed at the time of orbital decompression, and found them capable of targeting the retrobulbar fibroblasts. Interactions with fibroblasts resulted in pronounced T-cell cytokine production and fibroblast proliferation without evidence of fibroblast cytotoxicity. The T cell–retrobulbar fibroblast interaction may be responsible for the clinical manifestations of Graves' ophthalmopathy.

Epidemiology and Etiology

An accurate estimate of the prevalence of Graves' ophthalmopathy is difficult to determine and depends in part on the diagnostic criteria used to define the presence of ophthalmopathy. "Lid lag" and "stare" are nonspecific signs and can be seen with thyrotoxicosis stemming from etiologies other than Graves' disease. In an exhaustive review of the literature, Burch and Wartofsky[6] found an incidence of ophthalmopathy in patients with Graves' disease of 10% to 25% if these nonspecific signs were excluded, and 30% to 45% if lid findings were included as diagnostic criteria. When intraocular pressure on upgaze or CT findings also were included, the incidence increased to nearly 70%. The most severe form of Graves' ophthalmopathy with optic nerve involvement and visual impairment occurs in only 2% to 5% of patients with Graves' disease.[12,13]

Effects of Genetics and Sex

The role of genetic predisposition and MHC antigen patterns in patients with Graves' ophthalmopathy has been extensively studied, but remains poorly characterized.[6] Ethnicity seems to play some role; Tellez and coworkers[14] found that European patients with Graves' disease were six times more likely to develop ophthalmopathy than Asian patients with Graves' disease. More important are the influences of sex on the development of Graves' disease and the associated ophthalmopathy. A strong 3:1 female-to-male preponderance exists for Graves' disease,[15,16] which decreases to about 2:1 for patients with Graves' ophthalmopathy. Overall, male patients with Graves' disease have a higher incidence of ophthalmopathy that is more severe and tends to develop later in life.[6]

Effects of Tobacco

Several studies have reported an increased incidence of goiter in tobacco smokers compared with nonsmokers, attributing this to thiocyanate, a known goitrogen that is present in inhaled tobacco smoke.[17,18] Studies have also reported an association between smoking and the incidence and severity of Graves' ophthalmopathy.[14,19] This relationship was not found in patients with other forms of thyroid disease, and suggests the tobacco effects are specific to Graves' disease. It is possible that the decrease in female preponderance in Graves' ophthalmopathy, especially in the more severe forms, may be a reflection of the higher incidence of smoking among male patients, rather than a true sex difference.[6]

Effects of Thyroid Status

The role of thyroid hormonal status in the development and severity of Graves' ophthalmopathy has been particularly difficult to ascertain because of the overlap of thyrotoxicosis with antithyroid therapy in these patients. Thyrotoxicosis alone is thought to have little direct effect on the autoimmune process. It serves as a poor marker for disease severity because the prevalence and course of hyperthyroidism correlate poorly with that of Graves' ophthalmopathy.[6] An improvement in eye status with maintenance of euthyroidism during antithyroid therapy may be more a reflection of improving immune function than a decreased circulating thyroid hormone.

Elevated circulating TSH levels seem to promote eye disease in patients with Graves' disease. Hamilton and colleagues[20] have reported an increased incidence of progressive ophthalmopathy with hypothyroidism, which followed antithyroid therapy. Tamaki and associates[21] described a marked improvement in eye status and a reduction of circulating TRAb in two patients receiving thyroid hormone replacement during antithyroid therapy. The mechanism by which elevated TSH achieves its influence is unclear, but it may serve to up-regulate TSH receptors (apparent autoantigens; discussed later) in thyrocytes[22] and possibly lymphocytes.[23]

Natural History

On summarizing the available literature on the natural history of Graves' ophthalmopathy, Burch and Wartofsky[6] noted the disease tended to progress through a phase of rapid progression (6 to 24 months), followed by a prolonged plateau phase with subsequent slow but incomplete regression of eye changes. Lid retraction and soft tissue changes, such as chemosis and eyelid edema, tended to be short-lived with improvement or resolution over 1 to 5 years (60% to 90%). Ophthalmoplegia resolved incompletely and less rapidly, although 30% to 40% of patients showed some improvement in ocular motility without specific therapy. Proptosis is the eye finding least likely to improve or resolve spontaneously (10%). Trobe[24] reviewed 32 patients with untreated Graves' optic neuropathy and found that vision improved spontaneously in most, but 21% had a final visual acuity of 20/100 or worse, with 5 patients progressing to near blindness. Facing potential loss of sight, it is not surprising that attempts at medical and surgical intervention, some of them heroic, have occurred for the past 80 years.

Clinical Features

Thyroid Disease

A patient with Graves' ophthalmopathy most commonly visits an endocrinologist for management of thyroid disease or an ophthalmologist for evaluation of eye complaints. A thorough history, examination, and high level of suspicion are required to make the diagnosis. Classically, the patient is experiencing hyperthyroidism, and the expected hypermetabolic findings are present at the time of presentation with eye disease. In a review of more than 800 cases from the literature, Burch and Wartofsky[6] found, however, that 20% of patients presented with eye disease before any manifestation of hyperthyroidism, 39% presented concurrently with thyroid disease and eye disease, and 41% presented with eye disease after clinical hyperthyroidism already was evident. In 80% of the patients in whom both diseases eventually manifested, both became clinically evident within 18 months of each other, although some patients may never present with thyroid disease and eye disease, or many years may separate the two presentations.

Pretibial Myxedema

Pretibial myxedema, or thyroid dermopathy, is the localized thickening of the skin, usually in the pretibial area. It occurs in 4.3% of patients with Graves' disease, but at a higher rate (12% to 15%) in patients with Graves' ophthalmopathy,[25,26] and usually is a late manifestation. Conversely, almost all patients with pretibial myxedema have Graves' ophthalmopathy, although the dermopathy may precede the ophthalmopathy. Symptomatic lesions consist of shiny, erythematous-to-brown plaques, nodules, or areas of nonpitting edema, which most commonly occur in the anterior or lateral aspects of the leg or at sites of old or recent trauma. Involvement of other body sites is rare. Almost all patients have high circulating levels of TRAbs, although the true pathogenesis of the dermopathy is not understood. Pretibial myxedema usually is of cosmetic importance only, but if the feet or hands become massively swollen, it can cause functional difficulties.

Graves' Ophthalmopathy

As described previously, Graves' disease occurs more commonly in women and over a broad age range (16 to 81 years), with a mean age in the fifth and sixth decades.[27-29] Eye involvement is bilateral in most patients with Graves' disease, although 5% to 14% of patients have unilateral disease depending on the method of detection.[6] With careful testing (i.e., CT scan), 50% to 90% of these patients show changes in both eyes. In contrast, major asymmetry in the extent of eye involvement is common. Graves' ophthalmopathy remains the most common etiology of "unilateral" proptosis in adults.[30]

Ophthalmopathy Classification

The spectrum of eye changes ranges from eyelid retraction (resulting in the appearance of a "stare"), to proptosis, corneal exposure and ulceration, diplopia, and loss of vision. A clinical classification system for eye involvement by Graves' disease was proposed by Werner in 1969,[31] approved by the American Thyroid Association (ATA), and subsequently modified in 1977.[32] The ATA's detailed classification is shown in Table 126-1. This classification is strictly clinical and has been helpful for reporting purposes. The disease does not progress systematically through the classes, and may skip one or more classes entirely. In addition, the classification system has been criticized for not considering disease activity (stable or rapidly progressing), which is crucial for making patient treatment decisions.[33]

In response to these deficiencies and several other proposed classification schemes, an international ad hoc committee representing the American, European, Asia-Oceanic, and Latin America Thyroid Associations recommended in 1992 a new characterization of Graves' ophthalmopathy (Table 126-2). This system is recommended for use in attempting objective clinical assessment and documenting disease activity, as in clinical studies. The older ATA classification system is still used for educational purposes and clinical evaluation.

Eye Findings

Lid lag and the appearance of a stare are seen in the mildest form (ATA class I disease) of eye involvement by Graves' disease. This involvement is thought to occur initially as the result of an increased sympathetic sensitivity to catecholamines as seen with patients with hyperthyroidism.[34] As the disease progresses, and the lymphocytic inflammatory reaction infiltrates the extraocular muscles and orbital fat, the fibroblasts proliferate and deposit glycosaminoglycans, predominantly hyaluronic acid.[35,36] The resulting muscle and fat enlargement combines with interstitial edema to cause an increase in intraocular pressure.

Intraocular pressure is increased in primary gaze (straight ahead) and even more so in upward gaze (supraduction). This increase in intraocular pressure can lead to a misdiagnosis of glaucoma, with a subsequent delay in appropriate therapy.[28] Over time, increases in intraocular pressure also produce conjunctival chemosis, excessive lacrimation, periorbital edema, and photophobia (ATA class II disease).

As enlargement of orbital muscle and fat progresses, the volume of the orbital contents increases. The orbital cavity has four fixed bony walls with an average volume of 26 mL.[37] In healthy individuals, the globe takes up 30% of this volume, with retrobulbar and peribulbar structures taking up the remaining 70% of the volume. With nowhere else to expand, an increase of only 4 mL in the volume of the orbital contents results in 6 mm of proptosis (ATA class III disease).

As the extraocular muscles become increasingly enlarged by edema and infiltration, they also become dysfunctional, resulting in reduced ocular mobility and diplopia (ATA class IV disease). Over time, the inflammatory response provokes the deposition of collagen by the fibroblasts, replacing the normally elastic muscles of the eye and ultimately causing a permanent fibrotic, restrictive ophthalmoplegia.

Progressive proptosis also dramatically interferes with the protective mechanisms of the cornea, causing exposure, desiccation, irritation, and, ultimately, ulceration (ATA class V disease). Corneal ulceration becomes a vision-threatening problem, with a risk of permanent corneal scarring, and requires immediate attention.

In its most severe form, Graves' ophthalmopathy involves the optic nerve to impair vision (ATA class VI disease). Optic nerve

Table 126-1

Detailed Classification of Eye Changes of Graves' Disease

Classes	Grades	Ocular Symptoms and Signs
0		No signs or symptoms
I		Only signs, no symptoms (signs limited to upper lid retraction and stare, with or without lid lag and proptosis)
II		Soft tissue involvement with symptoms and signs
	o	Absent
	a	Minimal
	b	Moderate
	c	Marked
III		Proptosis ≥3 mm in excess of upper normal limit, with or without symptoms
	o	Absent
	a	3- to 4-mm increase over upper normal
	b	5- to 7-mm increase
	c	≥8 mm increase
IV		Extraocular muscle involvement (usually with diplopia, other symptoms or signs)
	o	Absent
	a	Limitation of motion at extremes of gaze
	b	Evident restriction of motion
	c	Fixation of a globe or globes
V		Corneal involvement (primarily a result of lagophthalmos)
	o	Absent
	a	Stippling of cornea
	b	Ulceration
	c	Clouding, necrosis, perforation
VI		Sight loss (caused by optic nerve involvement)
	o	Absent
	a	Disk pallor or choking, or visual field defect: vision 20/20 to 20/60
	b	Same, but vision 20/70 to 20/200
	c	Blindness (i.e., failure to perceive light, vision <20/200)

Table 126-2

Characterization of Graves' Ophthalmopathy: Recommendations of an International Ad Hoc Committee*

Category of Disease	Objective Criteria Monitored
Eyelid	Maximal lid fissure width Upper lid to limbus distance Lower lid to limbus distance
Cornea	Exposure keratitis assessed by rose bengal or fluorescein staining (indicate presence or absence)
Extraocular muscles	Single binocular vision in central 30 degrees of vision (indicate presence or absence, with or without prisms) One or more of the following measurement techniques Maddox rod test Alternate cover test Hess chart measurements Lancaster red-green test Optional Intraocular pressure in downward gaze CT or MRI
Proptosis	Exophthalmometer reading (CT or MRI measurement may also be used for measurement)
Optic nerve	Visual acuity Visual fields Color vision
Activity score	Sum of 1 point each for any of the following Spontaneous retrobulbar pain Pain with eye movement Eyelid erythema Eyelid edema or swelling Conjunctival injection Chemosis Caruncle swelling
Patient self-assessment	Satisfaction with the following (indicate change with therapy in each using a scale such as *greatly improved, improved, unchanged, worse, much worse*) Appearance Visual acuity Eye discomfort Diplopia

*Consensus of an 18-member ad hoc committee comprising representatives from the American, European, Asia-Oceanic, and Latin America Thyroid Associations.

involvement typically manifests as a painless gradual loss of visual acuity or visual field,[12] although it can occur precipitously over days to weeks. Although originally thought to be caused by ischemia or venous congestion of the nerve as a result of increased intraocular pressure, there now is convincing evidence to support crowding and compression of the optic nerve at the orbital apex by the enlarged extraocular muscles as the etiology of nerve dysfunction.[38]

Optic nerve function is measured in several ways, one or all of which may be impaired. In one study of 31 patients with optic nerve involvement,[28] visual acuity was 20/25 or worse in 100% of eyes; color vision was decreased in 64%; and visual fields were decreased in 70%, with inferior scotomata and cecocentral scotomata defects most common. Impaired visual fields or color vision also may be found in patients with normal visual acuity.[27]

Clinical Evaluation

Differential Diagnosis

Graves' ophthalmopathy presents a spectrum of clinical manifestations that are reminiscent of other clinical entities. Eye changes range from minimal—requiring a detailed eye examination or CT scan for identification—to dramatic, disfiguring, and vision-threatening changes that eclipse the manifestations of the underlying thyroid disease. The high prevalence of asymmetric eye involvement may also lead the clinician to suspect a unilateral disease process, rather than a systemic one. Although the differential diagnosis for proptosis is extensive (Table 126-3), most other disease entities have only superficial similarities to Graves' ophthalmopathy and can be quickly ruled out. Most importantly, the clinician should maintain a high degree of suspicion if the diagnosis of Graves' ophthalmopathy is to be made in a timely fashion.

Thyroid Function

A full endocrinology workup is essential in the diagnosis and management of Graves' disease. Laboratory testing should include thyroid function tests and a TSH level. In some apparently euthyroid patients, more detailed dynamic testing of thyroid function may be required to uncover thyroid dysfunction. These studies include the suppression of radioactive iodine uptake with triiodothyronine (T_3) to assess for non–TSH-mediated thyroid stimulation, the thyrotropin-releasing hormone stimulation test to determine the presence of low-grade suppression of the hypothalamic-pituitary axis, and TSH stimulation tests of thyroid reserve. Serologic evaluation for evidence of thyroid autoimmunity also can be performed, including microsomal antibody, thyroglobulin antibody, and TRAb assays. Overall, with sufficient scrutiny, most, if not all, patients with euthyroid ophthalmopathy can be shown to have some degree of thyroid dysfunction.[6]

Eye Evaluation

A thorough examination by a skilled ophthalmologist is crucial for the diagnosis and management of Graves' ophthalmopathy. Serial eye examinations are required to monitor disease activity, progression, and response to therapy. The eye examination should include attention to soft tissue changes, including lid edema and retraction, chemosis, scleral injection, limitation of ocular motility, documentation of proptosis (Hertel's exophthalmometer) and intraocular pressure in primary and upward gaze (Schiotz's tonometer), strabismus and visual function in the form of acuity (Snellen's wall chart), color vision (Ishihara's color plates), and visual fields (Goldmann's perimetry).

Imaging Studies

CT scans of the orbit can be helpful in the diagnosis of Graves' ophthalmopathy in euthyroid patients, and are essential if surgical intervention is being considered. Typical findings include a twofold to eightfold enlargement of the extraocular muscle bodies, sparing the tendinous portions (Fig. 126-1). The changes are bilateral in 90% of patients, although asymmetry in the extent of involvement is the rule. The medial and inferior rectus muscles are involved most commonly, although any or all of the muscles may be enlarged.[39] The orbital and extraocular muscle volume can be estimated using CT images.[40-42] Although estimates of extraocular muscle volume have correlated with the presence of optic neuropathy, subsequent studies have not found a correlation between muscle volume estimates and the severity of optic neuropathy or the effectiveness of decompression,[28,43] limiting the usefulness of these estimates.

Amyloidosis
Dermoid and epidermoid cysts
Foreign body

Ultrasound (orbital echography) has been reported to be reliable and effective in evaluating extraocular muscle size.[44] Although not as beneficial in the initial diagnosis and surgical planning as CT scan in patients with Graves' disease, it is proposed as an inexpensive, noninvasive method for monitoring response to therapy (steroids or radiation).

Magnetic resonance imaging (MRI) of the orbits has proved excellent for the evaluation of the soft tissues of the orbit. Extraocular muscle volume can be readily estimated from a single coronal MRI section.[45] Studies have suggested that T2-weighted MR images may provide a sensitive measure of active inflammation in the orbit, giving much needed information on disease activity.[46,47] MRI provides little detail of the bony anatomy of the orbit, which is required if surgical intervention is being considered.

Nuclear medicine studies, such as single photon emission computed tomography (SPECT) imaging using technetium 99m diethylenetriaminepentaacetic acid and gallium 67, have also been used to image the orbit. These studies give reliable information about the level of disease activity within the extraocular muscles.[48,49]

Management of Graves' Ophthalmopathy

A multispecialty team approach for the treatment of patients with Graves' disease and Graves' ophthalmopathy is recommended because of the multiple organ systems involved and the various diagnostic and therapeutic modalities needed to provide optimal care of this complex entity. Team members from endocrinology, radiology, nuclear medicine, radiotherapy, ophthalmology, otolaryngology, head and neck surgery, and neurosurgery are involved to varying degrees. A coordinating member of the team (usually the endocrinologist for Graves' disease and the ophthalmologist for Graves' ophthalmopathy) is crucial for maintaining records, tracking disease progression, and providing continuity of care for long periods.[50]

Medical Therapy

Thyroid Therapy

The management of the thyroid in patients with Graves' disease is controversial, and a complete discussion is beyond the scope of this chapter. The impact of thyroid management on Graves' ophthalmopathy is only now becoming clear. As previously discussed, the correlation between the severity of hyperthyroidism and the prevalence or course of Graves' ophthalmopathy is poor at best. For patients with thyrotoxicosis, the thyroid may be managed with antithyroid drugs (i.e., propylthiouracil and methimazole), radioactive iodine ablation (iodine 131), or thyroidectomy (usually subtotal). Reports on the effect of each of these modalities on the development or progression of ophthalmopathy are conflicting in the literature, although in a more recent prospective study, Tallstedt and colleagues[51] randomly assigned 168 patients into groups receiving antithyroid drugs, radioactive iodine ablation, or surgery. There was no difference in the rate of new-onset or progression of existing ophthalmopathy between the antithyroid drug and surgery groups (10% to 16%), but the radioactive iodine ablation group showed a higher incidence (33%) of these problems.

One possible mechanism for the increase in patients with ophthalmopathy receiving radioactive iodine ablation includes transient hypothyroidism and the release of thyroid antigens, promoting an acceleration of the autoimmune process. In support of this hypothesis, investigators have found that TRAb levels briefly decrease and then show a sustained increase after iodine 131 ablation for Graves' disease.[52] After thyroidectomy, however, TRAb levels showed a transient increase followed by a gradual decrease.[53] Potentially least concerning were TRAb levels, which gradually declined after antithyroid therapy alone. It would seem that radioactive iodine ablation of the thyroid may not be the best option for the management of thyrotoxicosis in patients with Graves' disease. As mentioned previously, thyroid hormone replacement and suppression during antithyroid drug therapy or after radioactive iodine or surgical ablation (before the onset of measurable hypothyroidism) seem to result in a decrease in the prevalence or progression of ophthalmopathy in patients with Graves' disease and should be considered.[21]

Local Therapy

Most patients with Graves' ophthalmopathy experience a self-limited disease course requiring only local measures for symptomatic relief. Corneal exposure and drying respond well to eye drops and nocturnal taping of the eyelid. Some clinicians have found the use of diuretics helpful in decreasing swelling. Sunglasses help with photophobia, and prisms may help with mild strabismus. Topical guanethidine eye drops have been found to reduce lid retraction and lid lag, reportedly by sympathetic blockade of Müller's muscle in the upper lid, but they are poorly tolerated and rarely used.

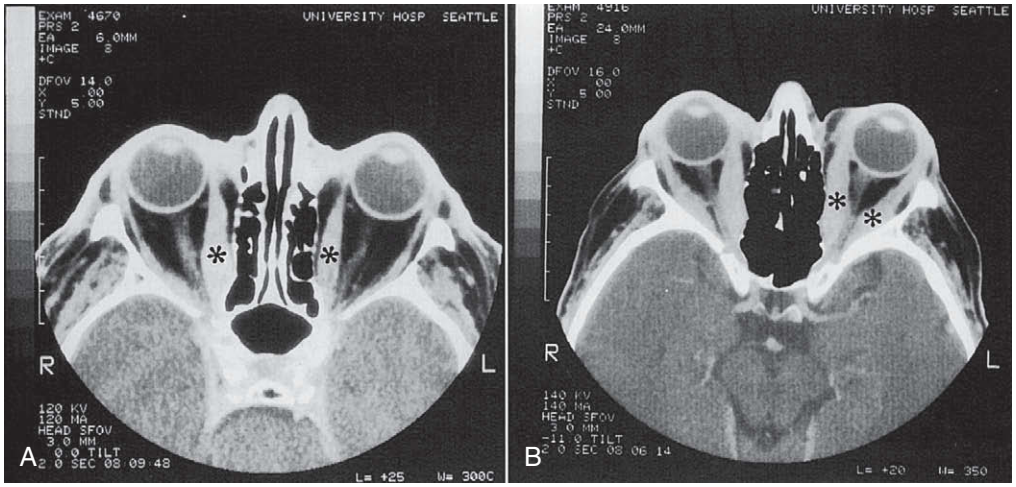

Figure 126-1. **A** and **B,** CT scans through the orbits in two patients with Graves' ophthalmopathy, showing medial rectus muscle enlargement (*asterisks*) with normal lateral rectus muscle size (**A**) and medial and lateral rectus muscle enlargement (*asterisks*) with orbital apex crowding, causing optic neuropathy (**B**).

Steroid Therapy

High-dose corticosteroids (prednisone, 80 to 100 mg/day) are commonly used as the first-line management of more severe Graves' ophthalmopathy. The administration of high doses is maintained for 2 to 4 weeks, followed by a slow taper over several months. Patients experience rapid relief of pain, erythema, and conjunctival edema, and improved vision. Trobe and associates[13] reported a 48% success rate after 2 months of therapy. Steroids may be only temporizing, however, with recurrence of visual loss on taper. Improvement in proptosis and ophthalmoplegia may also be seen with corticosteroid therapy, but generally less so, and these conditions are more likely to recur on steroid withdrawal. The multiple adverse effects of steroid therapy are well known and include glucose intolerance, weight gain, psychosis, peptic ulcer disease, and osteoporosis with vertebral fracture. Corticosteroid therapy should be considered temporizing, while either regression and stabilization of disease or definitive therapy is awaited.

Immunosuppression with cyclosporine also has been evaluated for patients with Graves' ophthalmopathy and has been found to be less effective than prednisone in single-agent therapy.[6] The beneficial effects of both drugs seem to be additive, and maintenance cyclosporine therapy may be corticosteroid-sparing. Careful drug-level monitoring is necessary to avoid nephrotoxicity. Other common adverse effects include hypertension, liver enzyme elevation, gum hypertrophy, and paresthesias. Plasmapheresis to remove circulating antibodies and other immunomodulatory drugs have also been used, but the results suggest further evaluation before widespread use.

Radiotherapy

Radiotherapy to the orbit has been used for more than 85 years for patients with Graves' ophthalmopathy. Traditionally, radiotherapy is accomplished by delivering 20 Gy in 10 fractions of 2 Gy over 2 weeks. The fractions are delivered to a field just behind the lateral canthus to spare the cornea and lens. In a 1989 review of the literature, Sautter-Bihl and Heinze[54] found an overall good to excellent response in 35% to 92% of patients, and improvement of impaired visual acuity in 33% to 85% of patients treated with orbital radiation. The mechanism of action of radiation to the orbit is thought to be in large part an effect on the lymphocytes infiltrating the orbital muscles and fat during the inciting stages of the disease. Patients treated early in the course of the disease with pronounced soft tissue involvement are most likely to benefit. Proptosis, ophthalmoplegia, and optic neuropathy are less responsive, and patients with long-standing stable disease are unlikely to benefit. The portion of the radiation dose delivered to the lens is less than 5% and has not been reported to be harmful.

More recent studies have cast considerable doubt on the efficacy of radiotherapy for Graves' ophthalmopathy. In 2003, Gerling and colleagues[55] found no difference in the documented improvement when patients were treated with very low dose radiotherapy (2.4 Gy) and more standard doses (16 Gy). In another study, improvement in symptoms and clinical findings was not different between patients treated with steroids alone compared with patients treated with steroids plus 24 Gy of radiotherapy.[56] In a prospective randomized trial treating one orbit of each patient with 20 Gy of radiotherapy, Gorman and coworkers[57] were unable to show any significant benefit over the nontreated orbit at 1 year. Long-term follow-up in an uncontrolled fashion also found no benefit from the radiotherapy.[58] Because radiotherapy has potential long-term adverse effects, its usefulness in Graves' ophthalmopathy should be questioned.

Surgical Therapy

Indications for surgical decompression of the orbit have evolved over the years and have included cosmetic management of proptosis, lid lag, and stare, and the management of optic neuropathy.[27,34,59,60] New-onset strabismus after orbital decompression has been reported in 30% to 64% of patients, suggesting that patient selection should be done with caution.[2,60] As a result, many centers perform orbital decompression primarily in the setting of optic nerve involvement combined with failure to respond or inability to tolerate steroid therapy, or for the relapse of symptoms with the taper of steroid therapy.[12,28] Radiotherapy is generally reserved for patients who refuse, cannot tolerate, or fail surgical decompression, although some authors still advocate primary radiotherapy.[61,62]

The goal of surgical decompression of the orbit is simply to expand the bony orbital confines to make room for the increased volume of the orbital contents. Surgical decompression was first described by Dollinger,[63] who advocated removal of the lateral orbital wall for decompression into the temporal fossa (Krönlein's procedure). Twenty years later, Naffziger[64] reported removal of the orbital roof with decompression into the anterior cranial fossa via a transcranial approach. Decompression into the paranasal sinuses was first advocated by Sewell,[65] who described decompression into the ethmoid air cells, and Hirsch,[66] who later reported inferior decompression into the maxillary sinus by removal of the orbital floor. Walsh and Ogura[67] combined the inferior and medial approaches into a single transantral decompression of two orbital walls using the Caldwell-Luc approach (Fig. 126-2). This approach is extracranial, decompresses two walls of the orbit into the largest empty space, and allows gravity to aid in the expansion of orbital contents into the paranasal sinuses. For these reasons, it has become the most widely used technique.

Predicting the results of transantral decompression in patients with severe Graves' ophthalmopathy remains a challenge. In a retrospective analysis of 428 patients, Fatourechi and colleagues[68] reported

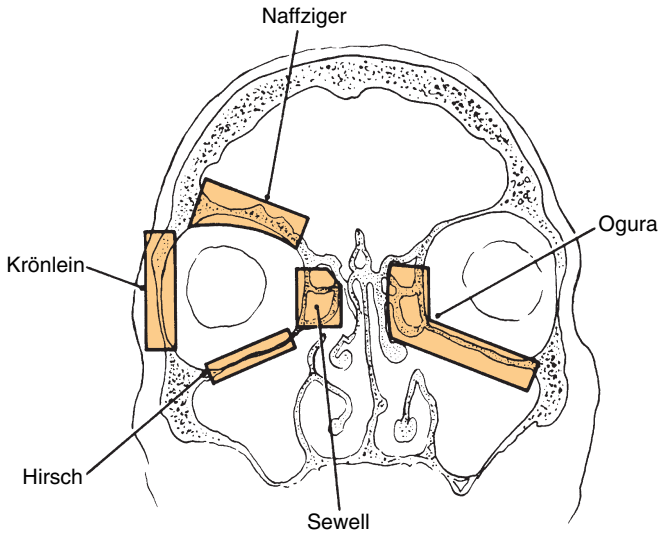

Figure 126-2. Diagram of a coronal section through the skull and paranasal sinuses showing portions of the orbit removed for various methods of orbital decompression.

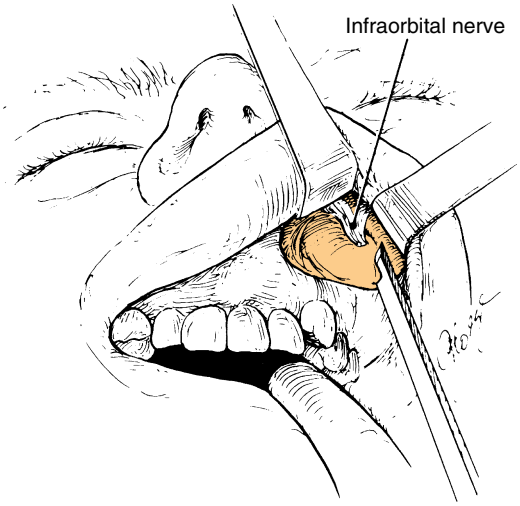

Figure 126-3. Sublabial buccogingival incision that exposes the anterior wall of the maxillary sinus. An osteotome is used to create the antrostomy.

that young men with long-standing eye symptoms were likely to have more severe initial proptosis. Only the severity of the initial proptosis and the longer postoperative follow-up period correlated with greater recession of proptosis after decompression. Failure of corticosteroid or orbital radiotherapy did not affect the degree of recession of proptosis or improvement in visual acuity. A greater degree of recession of proptosis postoperatively was associated with better visual acuity, but also with a greater likelihood of persistent strabismus. Patient satisfaction with postoperative eye appearance was associated only with procedures performed for cosmetic indications.

Transantral Orbital Decompression

SURGICAL TECHNIQUE. The transantral decompression (Walsh-Ogura method) of the orbital floor and medial wall is performed during general anesthesia with an oral Ray endotracheal tube secured in place. The eyes are protected with topical ointment and are not taped to allow examination of the pupil during the procedure. Intravenous broad-spectrum antibiotics and high-dose corticosteroids (dexamethasone, 8 to 10 mg) are administered before the surgery. A curved sublabial incision with a standard Caldwell-Luc antrostomy and ethmoidectomy is performed (Fig. 126-3). Care is taken to identify and preserve the inferior orbital nerve in its bony canal. An extensive ethmoidectomy should be performed, while preserving the lamina papyracea, middle turbinate insertion, and fovea ethmoidalis (Fig. 126-4). The remaining mucosa is carefully stripped from the maxillary sinus roof, keeping in mind that the inferior orbital nerve is partially or completely dehiscent in 29% of patients.[69]

The bone of the maxillary sinus roof (orbital floor) medial to the infraorbital nerve is carefully removed (Fig. 126-5). This maneuver can be performed using a drill with cutting or diamond burrs or with small osteotomes, as long as the underlying periorbita is not violated. Some surgeons find the operating microscope useful at this stage of the procedure. The lamina papyracea (medial orbital wall) is gently fractured medially and removed up to the posterior ethmoid neurovascular bundle, preserving the periorbita. A No. 12 scalpel blade is used to make incisions in the posterior-to-anterior direction through the periorbital fascia, which allows the immediate herniation of orbital fat through the incision and into the sinuses (Fig. 126-6). This process is begun medial and superior to avoid the loss of visualization as the fat herniates from the orbit. The number of incisions required is determined intraoperatively by assessing the degree of residual proptosis after each incision.

Calcaterra and Thompson[34] recommended operating on the more severe eye first with planned incomplete recession because an additional 1 to 2 mm of recession develops during the first 3 months after surgery. The less severe eye then is decompressed to match the position of the first eye. Four to six incisions in the periorbita usually are adequate.[70] Finally, a large nasoantral window is created, and the sinus is packed with a large Penrose drain coated in antibiotic ointment, which is brought out through the nose for removal the next day. The sublabial incision is closed with absorbable suture. The patient is given antibiotics and corticosteroids intravenously overnight and then orally after discharge from the hospital.

Immediately after surgery, all patients (unless it is medically contraindicated) are given high-dose corticosteroids with a slow taper. The rate of steroid taper is determined by the clinical response to the surgery. In one study, steroid use was discontinued in 80% of patients within 2 months of surgery.[28]

SURGICAL OUTCOME. The results of transantral orbital decompression surgery depend on the indications for the operation. For patients with optic neuropathy, Walsh-Ogura decompression was effective in improving vision in 92% of patients (Fig. 126-7). Equally important, these patients had stabilization of disease with successful taper of steroid therapy. Major improvement in proptosis of 1 to 12 mm can be achieved (Fig. 126-8A), with an average improve-

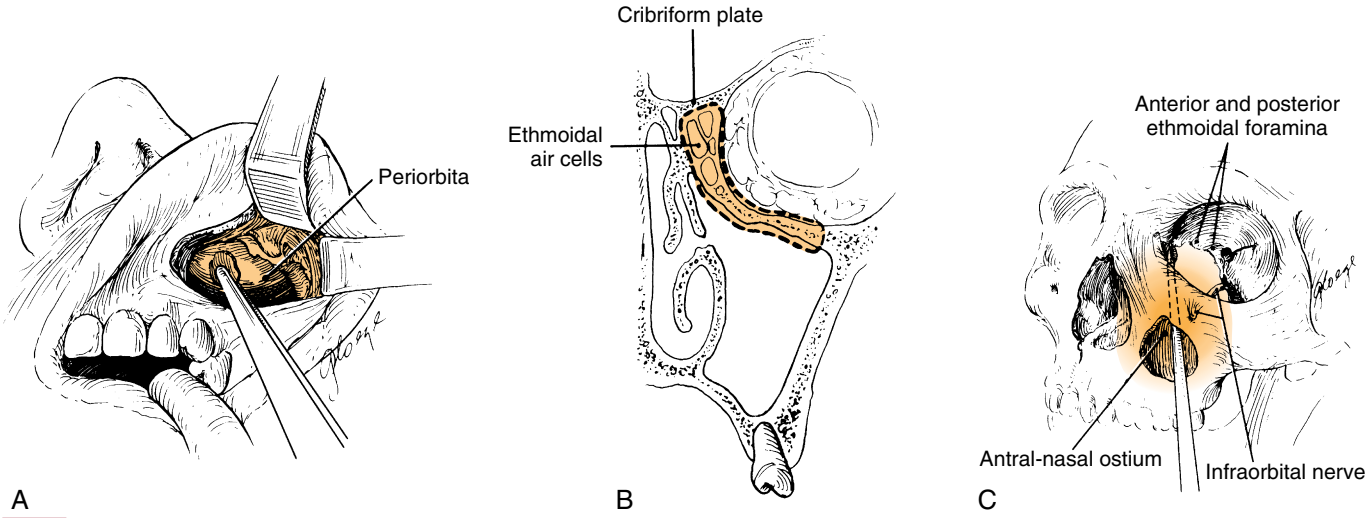

Figure 126-5. **A,** Removal of the floor of orbit after eggshell fracturing of bone. **B,** Coronal section of paranasal sinuses showing the extent of bone removal. **C,** View of the skull showing completion of ethmoidectomy and removal of the lamina papyracea.

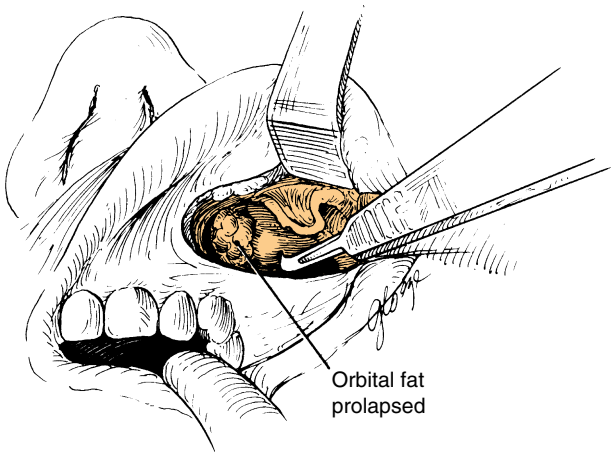

Figure 126-6. Radial incisions in the intact periorbita with a scalpel, permitting prolapse of orbital fat into the sinuses.

ment of 3.4 to 5.3 mm.[28,45,51,60] This decrease in proptosis is of functional and cosmetic benefit and is not seen with either medical therapy or radiotherapy. Major reduction in intraocular pressure (100% of patients) (Fig. 126-8B), improvement of extraocular motility (36%), and improvement of strabismus (47%) are other benefits of decompression.

Transantral decompression failed to stabilize the disease in 3% to 8% of patients who underwent surgery for severe ophthalmopathy.[28,60] In this setting, repeat CT scanning with coronal cuts can be helpful to assess the adequacy of the decompression, and to decide between further surgery using the same approach or via a lateral or superior approach,[71] or proceeding with radiotherapy.

The earlier the diagnosis of Graves' optic neuropathy is made and intervention initiated, the better the outcome will be. When preoperative visual acuity was limited to detecting hand motion or worse, decompression provided little improvement in vision (see Fig. 126-7).[28] When visual acuity allowed counting fingers or better, all patients experienced a favorable outcome.

Ocular dysmotility and strabismus remain a major problem in surgical patients despite decompression. Extraocular motility was impaired (primarily in supraduction) in 92% of patients undergoing decompression; only one third showed improvement, and 9% experienced a worsening of motility postoperatively.[28] Strabismus (diplopia) was present preoperatively in 67% to 85% of patients and in 71% to

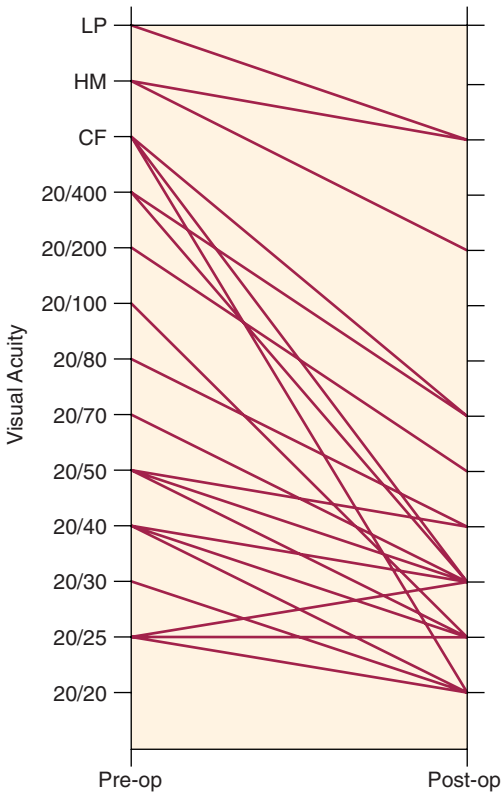

Figure 126-7. Preoperative (*left*) and postoperative (*right*) best corrected visual acuity for 36 eyes in 20 patients undergoing transantral orbital decompression for Graves' optic neuropathy. Orbital decompression for the preservation of vision in Graves' ophthalmopathy.* Arch Otolaryngol Head Neck Surg. *1993;119:229.)*

80% of patients postoperatively.[28,60] When the eye disease was stable, 70% of patients underwent extraocular muscle surgery to correct diplopia, and some were able to be corrected with prisms alone. One long-term follow-up evaluation (average 8.8 years) of 355 patients with decompression reported only 17% having double vision most or all of the time.[60]

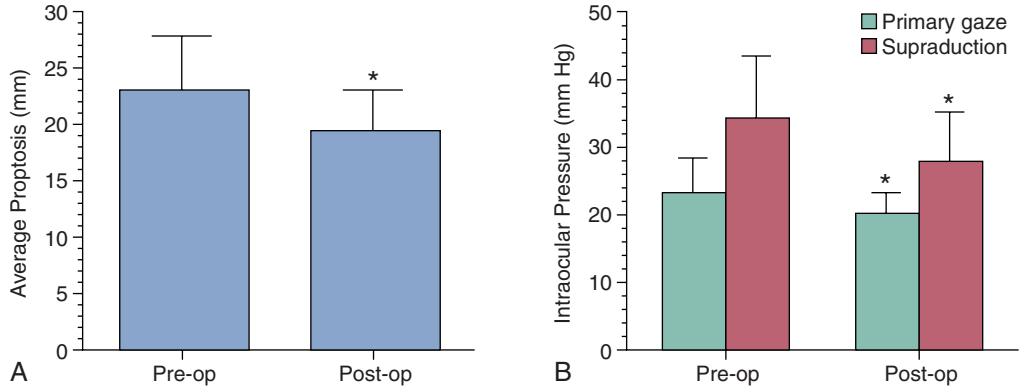

Figure 126-8. A, Preoperative (*left*) and postoperative (*right*) average proptosis for 36 eyes undergoing decompression (see Fig. 126-7). **B,** Intraocular pressure in the same eyes in primary gaze and upward gaze before and after decompression surgery. *$P < .05$.

Transantral decompression for cosmetic indications should be evaluated carefully because it carries the risk of lower patient acceptance of adverse effects than when vision is threatened. Fatourechi and colleagues[59] reviewed the outcomes of 34 patients who underwent transantral decompression for cosmesis and noted a dramatic improvement in proptosis (average 5.2 mm), but no major change in asymmetry between the eyes. Postoperative diplopia developed in 73% of patients who did not have diplopia preoperatively. Half of the patients underwent subsequent extraocular muscle surgery and eyelid surgery. On long-term follow-up evaluation (average 12 years after surgery) of 29 patients, 82% reported they were satisfied with their current eye status. Decompression surgery for cosmetic indications may be appropriate in a select group of patients who are willing to undergo subsequent eye muscle surgery for diplopia.

SURGICAL COMPLICATIONS. Patients uniformly complain of hypoesthesia in the distribution of the inferior orbital nerve immediately after decompression as a result of intraoperative stretching of the nerve with retraction. This hypoesthesia resolves spontaneously over several months in greater than 95% of patients. In one large series, Garrity and associates[60] reported other infrequent complications, including sinusitis (4%), lower eyelid entropion (9%), cerebrospinal fluid leaks (3%), and frontal lobe hematoma (0.2%). Blindness from nerve injury or orbital hemorrhage is rare, but does occur.[48,72] Although theoretically possible, orbital infection has not been reported.

Modifications of Transantral Orbital Decompression

Transantral orbital decompression has held up well to the test of time since its description in 1957. Only in the past several years have advances in surgical technique and instrumentation led to the description of major modifications to the Walsh-Ogura operation. A transorbital approach using a modified blepharoplasty (subciliary) incision provides excellent exposure to the anterior orbital floor and decreases the risk to the infraorbital nerve.[12] This approach also provides access for a lateral orbital wall decompression without disrupting the orbital rim or canthal tendon, providing a three-wall decompression.[73] This method is reported to have a lower incidence of postoperative strabismus, although the reason for this is unclear. Other authors have reported using the transconjunctival approach for the antral-ethmoidal decompression.[72,74] The major criticism of these anterior approaches is limited exposure to the medial orbit, which can restrict the degree of decompression around the orbital apex as is required in patients with optic neuropathy.

Endoscopic Orbital Decompression

With the rapid development and dissemination of endoscopic instrumentation and techniques for transnasal paranasal sinus surgery, it is not surprising that this technology has been applied to include antral-ethmoidal decompression of the orbit. Despite concerns about adequate anterior orbital floor access, Kennedy and coworkers[75] reported equivalent results with transantral decompression and endoscopic decompression. Reports of an average of 3.2- to 5.1-mm reduction of proptosis with an endoscopic decompression of the medial and inferior orbital walls compare well with the traditional approach.[76-78] Metson and Samaha[77] reported a modification to the standard endoscopic decompression that preserves a horizontal sling of periorbita to support the globe position without limiting the degree of decompression. This modification has resulted in a significant decrease in the incidence of new-onset or worsening diplopia after surgery.

Advances in image-guided surgery have resulted in improved intraoperative localization during endoscopic sinus surgery. This technology has found a role in endoscopic orbital decompression surgery as well. The use of the CT-guided technology allows a safer and more aggressive decompression of the orbital apex, orbital nerve (if indicated), and superior medial orbital wall. The inferior orbital nerve also can be easily identified and preserved. Equally helpful is the ability to assess and measure the degree of orbital content decompression into the sinuses intraoperatively using measurements on the CT scans (Fig. 126-9).

Combined Endoscopic and Open Approach to Orbital Decompression

For a more thorough optic nerve decompression, Khan and associates[79] have described a combined transconjunctival-endoscopic decompression of the orbit. The addition of a small medial external skin incision also aided the retraction of the orbital contents to allow the dissection of the medial wall beyond the posterior ethmoidal neurovascular bundle up to the optic canal. Experience with 72 orbital decompressions in 41 patients resulted in an average reduction of proptosis of 3.65 mm, an 89% improvement in vision, and minimal complications.[80] Other authors have combined the endoscopic orbital decompression with a percutaneous lateral orbital wall decompression via the upper lid crease resulting in additional decompression (≤6.9 mm).[76,81] In addition, Metson and colleagues[82] have successfully performed combined endoscopic and lateral wall decompressions during local anesthesia, which has the advantage of avoiding general anesthesia and permitting intraoperative monitoring of visual function, crucial for surgery on an only-seeing eye. In this setting, if both eyes are to be decompressed, they are done so in stages.

Balanced Orbital Decompression

In an attempt to reduce the incidence of new-onset diplopia after orbital decompression surgery, several authors have advocated removing the medial and lateral walls of the orbit without decompressing the orbital floor. This "balanced" approach decompresses equally medially and laterally and is less likely to affect the position of the globe.[81,83,84] Postoperative new-onset diplopia is reported in 0% to 15% of patients with this technique. The degree of decompression with this two-wall approach can be comparable to the three-wall medial-inferior-lateral decompression if orbital fat is resected at the time of the decompression.[81]

Combined Endoscopic Orbital and Optic Nerve Decompression

A more recent adjunct to standard endoscopic orbital decompression for dysthyroid ophthalmopathy is endoscopic optic nerve decompression. In certain cases of thyroid ophthalmopathy with progressive optic neuropathy, it has been hypothesized that direct compression of the optic nerve is the cause of visual deterioration. In a study on patients with optic neuropathy, analysis of CT scans showed that patients have increased apical crowding with flattening of the optic nerve at or near the orbital apex from compression by enlarged extraocular muscles compared with controls.[38] The compressive forces are thought to result in conduction block and focal demyelination, as the optic nerve remains in its fixed bony canal. Release of the nerve from its bony confines may alleviate the detrimental effects of the compressive forces.[85]

Previously, surgical approaches for optic nerve decompression were developed for traumatic optic neuropathy and have included transorbital, extranasal transethmoid, transantral, intranasal microscopic, and craniotomy approaches. Advances in endoscopic equipment, in addition to curved diamond burrs and image guidance systems, have allowed for safe endoscopic optic nerve decompression all the way back to the orbital apex. After a standard sphenoethmoidectomy is performed, the sphenoid face is widely opened, and the carotid artery and optic canal bulge are identified on the lateral sphenoid wall. The medial orbital wall is decompressed, and the thick bone overlying the optic canal is thinned with a diamond burr with careful avoidance of the prominence overlying the carotid artery. A microcurette is used to fracture the bone medially and allow for decompression of the optic nerve from its bony canal. Preliminary studies have not shown whether the additional incisure of the optic nerve sheath is necessary for adequate decompression considering the possible damage to optic nerve fibers and the ophthalmic artery, and cerebrospinal fluid leak.[85,86]

Reports of this technique are very preliminary in the literature. Luxenberger and colleagues[86] described four patients in whom a combined endoscopic orbital and optic nerve decompression was performed. In that study, two patients had improved vision, one patient's vision improved and then deteriorated, and the final patient did not have sufficient ophthalmologic data. In a more recent review of this new technique combining endoscopic optic nerve decompression with standard endoscopic orbital decompression, Pletcher and associates[85] noted an improvement in visual acuity in 8 of 10 patients with nontraumatic optic neuropathy, including Graves' ophthalmopathy.

Other Approaches for Orbital Decompression

A modification of the Walsh-Ogura method called the three-wall orbital decompression refers to the addition of the lateral wall decompression to the standard antral-ethmoidal decompression. This addition can be achieved by any combination of approaches, including a modified blepharoplasty incision, a sublabial or transconjunctival incision plus an anterior orbitotomy, or a bicoronal forehead flap. The advantage of the three-wall decompression is that it allows the further enlargement of the orbital volume by expansion into the temporal fossa and the paranasal sinuses. Metson and colleagues[76] were able to increase the recession of proptosis from an average of 3.2 to 5.6 mm with the addition of the lateral decompression to the endoscopic antral-ethmoid

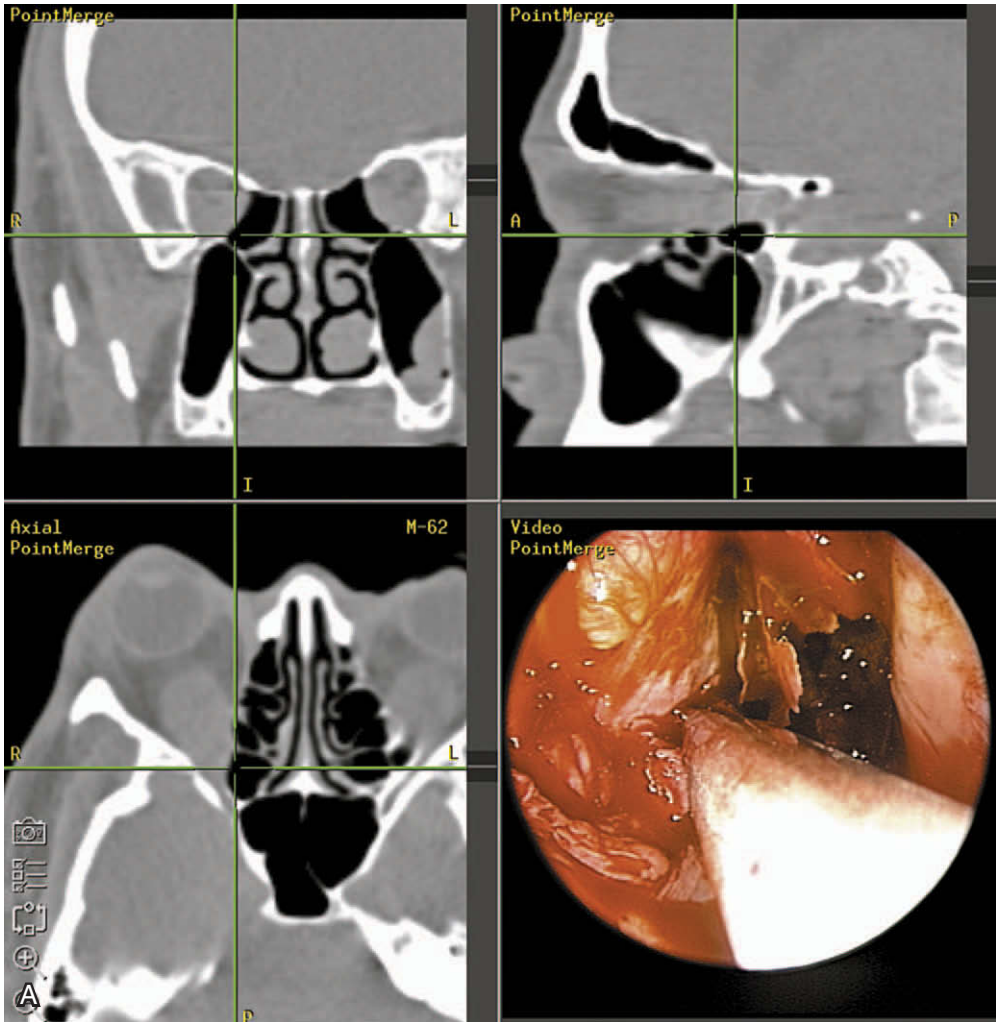

Figure 126-9. View from a CT image–guided system during orbital decompression surgery. **A,** Images showing initial periorbita incision at the orbital apex with herniation of orbital fat seen on the video image.

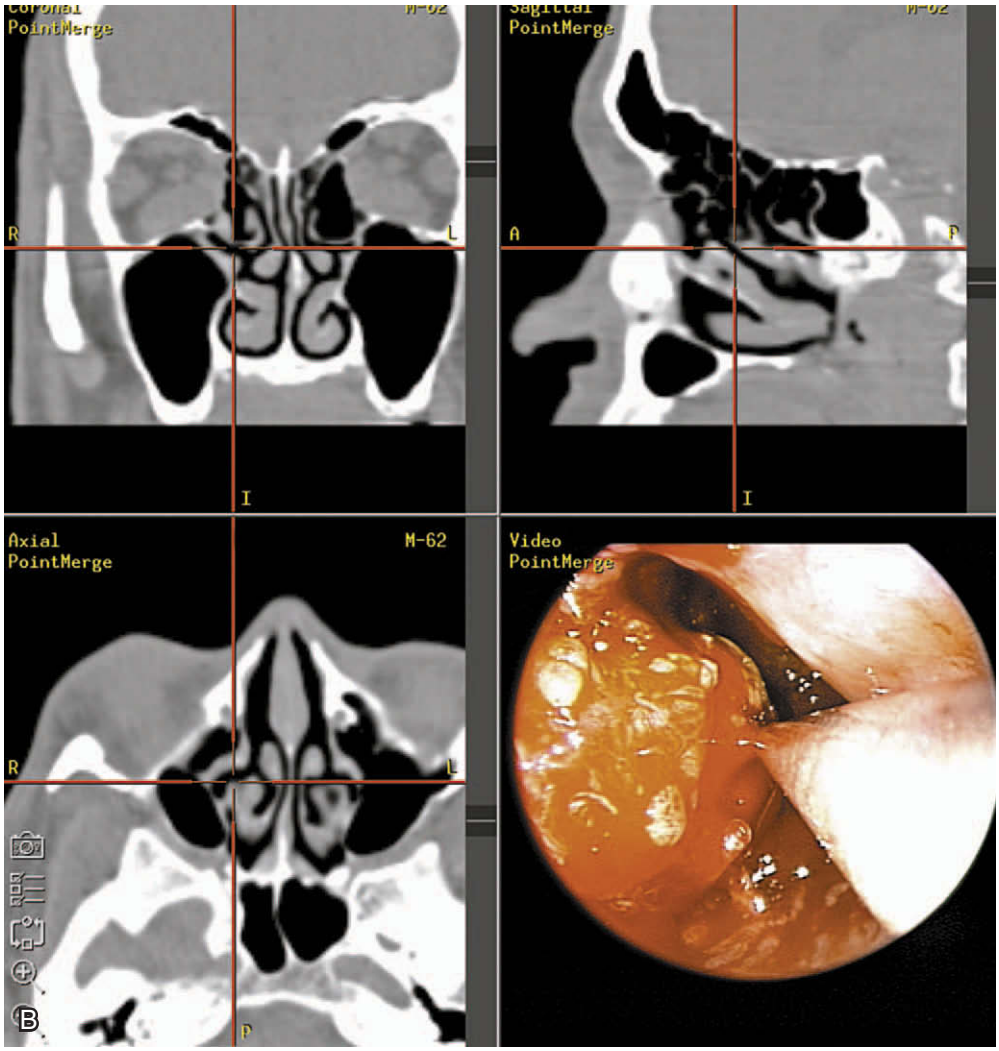

Figure 126-9, cont'd **B,** Images showing inferomedial periorbita incision with extensive orbital fat decompression into the sinus cavity. The degree of decompression can be readily assessed on the CT images.

decompression. Other authors[87,88] prefer the bicoronal approach to the three-wall decompression, even for unilateral decompressions. Although dramatic decompression is reported (average 7.5 mm), a high complication rate can be expected, including infraorbital hypoesthesia (70%), supraorbital hypoesthesia (60%), and frontalis palsy (30%).[87]

A two-wall decompression of the superior-lateral orbit can be achieved through a bicoronal incision with subsequent frontal craniotomy[64,89] or a lateral rim approach.[90] This approach allows decompression of the orbital contents into the anterior cranial fossa and temporal fossa. Expansion of orbital contents into the empty paranasal sinuses with the help of gravity would be predicted to provide a more adequate decompression, although in a cadaveric study, Stanley and coworkers[91] found the superior-lateral decompression to be as effective as the antral-ethmoidal decompression in withstanding intraocular pressure increases and in allowing orbital recession. The craniotomy approach has the advantages of direct access to the optic canal for superior decompression and of potential additional medial orbital wall decompression via the ethmoid sinuses. The orbital rim approach has the advantage of less dural exposure and the ability to advance the superior orbital rim with plates, screws, and bone grafts to increase orbital volume further.[90] Because the superior-lateral decompression is a more involved procedure with the violation of the cranial cavity, regardless of the approach, most centers reserve it for patients in whom antral-ethmoidal decompression has failed.

Classic descriptions of orbital decompression have always referred to the removal of one or more orbital bony walls. Trokel and associates[62] have reported successful decompression of the orbit strictly by the removal of orbital fat via superior and inferior orbitotomies without any bone removal. This procedure was reserved primarily for cosmetic indications in patients with inactive disease. An average reduction in proptosis of 1.8 mm was achieved, although patients with large amounts of fat seen by CT scan and with greater preoperative proptosis had more dramatic reductions. There were no new long-term motility problems commonly reported with bony orbital decompression for cosmesis, which may be an important decompression option for cosmetic indications in an attempt to reduce postoperative strabismus and the need for subsequent eye muscle surgery.

Ancillary Procedures

Extraocular Muscle Surgery

Extraocular motility problems resulting from Graves' ophthalmopathy are not likely to resolve spontaneously with disease regression and are mostly refractory to medical management. Extraocular motility problems are also the manifestation of eye involvement most likely to develop or worsen after orbital decompression.[92] Although disturbing, this is not surprising because irreversible extraocular muscle fibrosis is seen late in the disease. In one study, 70% of patients with decompression ultimately underwent eye muscle surgery for strabismus after the eye disease was stable.[60]

The indications for eye muscle surgery are diplopia in the primary and reading positions, with the goal being to restore single vision in

these positions. It is unlikely that eye muscle surgery would achieve single vision in all positions because of the baseline restrictive ophthalmoplegia induced by the disease. Dyer[93] reviewed 290 patients with Graves' ophthalmopathy requiring eye muscle surgery, and found 59% required a single procedure, 30% required two procedures, and 12% required three or more procedures to achieve single vision in the primary and reading positions.

The timing of eye muscle surgery is crucial for predictable results. Patients not requiring orbital decompression for Graves' ophthalmopathy should manifest stable disease with corticosteroid administration for 6 months to avoid subtle changes in the muscles over time. If these patients have serious proptosis, orbital decompression should be considered before eye muscle surgery, which may exacerbate the proptosis and corneal problems.[93] In addition, a decompression is likely to alter the position of the globes and disturb the gaze, and it should be completed before eye muscle surgery. Because recession of the globe is progressive for several months after an orbital decompression, it is advisable to delay eye muscle surgery for 2 to 3 months.

Eyelid Surgery

Surgery on the eyelids may be required early or late in the management of Graves' ophthalmopathy. Early in the disease, a lateral tarsorrhaphy may be needed urgently to provide corneal coverage and protection as a temporizing measure while medical therapy is instituted. Late in the course of the disease, eyelid surgery may be indicated for cosmesis and corneal protection in patients with permanent lid retraction. Multiple upper eyelid procedures have been described, including excision or recession of Müller's muscle, levator aponeurosis transection or recession with or without scleral grafts, and levator myotomy.[6] Similar procedures have been described for the lower lid. In the overall rehabilitation of the eye, eyelid surgery should be delayed for 1 year after control of hyperthyroidism and at least 6 months after eye disease stabilizes.

Summary

Although more recent studies on the etiology of Graves' disease suggest a common thyroid-eye antigen (TSH receptor), this difficult and debilitating disease is still not preventable. Further advances in the identification of the specific autoantigenic site in the eye and the thyroid, and in antigen-specific immunotherapy are necessary before a major shift in management can occur. Until that time, therapy for Graves' disease and the associated Graves' ophthalmopathy remains palliative. A team approach to these patients is warranted because of multiple organ system involvement and the complexity of manifestations encountered. Optimal therapy can be provided only through close collaboration between team members.

CHAPTER ONE HUNDRED AND TWENTY-SEVEN

Anatomy of the Temporal Bone, External Ear, and Middle Ear

Howard W. Francis

Key Points

- The temporal bone consists of four embryologically distinct components: the squamous, mastoid, petrous, and tympanic parts.
- The temporal line is located about 5 mm inferior to the lowest level of the middle fossa floor.
- The mastoid antrum is located deep to the depressed cribriform area located posterior to the spine of Henle, known as Macewen's triangle.
- The stylomastoid foramen is located at the anterior limit of the digastric groove.
- The arcuate eminence is the prominence of the superior semicircular canal on the middle fossa floor.
- Potential paths of tumor spread from the external auditory canal (EAC) and include the bony-cartilaginous junction, the foramen of Huschke, and the fissures of Santorini.
- The outer and middle ears are derived from the first and second branchial grooves and pouches. The middle ear structures arise from the corresponding arches.
- The epitympanum and mesotympanum are separated by the ossicular chain and associated mucosal folds leaving only narrow apertures for air supply to the attic and antrum.
- Middle ear landmarks of the facial nerve include the cochleariform process, the oval window, and the pyramidal eminence.
- The most vulnerable portion of the ossicular chain is the long process of the incus, which possesses a single nutrient vessel and lacks collateral circulation.
- The supratubal recess, located at the anterior extreme of the attic and superior to the opening of the eustachian tube, is a site in which cholesteatoma or blind surgical dissection can injure the facial nerve. The geniculate ganglion is located just deep to its medial wall and may be dehiscent.
- The labyrinthine segment of the facial nerve is particularly vulnerable to injury because of watershed vertebrobasilar/external carotid circulation, narrow bony canal, and proximity to the genicular ganglion where herpetic infections and traumatic distortion of thin surrounding bone may produce nerve swelling and entrapment in the labyrinthine segment.

Multiple intracranial and extracranial regions interface with the temporal bone, the anatomy of which reflects its unique role in the embryology of the head and neck, and in the transit of vessels, nerves, and pathogens between these regions. Understanding of this anatomy is required for a full appreciation of the etiology and safe and effective treatment of diseases of the ear. This chapter presents anatomic features of the ear that inform the clinician's understanding of disease and surgical management. More detailed descriptions of structure can be found in cited references.

Osteology of the Temporal Bone

The temporal bone articulates with the sphenoid, parietal, occipital, and zygomatic bones, contributing to the cranial, skull base, and facial structure. The temporal bone has a pyramidal shape, the sides of which form the middle fossa floor (superior face), the anterior limit of the posterior fossa (posterior face), muscle attachments of neck and infratemporal fossa (anteroinferior face), and the muscular-cutaneous–covered side of the head (lateral), which forms the base of the pyramid. The temporal bone consists of four embryologically distinct components: the squamous, mastoid, petrous, and tympanic parts.[1]

The squamous part forms the lateral wall of the middle fossa (Fig. 127-1). It consists of a plate of bone with an anterior extension known as the zygomatic process, which forms the bony roof of the glenoid fossa. The temporalis muscle inserts on the outer cortex, whereas the masseter muscle inserts on the zygomatic process. A horizontal ridge known as the temporal line is formed along the most inferior insertion by the temporalis muscle, is aligned with the zygomatic process, and is used as a surface landmark that estimates the location of the middle fossa floor,[2] with an average offset of about 4.7 mm.

The mastoid part is a bulbous bony structure shaped by the expansion of air-filled spaces within (see Fig. 127-1). The constant pull by the sternocleidomastoid muscle and posterior belly of the digastric muscle elongates the mastoid inferiorly to form the mastoid tip or process. The mastoid cortex is perforated by multiple small emissary vessels that drain from the central air cell or antrum, forming a depressed cribriform area at the anterior junction of the mastoid process with the tympanic bone. The foramen of a single emissary vein is evident near the posterior limit of the outer mastoid cortex, and communicates with the sulcus of the sigmoid sinus, which is evident on the posterior medial aspect of the temporal bone. The site of the sternocleidomastoid muscle

insertion is indicated by a rough, irregular surface at the mastoid tip. Medial to the mastoid tip, the posterior belly of the digastric muscle is inserted in a sulcus that terminates anteriorly at the stylomastoid foramen. Medial and almost parallel to the digastric sulcus is the sulcus for the occipital artery.

The petrous part has the shape of a pyramid whose base is united with the mastoid laterally; the apex is oriented anteromedially between occipital and sphenoid bones. The *anterior surface* forms the posteromedial margin of the middle fossa floor (Fig. 127-2). Significant surface features include (1) medially, the arcuate eminence formed by the prominence of the superior semicircular canal, and the sulcus of the superior petrosal sinus; (2) anteriorly, at the junction with the greater sphenoid wing, the musculotubal canal containing the more superficial semicanal of the tensor tympani and a deeper semicanal of the eustachian tube; and (3) at the apex, a smooth depression occupied by the trigeminal ganglion, just posterior to which is located foramina and sulci of the greater and lesser superficial petrosal nerves, running parallel to the sphenoid suture line. The roof of the middle ear and mastoid is located lateral to the arcuate eminence.

The *posterior surface* of the petrous part of the temporal bone is oriented in the vertical plane forming the anterior bony limit of the posterior fossa (Fig. 127-3). This surface is framed by sulci for the sigmoid sinus, and the superior petrosal and inferior petrosal sinuses. At the center of the posterior face is the porus acusticus at the fundus of which can be seen the falciform (horizontal) crest, Bill's bar (vertical crest), and foramina of cranial nerves VII and VIII. The subarcuate artery emerges from a depression superior and lateral to the acoustic meatus, whereas the endolymphatic sac and duct occupy the depression and opening located inferolaterally, known as the operculum. The jugular foramen is formed at the junction between the petrous and occipital bones (Fig. 127-4), and is partitioned into the pars nervosa (posterior) and pars venosa (anterior) by the jugular spine or process.[3]

The *inferior surface* of the temporal bone is irregular because of the presence of multiple muscle attachments (Fig. 127-5). The external aperture to the cochlear aqueduct is located just medial and anterior to the jugular spine within the pars nervosa, and marks the superiormost limit of the jugular foramen. The glossopharyngeal nerve enters the jugular foramen adjacent to the opening of the cochlear aqueduct. In the translabyrinthine approach to the internal auditory canal, the cochlear aqueduct is an important inferior limit of dissection used to protect the lower cranial nerves. The cochlear aqueduct eventually opens into the scala tympani at the cochlear base.[4-6] The jugular bulb occupies a dome-shaped compartment located lateral to the pars venosa of the jugular foramen directly under the middle ear space. The inferior foramen of the carotid canal is located directly anterior to the jugular bulb depression, from which it is separated by a wedge-shaped bone called the keel. The tympanic canaliculus penetrates the keel to transmit sensory and preganglionic parasympathetic fibers from the inferior

ganglion of the glossopharyngeal nerve into the middle ear as Jacobson's nerve.[1,5] The styloid process is located anterior to the stylomastoid foramen, and both are located at the anterior limit of the digastric groove.

The tympanic part of the temporal bone forms the anterior wall, floor, and part of the posterior wall and roof of the bony external auditory canal (EAC), and the anterior wall and floor of the middle ear (see Fig. 127-1). The anterior edge of this open ring forms the tympanosquamous suture line within the EAC, and the petrotympanic suture line within the middle ear, through which the chorda tympani exits the ear. The posterior edge of the tympanic ring forms the tympanomastoid suture line, which curves from the posterior EAC inferiorly to within millimeters of the stylomastoid foramen, serving as a landmark for the main trunk of the facial nerve as it exits the temporal bone (see Fig. 127-5).

External Ear

The auricle is a funnel-shaped cartilaginous structure that is continuous with the meatus and EAC (Fig. 127-6). Intricate ridges and depressions formed by the auricular cartilage and cutaneous envelope are shown and labeled in Figure 127-5. The blood supply of the external ear originates from the external division of the carotid artery via the posterior auricular and superficial temporal vessels. The EAC (Fig. 127-7) is about 2.5 cm long and is composed of a lateral cartilaginous (membranous) portion and a medial bony portion.[1,7] The membranous portion accounts for the lateral third of the EAC, whereas the bony portion forms the medial two thirds. The skin lining the membranous canal is thicker, more mobile, and endowed with sebaceous and apocrine (ceruminous) glands and hair follicles. Sebaceous and apocrine ducts empty into a follicular canal surrounding each hair follicle.[5,7]

The bony portion of the canal is lined by thin, immobile skin that lacks hair and glands, and is continuous with the epithelium of the tympanic membrane. The bony-cartilaginous junction is the narrowest point or isthmus of the EAC, where a fibrous interface serves as a potential pathway for spread of malignant disease beyond the ear. For this reason, en bloc resection of the lateral temporal bone is necessary to eradicate primary malignancies of the EAC. The bony-cartilaginous junction is also the site at which underlying osteomyelitis manifests as mounds of granulation tissue in the EAC, a finding that is pathognomonic for malignant otitis externa. The incomplete ossification of the anterior bony canal produces an opening into the infratemporal region, known as the foramen of Huschke, which may also serve as a means for extension of malignant tumors from the EAC to the deep lobe of the parotid gland. Naturally occurring defects in the cartilaginous portion of the EAC, known as the fissures of Santorini, also provide avenues of spread to the superficial lobe of the gland.

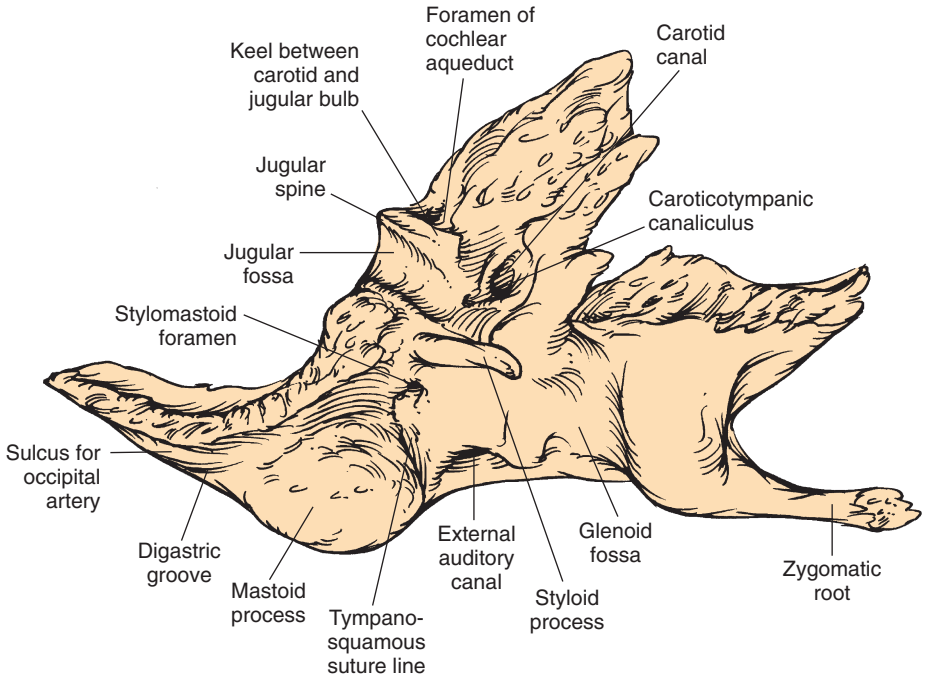

Figure 127-5. Inferior view of the left temporal bone. Note the linear relationship between the stylomastoid foramen, digastric groove, and styloid process. *(Redrawn from art by Sarah Williamson, provided courtesy of H. W. Francis and J. K. Niparko.)*

The external ear is developed from ectodermal and mesodermal components of the first and second branchial arches and the intervening first branchial groove.[8,9] Distinct condensations of tissue, known as the hillocks of His, give rise to the tragus and most of the helix from the first branchial arch, and to the antihelix, antitragus, lobule, and inferior helix from the second branchial arch. Sensory innervation is provided by the corresponding first branchial nerve: the auriculotemporal branch of the trigeminal nerve and a cutaneous branch of the facial nerve. The EAC develops from the dorsal portion of the first branchial cleft, which extends toward and eventually makes contact with endoderm of the expanding tubotympanic recess. There is a transient obstruction of the medial canal by proliferating epithelial cells to form a meatal plug that eventually dissolves, leaving a patent canal.

Errors of embryogenesis may result in impaired hearing or render the ear vulnerable to other conditions. The failed or incomplete involution of the meatal plug results in canal atresia or severe stenosis with conductive hearing loss and the risk of canal cholesteatoma. Auricular anomalies may also result from imperfect development of the hillocks of His with consequences ranging from anotia to the development of preauricular cysts and sinuses by duplication of the first branchial groove and arch.[10]

Tympanic Membrane

The tympanic membrane forms the medial wall of the EAC and much of the lateral wall of the middle ear space. It is a four-layered, concave-shaped membrane connected centrally to the manubrium of the malleus and peripherally to the tympanic sulcus.[1,4,5] The tip of the malleus is attached to the depression known as the umbo, superior to which the manubrium forms the mallear stria, which extends to the mallear prominence formed by the lateral process (Fig. 127-8).

Two dense fibrous layers provide the structural support for thin EAC skin laterally and middle ear mucosa medially. The outer radiate fibrous layer inserts on the manubrium of the malleus, and the deeper circular fibrous layer is arranged circumferentially near the circumference of the tympanic membrane. Both layers become integrated peripherally into a fibrocartilaginous ring, the annular ligament that anchors the tympanic membrane to a bony sulcus within the tympanic ring. This tympanic sulcus terminates superiorly at anterior and posterior spines, to which the most superior edge of the fibrous layer is attached to form posterior and anterior mallear folds that insert on the lateral process of the malleus. The small area of tympanic membrane located superior to the anterior and posterior mallear folds lacks a fibrous layer and is attached superiorly to the bony rim of the notch of Rivinus. The thinner superior segment of tympanic membrane is known as pars flaccida or Shrapnell's membrane, and the thicker inferior area is known as pars tensa.

The otoscopic examination consists of the careful evaluation of the EAC skin, the surface anatomy of the tympanic membrane, and direct or indirect examination of middle ear anatomy as seen through the translucent membrane or perforations. The round window, long process of the incus, incudostapedial joint, and chorda tympani are identifiable through the intact tympanic membrane to varying

degrees as seen in Figure 127-6, depending on its translucency, extent of retraction, and the mucosal health within the middle ear.

Middle Ear

The middle ear is an air-filled space formed by extension of the foregut into the anlage of the temporal bone. The expanding first pharyngeal pouch forms multiple cul-de-sacs that coalesce to form a common airspace partitioned by the ossicular chain and associated ligaments and mucosal folds. The resorption of mesenchymal tissue further expands the size of the middle ear and mastoid into niches, compartments, and bony tracts of air cells.[1,9,11] These additional areas vary considerably among individuals and between ears, influenced by heredity, airflow via the eustachian tube, and disease in the early years of life.

The eustachian tube is the conduit through which air is exchanged between the middle ear space and upper aerodigestive tract. It is angled by about 45 degrees from the middle ear to the nasopharyngeal opening at the torus tubarius.[12-14] The proximal third of the tube is formed in petrous bone. The distal two thirds segment is fibrocartilaginous and is collapsed at rest. The fibrocartilaginous portion is composed of an open tube that is shaped like an inverted "J" in cross section. A fibrous membrane closes this tube laterally. The tensor veli palatini muscle is inserted on this membrane retracting it on muscular contraction to enlarge the tubal lumen during swallowing and yawning. The bony-cartilaginous junction is the narrowest point along the eustachian tube. The internal carotid artery is closely associated with the medial wall of the eustachian tube at its tympanic opening, where the overlying bone may be quite thin or even dehiscent.

The middle ear cavity can be spatially divided into hypotympanum, mesotympanum, and epitympanum, the limits of which are defined by their location relative to the tympanic anulus (see Figs. 127-8 and 127-9). The mesotympanum is the space just medial to the tympanic membrane, which extends from the eustachian tube opening anteriorly to the facial nerve posteriorly. The carotid artery is located medial to the eustachian tube opening, and the tensor tympani muscle occupies the semicanal superior and parallel to the eustachian tube. The cochlear promontory forms the medial wall of the mesotympanum marked posteriorly by the oval window superiorly, which is occupied by the stapes, and the round window inferiorly. The mesotympanum extends into a recess of varying depth that lies posterior to the oval and round windows, and medial to the vertical facial nerve. Known as the sinus tympani, this space may harbor occult cholesteatoma despite careful and thorough removal of bone around the facial nerve, which

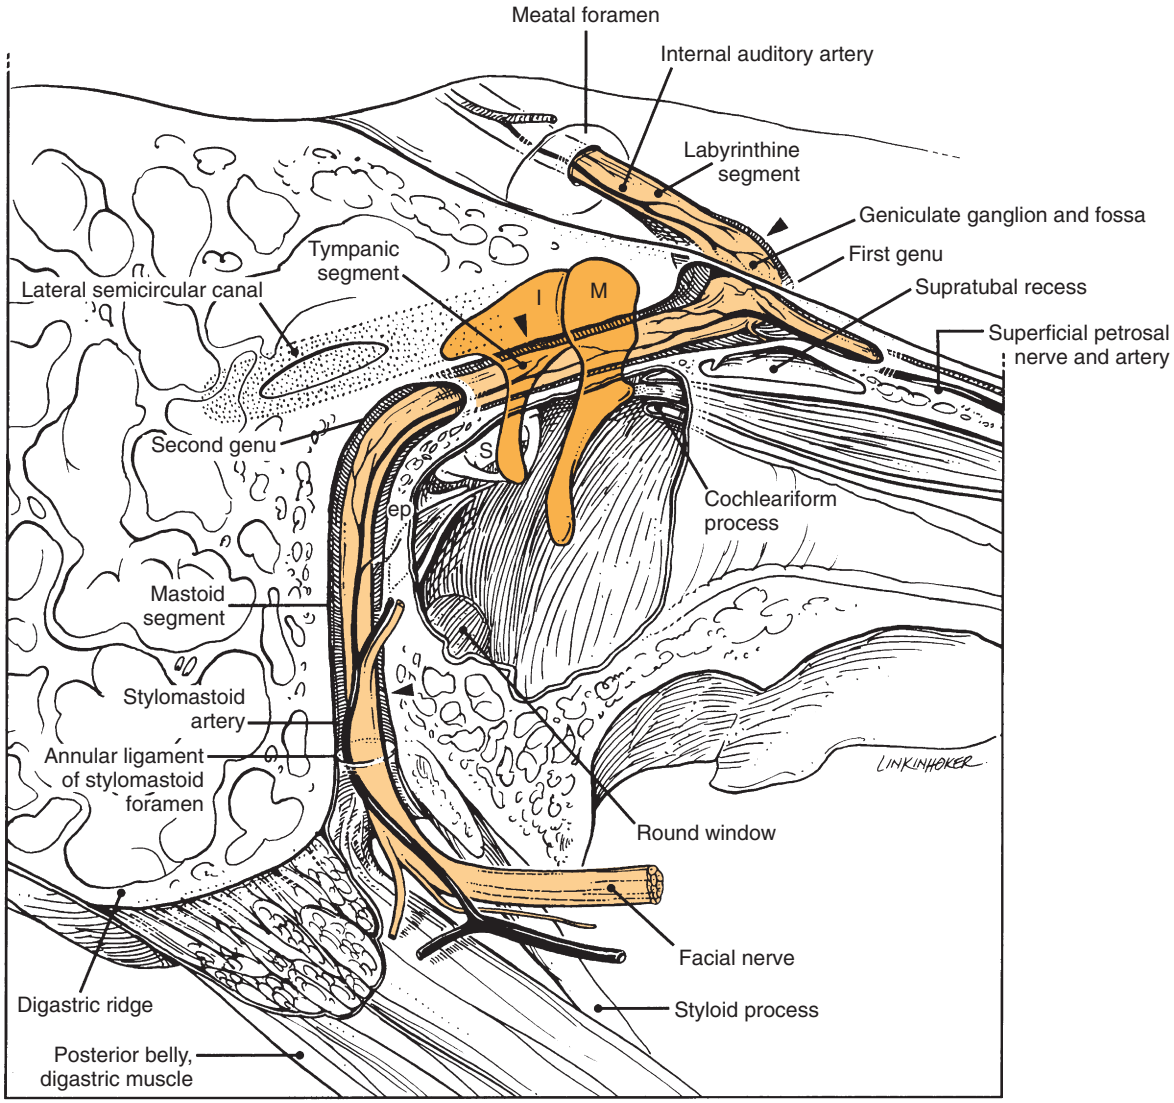

Figure 127-9. Anatomy of the infratemporal portion of the facial nerve and associated middle ear structures. Sites of vulnerability to injury (*arrowheads*): *Perigeniculate region*—increased susceptibility of geniculate fossa to fracture, nerve compression and ischemia occur in the narrow meatal foramen and labyrinthine segment in response to nerve injury, first genu is tethered by the greater superficial petrosal nerve increasing susceptibility to shearing injuries, vascular watershed area of branches of the external carotid artery and posterior circulation, geniculate ganglion is susceptible to injury during surgical dissection in the supratubal recess of the anterior epitympanum. *Tympanic segment*—the nerve is most frequently dehiscent above oval window, distal tympanic segment and second genu susceptible to injury in cholesteatoma surgery owing to pathologic dehiscence or distorted anatomy and failure to identify important surgical landmarks. *Mastoid segment*—in the lower portion of its vertical course and just distal to the stylomastoid foramen the nerve is positioned lateral to the tympanic anulus and is susceptible to injury during surgery of the external auditory canal. *(From Francis HW. Facial nerve emergencies. In: Eisele D, McQuone S, eds.* Emergencies of the Head and Neck. *St. Louis: Mosby, 2000:337-366.)*

forms its lateral wall. The pyramidal eminence transmits the stapedial tendon to the stapes superstructure, and is located just anterior to the second genu of the facial nerve as it transitions from the tympanic (horizontal) to mastoid (vertical) segment. The inferior anulus of the tympanic membrane marks the inferior limit of the mesotympanum and superior limit of the hypotympanum. The hypotympanum is limited inferiorly by the jugular bulb posteriorly and may extend inferomedial to the cochlea.

The ossicular chain, associated ligaments, and mucosal folds almost completely partition the epitympanic space from the mesotympanum except for small openings anterior and posterior to the stapes superstructure (Fig. 127-10).[12] The body of the incus articulates with the head of the malleus to form an ossicular mass that occupies most of the epitympanum. These ossicles are suspended within this space without touching its bony walls, by the anterior and superior malleal and posterior incudal ligaments. They are further supported by investments of the lateral and long processes of the malleus into the tympanic membrane, and by the incudostapedial articulation. The presence of a single nutrient vessel within the long process of incus and the absence of collateral circulation render this segment of bone susceptible to aseptic necrosis secondary to middle ear infections (Fig. 127-11).

The lateral process of the malleus and spines of the notch of Rivinus are otoscopic landmarks for the inferior limit of the epitympanum. The superior medial wall of the bony canal or scutum forms the lateral wall of the epitympanum, and is subject to erosion by cholesteatomas arising secondary to retraction of the pars flaccida. The epitympanum is divided further into (1) Prussak's space, just medial to pars flaccida and lateral to the head and neck of the malleus; (2) the compartment anterior to the malleus; and (3) the posterior compartment, which communicates with the antrum. The folds and ossicles

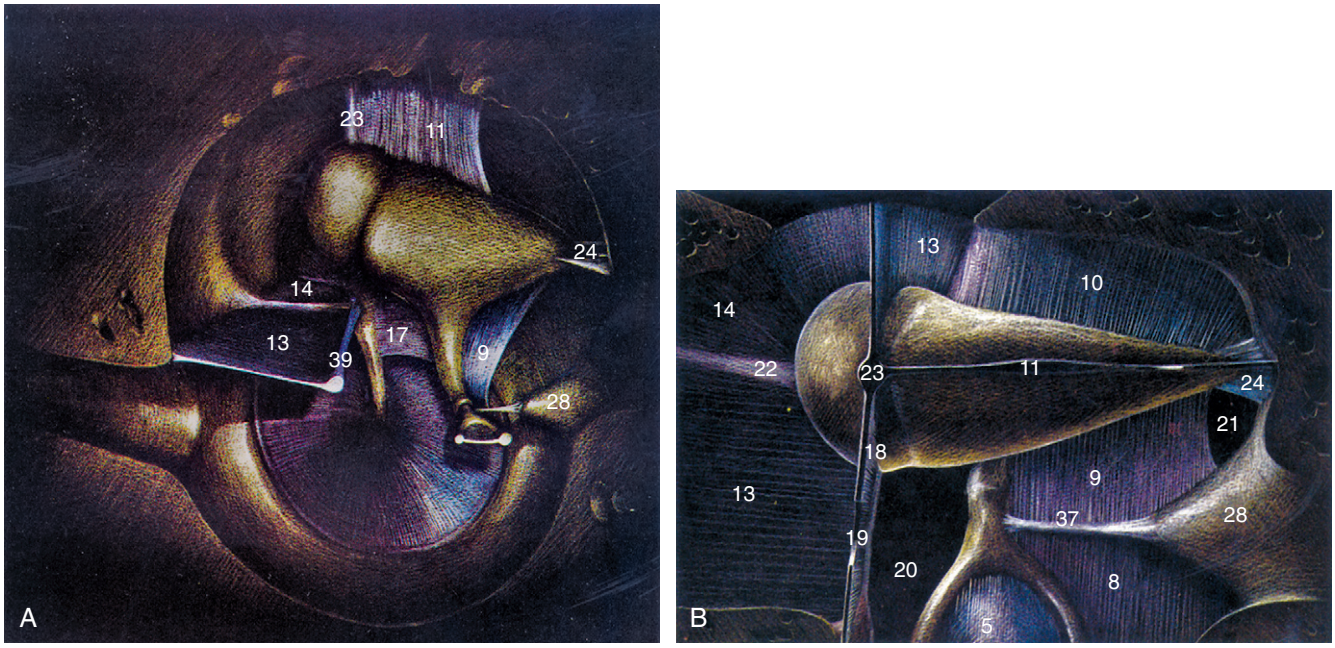

Figure 127-10. **A** and **B,** Partitioning of the middle ear by ossicular chain and associated mucosal folds. Lateral (**A**) and inferior (**B**) views of the middle ear show separation of mesotympanic and epitympanic regions by the tensor fold (no. 13), the interosseous fold (no. 17), and the medial incudal fold (no. 9), leaving the isthmus tympani anticus (no. 20) and isthmus tympani oticus (no. 21) as the only remaining openings. *5,* obturatoria stapedis; *8,* plica stapedis; *11,* superior incudal fold; *14,* anterior malleal fold; *18,* superior malleal fold; *19,* incisura tensoris; *22,* anterior malleal ligament; *23,* superior malleal ligament; *24,* posterior incudal ligament; *28,* pyramidal eminence; *39,* tensor tympani tendon. *(From Proctor B. The development of the middle ear spaces and their surgical significance. JLO. 1964;78:631-648.)*

that partition this space provide distinct pathways along which cholesteatoma can spread within and beyond the attic.[6,12] Attic retraction cholesteatomas are directed posteriorly from Prussak's space through an opening into the posterior epitympanum. From here, there is extension into the antrum through the aditus ad antrum or inferiorly into the posterior mesotympanum, or both. In advanced cases, disease may extend medial to the ossicles and to the anterior attic. In cholesteatoma surgery, removal of the incus and the head of the malleus is required to identify and address the anterior extension of disease.

The close association between the tympanic segment of the facial nerve and pathology in the attic requires a detailed understanding of neuroanatomy of this region (see Fig. 127-9). The geniculate ganglion and first genu of the facial nerve are located just medial to a bony cul-de-sac at the anterior limit of the attic, known as the supratubal recess. The posterior opening of this recess is marked by the cochleariform process inferiorly and the "cog" superiorly, an incomplete bony septum oriented in the coronal plane.[15] The facial nerve is vulnerable at the first genu to disease or surgical dissection within the supratubal recess, from which it may be separated by minimal or no bone.[16] The cog should be removed to visualize the entire supratubal recess for safe removal of disease.[15] The tympanic segment of the facial nerve projects in a posterior direction at a slight inferior incline. It skims just superior to the cochleariform process, which serves as a durable landmark for the midportion of the tympanic segment of the facial nerve.

The fallopian canal serves as the bony superior limit of the oval window niche. In 55% of cases, however, the facial nerve is partially exposed because of bony dehiscence. In some cases, the nerve herniates from the canal into the oval window niche, becoming vulnerable during stapes surgery. The pyramidal eminence, from which the stapedius tendon emerges to insert on the stapes capitulum, is a reliable landmark for the second genu of the facial nerve distal to which the nerve is directed vertically toward the stylomastoid foramen. The facial nerve is most vulnerable to iatrogenic injury just proximal to the second genu and in its vertical path.[17] An understanding of facial anatomy and the use of sound surgical technique are required to identify and preserve the nerve and its function during ear surgery.[18]

The tegmen tympani forms the superior limit of the epitympanum, which also corresponds to the cortical floor of the middle fossa. This bone may be very thin and even dehiscent in some cases. Ectopic arachnoid granulations positioned on the bony floor of the middle fossa may erode over time into the mastoid owing to pulsations of cerebrospinal fluid. When accompanied by the thinning of dura, meningoencephaloceles develop that may spontaneously leak cerebrospinal fluid to generate middle ear effusions, rhinorrhea, or otorrhea.[6,19,20]

The lateral and superior semicircular canals form the medial walls of the posterior epitympanum at its opening into the antrum, known as the aditus ad antrum. The lateral semicircular canal forms a prominence at the inferior aspect of the aditus ad antrum. Impacted cholesteatoma erodes the otic capsule that forms this prominence leading to the formation of a perilymphatic fistula over time. The second genu of the facial nerve hugs the anteroinferior aspect of the lateral semicircular canal (see Fig. 127-9).

Facial Nerve

The facial nerve provides afferent and efferent innervation to structures derived from the second branchial arch. Most fibers are *special visceral efferents* that supply nerve input to striated muscles of facial expression, the stapedius muscle, the stylohoid muscle, and the posterior belly of the digastric muscle.[5,18,21] *General visceral efferent fibers* form the nervus intermedius, which innervates (1) the lacrimal gland and seromucinous glands of the nasal cavity via the greater superficial petrosal nerve and pterygopalatine ganglion, and (2) the submandibular and sublingual glands via the chorda tympani and the submandibular ganglion. *Special sensory fibers* for taste innervate the anterior two thirds of the tongue via the chorda tympani, and the tonsillar fossae and palate via the greater superficial petrosal nerve. The geniculate ganglion contains the cell bodies of these sensory neurons. *Somatic sensory fibers* provide sensation to touch of the EAC and conchal skin of the auricle, and proprioceptive information from the facial muscles. *Visceral afferent fibers* supply the mucosa of the nose, pharynx, and palate. Motor, preganglionic, and sensory modalities have the

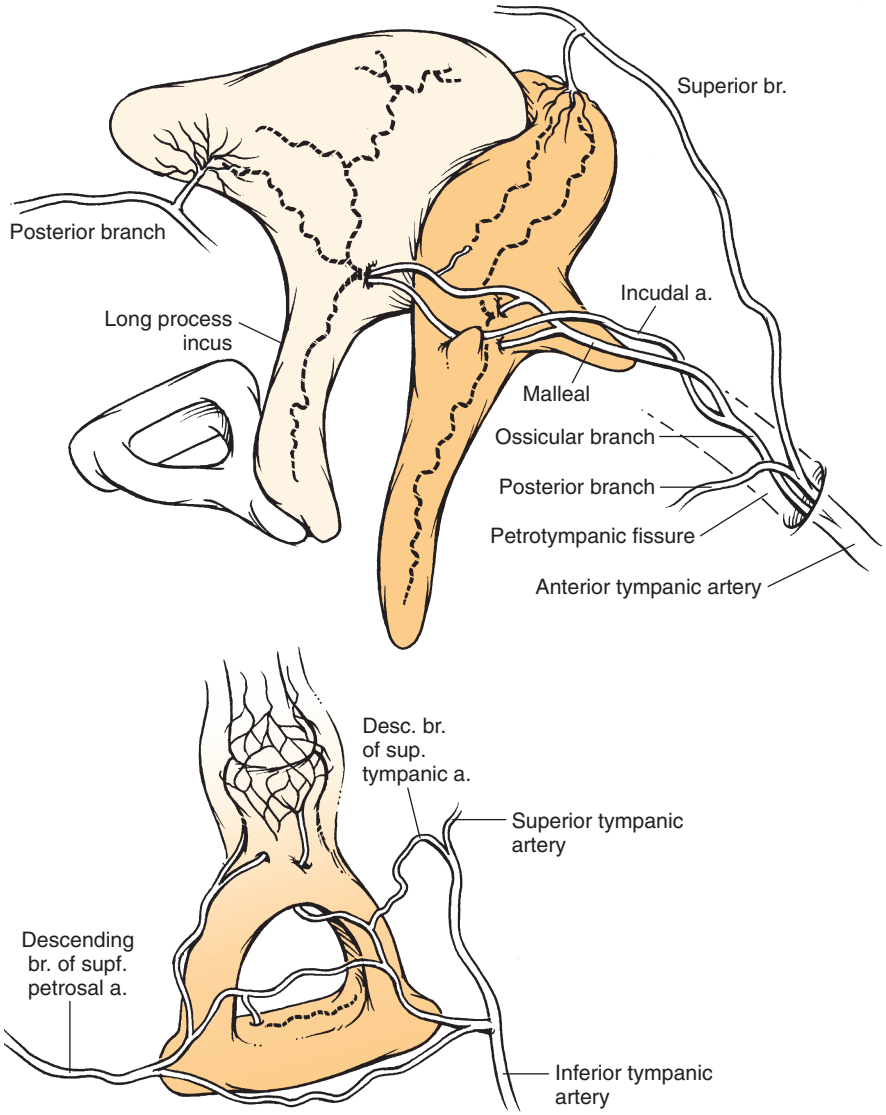

Figure 127-11. Blood supply of the middle ear ossicles. The long process of the incus has a single nutrient vessel. Other portions of the ossicular chain are supplied by two or more sources. *(Redrawn from Nager G.* Pathology of the Ear and Temporal Bone. *Baltimore: Williams & Wilkins; 1993.)*

following brainstem origins: the motor nucleus (motor), the superior salivatory nucleus (preganglionic), and the nucleus of the solitary tract (sensory).

The facial nerve traverses the temporal bone within a bony canal known as the fallopian canal, which begins at the fundus of the internal auditory canal and terminates at the stylomastoid foramen (see Fig. 127-9).[1,4-6] Within the internal auditory canal, the nerve lacks a fibrous sheath or endoneurium and is surrounded by a thin layer of arachnoid. The labyrinthine segment is the first, shortest, and narrowest segment of the fallopian canal.[22,23] It travels superior to the cochlea and opens into the geniculate fossa located just deep to the supratubal recess. The geniculate ganglion is separated from the middle fossa by only a very thin layer of bone, which is dehiscent in about 25% of ears. The facial nerve acquires a fibrous sheath at and distal to the geniculate ganglion. This is also the location of the facial hiatus, where the greater superficial petrosal nerve projects anteriorly along the middle fossa floor, and of the first genu, at which the main trunk makes an acute posterior and slightly inferior turn to enter the tympanic or horizontal segment of the fallopian canal. The horizontal segment of the facial nerve occupies the medial wall of the anterior attic, skims over the superior aspect of the cochleariform process, and forms the superior wall of the oval window niche posteriorly.

At the pyramidal eminence, from which the stapedial tendon emerges, the facial nerve makes a second genu into the mastoid or vertical segment. This turn is positioned just anteroinferior to the lateral semicircular canal, and anterior to a line drawn through the short process of the incus. A superior extrapolation of the vertical segment would approximately bisect the prominence of the lateral semicircular canal. Although the anatomic position of the horizontal segment is quite consistent, particularly relative to the cochleariform process, oval window, and pyramidal eminence, there is greater variability in the path taken by the vertical segment before exiting the stylomastoid foramen. Chorda tympani and stapedial branches occur at varying points along this segment. The space between the mastoid segment of the facial nerve and the chorda tympani is a space through which a posterior tympanotomy (or facial recess) can be surgically created to access the middle ear. The distal aspect of the vertical segment of the fallopian canal and the stylomastoid foramen itself are lined by the aponeurosis of the posterior belly of the digastric muscle. As the facial nerve exits the fallopian canal, it receives blood supply from this closely applied aponeurosis. The preservation of this relationship on rerouting the nerve during skull base surgery may result in better facial nerve function.[24,25] Identification of this aponeurosis anterior to the cephalic edge of the digastric muscle serves as a valuable landmark for the stylomas-

toid foramen and the vertical segment of the nerve as it exits. A more in-depth discussion of facial nerve anatomy is also helpful in understanding the mechanisms of injury.

Each segment of the facial nerve has unique anatomic features that render it susceptible to injury.[26] The fallopian canal not only provides a protective path for the facial nerve in the temporal bone, but also plays an important role in the pathophysiology of injury. The narrow meatal foramen[23] and labyrinthine segment[22] are sites where facial nerve edema secondary to inflammatory or traumatic causes leads to progressive compression, vascular compromise, and axonal injury. This narrow segment is made further vulnerable by being a watershed area between terminal arterioles of the vertebrobasilar and external carotid artery systems. Vertebrobasilar supply is via labyrinthine branches of the anterior inferior cerebellar artery, and supply by the external carotid artery is via the petrosal branch of the middle meningeal artery and the stylomastoid artery that branches from the posterior auricular artery.[27] The labyrinthine segment is made further vulnerable by the lack of epineurium and associated vascular plexus that provides a barrier to injury and a rich collateral blood supply.

The facial nerve is susceptible to injury in the region of the geniculate ganglion for three main reasons. First, the thin and sometimes dehiscent bone surrounding the geniculate ganglion makes it a common path through which temporal bone fractures travel. Second, as previously discussed, the ganglion is susceptible to injury from pathology or surgical dissection within the supratubal recess. Third, the greater superficial petrosal nerve, which projects anteriorly, tethers the facial nerve at the hiatus and may exert intraneural traction and shearing forces during temporal bone trauma. Any of these traumatic mechanisms, in addition to inflammation due to herpetic infection, may compromise facial nerve integrity through direct axonal injury, or may produce edema and secondary compressive injury in the adjacent labyrinthine segment.

The tympanic segment is the most common site of congenital dehiscence of the bony canal, especially above the oval window.[23] Bony dehiscence by cholesteatoma is also common proximal to the second genu, where the adjacent aditus ad antrum acts as a bottleneck through which disease must pass en route to the antrum, eroding structures in the posterior attic along the way. The dehiscent horizontal fallopian canal places the facial nerve at risk for injury by the unwary surgeon, especially when disease or previous surgery alters anatomy. The vertical segment has the most variable path, especially in association with congenital malformations, such as canal atresia. The nerve also courses lateral to the tympanic anulus as it approaches the stylomastoid foramen and can be injured in transcanal procedures.[17] In the newborn, the mastoid tip is underdeveloped, placing the styloid process and the adjacent facial nerve more superficial in the neck. The nerve is susceptible to surgical injury in routine postauricular approaches and to compression injuries during forceps delivery.

Mastoid and Other Pneumatized Regions of the Temporal Bone

Similar to the mastoid, all pneumatized regions of the temporal bone consist of a collection of mucosa-lined bony compartments that are ventilated through the aditus ad antrum or via other cell tracts that open into the middle ear space. This network of bony air cells primarily arises from the diploë of squamous and petrous portions of the temporal bone. The mastoid is the largest pneumatized region, located lateral to the labyrinth and communicating directly with the attic via its medial compartment, the antrum. The mastoid also extends posteriorly into the occipital bone and communicates with medial cell tracts. The vestibular portion of the inner ear forms the medial wall of the antrum, and Körner's septum, the embryologic junction between petrosal and squamosal portions of the temporal bone, forms the lateral limit.

There is considerable variation in the extent of temporal bone pneumatization and the architecture of cell tracts in and around the mastoid. The extent of pneumatization depends on early otologic history, including factors that influence middle ear ventilation,[28] history of otitis media,[29] and presumably heredity. The interaction between osteoclastic activity and the resorption of mesenchymal cells determines the speed of pneumatization, and is influenced by genetic and local middle ear factors.[11]

The extent and anatomic distribution of pneumatization has relevance to the surgical management of ear disease. Surgical access is aided by the presence of large pneumatized regions that permit navigation to deeper structures without compromise of intracranial contents, the labyrinth, the facial nerve, and the sigmoid sinus. The decision to maintain or remove the bony separation between the mastoid and EAC is also influenced by the extent of pneumatization. Poor pneumatization is associated with a greater likelihood of chronic ear disease[28] because it is a marker of reduced capacity to ventilate the middle ear and mastoid. Exteriorization of the poorly aerated mastoid may avoid chronic consequences of hypoventilation, including otomastoiditis and cholesteatoma.

Pneumatization may be organized into regions and tracts. The primary regions of pneumatization are as follows[5,30]:

- The mastoid (the antrum, central mastoid tract, tegmental, sinodural, sinal, facial, and tip cells)
- Perilabyrinthine (supralabyrinthine and infralabyrinthine areas)
- Petrous apex (peritubal area and apical area)
- Accessory region (zygomatic, squamous, occipital, styloid)

Air cell tracts are paths along which diploic bone and mesenchyme are resorbed during maturation, and through which air subsequently flows to deeper spaces. These tracts circumnavigate the labyrinth, and cortical plates of bone that line the middle and posterior fossa dura, sigmoid sinus, carotid artery, and facial nerve. They have relevance to the surgical access of temporal bone and intracranial areas, and the pathogenesis and spread of ear disease. These tracts are also pathways for drainage of spinal fluid to the ear canal or nasopharynx associated with surgery, trauma, or spontaneous meningoencephaloceles. These tracts can be categorized as follows:

- Posterosuperior (sinodural)
- Posteromedial (retrofacial and retrolabyrinthine)
- Subarcuate
- Perilabyrinthine (supralabyrinthine and infralabyrinthine)
- Peritubal (associated with the eustachian tube)

When obstructed by edema, postinflammatory scarring, or organized clots, unventilated deeper spaces may accumulate sterile fluid, including transudates or by-products of inflammation and hemoglobin to form the so-called cholesterol granuloma,[31] an expanding collection of thick dark fluid often compared with crankcase oil. Superinfection of these obstructed tracts creates a chronic source of sepsis that is not always cleared with antibiotics alone. Because of its deep location and narrow air cell tracts, the petrous apex is vulnerable to these postobstructive processes, making it a well-recognized location for cholesterol granulomas and apicitis. Gradenigo's syndrome consists of symptoms that result from the inflammatory effect of petrous apicitis on adjacent intradural structures, including cranial nerves VI and V_1, accompanied by otorrhea.[32]

CHAPTER ONE HUNDRED AND TWENTY-EIGHT

Anatomy of the Auditory System

Christina L. Runge-Samuelson

David R. Friedland

Key Points

- The neuroanatomy of the central and peripheral auditory systems is organized to extract specific information from the complex waveforms of speech and music.
- The cochlea is organized tonotopically with low frequencies at the apex and high frequencies at the base. This tonotopic organization is reiterated throughout the central auditory system.
- The organ of Corti is the principal sensory structure in the cochlea and contains the inner and outer hair cells.
- Afferent auditory neurons are bipolar, have their cell bodies in the spiral ganglion, and connect the hair cells to the central auditory system.
- The cochlea generates auditory nerve impulses that are fed to the cochlear nucleus where parallel ascending pathways independently extract temporal, spectral, and intensity cues from environmental stimuli.
- The cochlear nucleus is the only entry point for all peripheral auditory information to the central nervous system.
- The superior olivary complex and inferior colliculus are important in sound localization.
- The inferior colliculus is the gateway for almost all ascending and descending pathways between the telencephalon and the lower centers.
- The medial geniculate body and auditory cortex integrate auditory information with multiple other sensory modalities.
- Efferent auditory neurons arise from the superior olivary complex and innervate outer hair cells of the ipsilateral and contralateral cochlea.

This chapter provides a basic overview of the anatomy of the auditory system from the cochlea to the cortex. Auditory processing involves the encoding of sound energy into electrical signals. This process begins in the periphery at the cochlea and progresses through the cochlear nerve, the brainstem, and the midbrain, and undergoes final integration within the cortex. Knowledge of the neuroanatomy of these regions is important for understanding most forms of congenital and hereditary deafness; auditory processing disorders; and the indications for, and functions of, cochlear and auditory brainstem implants. These neuroanatomic regions also may play crucial roles in age-related difficulties with word recognition, hearing in noise, and the generation and perception of tinnitus.

Cochlear Anatomy

Osteology

The inner ear is contained in the petrous apex of the temporal bone, and is encased in a bony structure called the osseous or bony labyrinth. The bone forming the cochlea and vestibular labyrinth is the hardest bone in the human body and is akin to ivory in its density. The labyrinth consists of three continuous sections: the vestibule, the cochlea, and the semicircular canals. The initial point of communication between the middle and inner ears occurs at the oval window of the vestibule, where the stapes footplate abuts the oval window membrane. At the basal end of the cochlea is the round window membrane, which communicates with the middle ear space. The cochlea is a snail-shaped structure that has a wide diameter at the base, which narrows for 2¾ turns until it reaches its apex. Figure 128-1 shows a cross section of the cochlea, illustrating the cuts through each turn.The core of the cochlea is the modiolus, which is highly porous bone that allows passage of auditory nerve fibers as they travel from the internal auditory meatus to the hair cell synapse. Extending from the modiolus into the osseous labyrinthine space is a bony shelf, or the osseous spiral lamina. The osseous spiral lamina coils around the center of the cochlea and provides partial division of the upper and lower cochlear chambers into the scala vestibuli and scala tympani. At the apex of the cochlea, they communicate at the helicotrema. The spiral lamina is also the point of attachment for the basilar membrane, which is the lower border of the membranous labyrinth encasing the scala media.

Along the length of the cochlea, the widths of the spiral lamina and basilar membrane are inversely related, with the spiral lamina wider at the base and narrowing toward the apex, and the basilar membrane narrower at the base and wider at the apex. This is one of several contributing factors to the frequency specificity of basilar membrane motion. At the basal turn of the cochlea is the cochlear aqueduct, a bony channel that allows communication between the perilymphatic fluid and cerebrospinal fluid of the subarachnoid space in the posterior fossa.

Membranous Labyrinth and Inner Ear Fluids

The membranous labyrinth of the cochlea follows the shape of the osseous cochlea and forms a third cochlear chamber—the scala media. The sensory organ of hearing resides within the membranous labyrinth. Figure 128-2 shows a cross section of the membranous labyrinth and its structures. The membranous labyrinth is bordered superiorly by

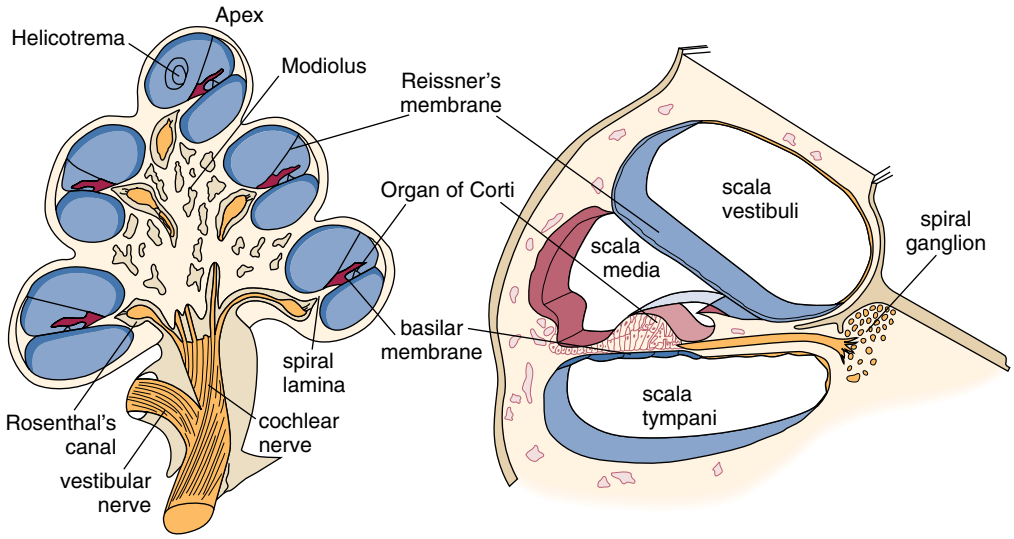

Figure 128-1. Cross section of the cochlea showing the passage of the cochlear nerve through the modiolus to the organ of Corti (*left*). Higher power view shows the osseous cochlear duct and membranous compartments within the cochlea (*right*).

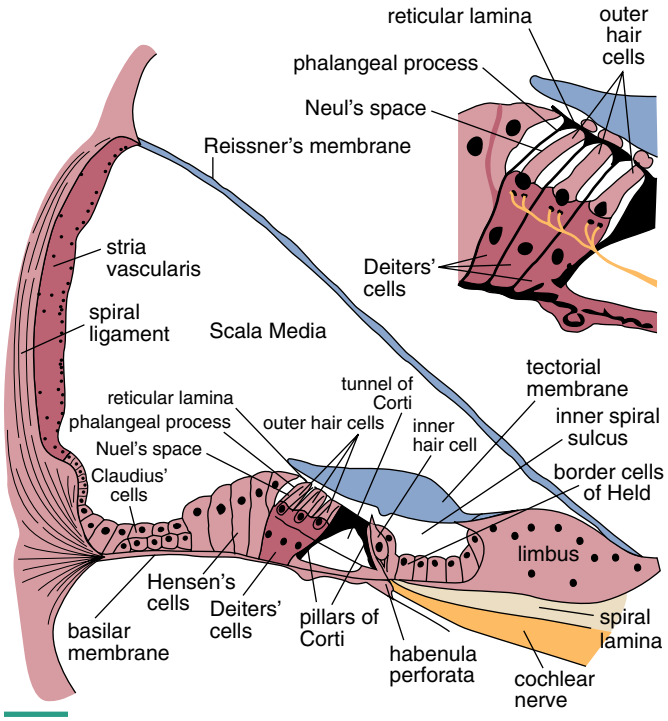

Figure 128-2. Cross section of the organ of Corti showing the major cellular structures.

Reissner's membrane, inferiorly by the basilar membrane, and laterally by a portion of the outer cochlear wall to which it is anchored by the spiral ligament. Within the membranous labyrinth, along the lateral wall, is the stria vascularis, highly vascular tissue that is responsible for the metabolic environment of the scala media. The intricate structures that comprise the organ of Corti are situated on the basilar membrane.

The organ of Corti runs longitudinally along the length of the basilar membrane and consists of many types of epithelial cells and structures. Medially, seated atop the osseous spiral lamina is the spiral limbus, a thickened band of periosteum that serves as the point of medial attachment for Reissner's membrane and gives rise to the tectorial membrane. The tectorial membrane lies over the inner and outer hair cells. It is a compliant gelatinous structure composed primarily of collagen II fibers, and serves as a mass load that moves similar to a rubber band.[1-3] Lateral to the spiral limbus is the inner spiral sulcus, which is lined with the border cells of Held. One row of inner hair cells is present, and the cell bodies are surrounded by supporting cells called phalangeal cells.

Between the inner and outer hair cells lie the pillars of Corti, which originate on the spiral lamina and basilar membrane and converge at the top to form the tunnel of Corti. Lateral to this are three rows of outer hair cells, which are securely cupped inferiorly by the supporting Deiters' cells. Each Deiters' cell has a phalangeal process that projects apically, and the space between the outer hair cell and phalangeal process is referred to as Nuel's space. The phalangeal cells, phalangeal processes of the Deiters' cells, and the superior surfaces of the hair cells form the reticular lamina, a tightly interwoven matrix that supports the apices of the hair cells. The reticular lamina forms a barrier from endolymph, the fluid in the scala media, which owing to its ionic composition is toxic to hair cells. Lateral to the outer hair cells are Hensen's cells and Claudius' cells.

The two fluid systems within the cochlea create an environment crucial to the mechanical displacement of the basilar membrane traveling wave and to the cellular depolarization and subsequent synaptic activity. Between the osseous and membranous labyrinths is perilymphatic fluid, or perilymph, which has a high concentration of sodium and low concentration of potassium, similar to what is found in cerebrospinal fluid and blood serum. The presence of perilymph in the intercellular spaces within the organ of Corti has been identified in humans and guinea pigs.[4,5]

Within the membranous labyrinth is endolymphatic fluid, or endolymph, with a high concentration of potassium and low concentration of sodium, such as is typically found intracellularly. The ionic concentrations of endolymph are maintained by the cells within the stria vascularis. The endolymphatic sac communicates with the membranous labyrinth via the endolymphatic duct and vestibular aqueduct. Disorders of the endolymphatic system resulting from disease, congenital deformities, or other insults can lead to potentially severe auditory and vestibular symptoms. An enlarged vestibular aqueduct, defined as a diameter larger than 1.5 mm at the vestibular aqueduct midpoint or greater than 2 mm at the operculum, may lead to sudden and progressive sensorineural hearing loss in children, particularly after even minor head trauma.[6]

Hair Cells

The inner and outer hair cells function as receptor cells that transduce mechanical movement into an electrochemical signal to stimulate the

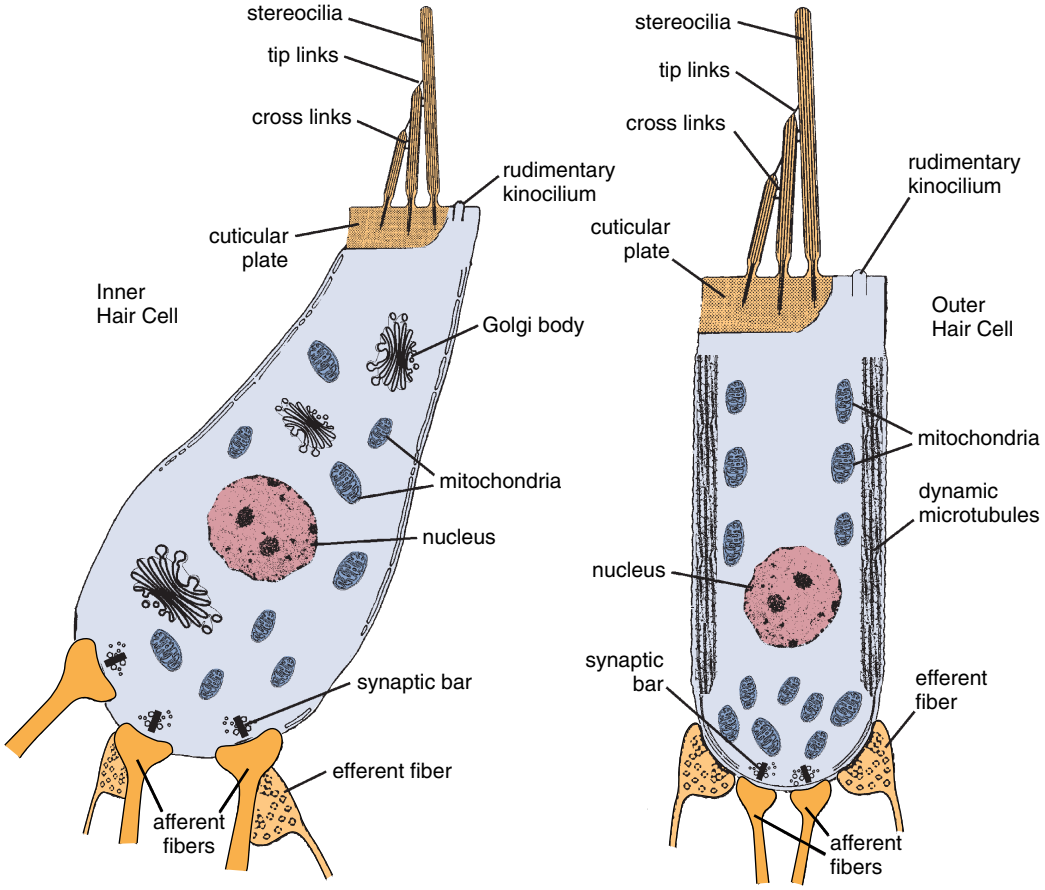

Figure 128-3. Schematic depictions of inner (*left*) and outer (*right*) hair cells. Inner hair cells are flask-shaped, receive extensive afferent innervation, and receive indirect efferent innervation. Outer hair cells are cylindrical and receive direct afferent and efferent innervation.

auditory nerve. Figure 128-3 presents schematic examples of inner and outer hair cells. The apical portion of all hair cells includes a thickened region called the cuticular plate, which in conjunction with the supporting cells forms the reticular lamina. Rooted in the cuticular plate of each hair cell and projecting through the reticular lamina are bundles of actin filaments called stereocilia, stiff hairlike structures that deflect with mechanical disturbances. Adjacent to this is a noncuticular region that contains a rudimentary kinocilium.

There are approximately 3500 inner hair cells arranged in one row on the modiolar side of the tunnel of Corti and 12,000 outer hair cells in three rows on the strial side. Figure 128-4 is a scanning electron micrograph of the reticular lamina of the organ of Corti showing the stereocilia arrangement for the three rows of outer hair cells and single row of inner hair cells. The stereocilia on outer hair cells form a "V" or "W" shape with the bottom facing away from the modiolus. The inner hair cell stereocilia form a shallow "U" that opens toward the modiolus. On each hair cell, there are rows of stereocilia, two or more on inner hair cells, and three or more on outer hair cells. For both types of hair cells, the stereocilia lengths are graduated from longest on the strial side to shortest on the modiolar side. The longest stereocilia on the outer hair cells contact the tectorial membrane, which results in deflection of the stereocilia with basilar membrane movement. The stereocilia are connected to each other by filamentous links laterally by cross-links and from the tips of shorter stereocilia to the sides of the taller ones by tip-links. These ensure that the connected stereocilia move as a unit when the longer stereocilia are deflected.

The structural aspects of the inner and outer hair cell bodies themselves differ significantly and are reflective of their functional differences. The inner hair cells are flask-shaped, wide at the bottom and narrower at the top, and contain high concentrations of organelles that

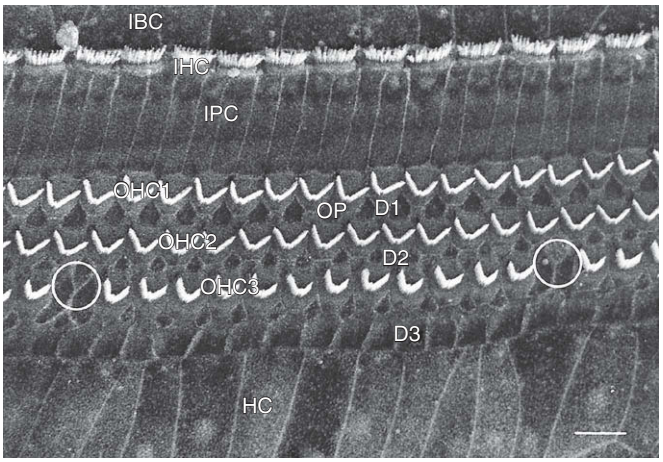

Figure 128-4. Scanning electron micrograph showing reticular lamina of organ of Corti. Note inner border cells (IBC), inner hair cells (IHC), inner pillar head plate (IPC), three rows of outer hair cells (OHC), three rows of Deiters' cell phalangeal processes (D), outer pillar cell phalangeal process (OP), and Hensen's cells (HC). Two phalangeal scars (*circled*) are present in row 3, which indicates loss of two outer hair cells. Bar = 10 µm.

are involved in metabolic activity, particularly Golgi bodies and mitochondria. Although highly metabolic, inner hair cells are considered to be passive transducers in the auditory system. Outer hair cells are cylindrical in shape and contain microfilaments and microtubules along the length of the cell that give rise to motile activity.[7] The motile properties have been shown empirically to result in highly tuned, frequency-specific contractile activity even when stimulated in isolation from the basilar membrane.[8] All hair cells have synaptic bars at afferent synapses, which serve as sites for presynaptic vesicle docking and release for subsequent stimulation of auditory nerve fibers.

Innervation

Afferent innervation of the cochlear hair cells consists of approximately 30,000 auditory nerve fibers in humans, and is responsible for providing ascending information from the cochlea to the central auditory system. The cell bodies of afferent fibers make up the spiral ganglion that resides in Rosenthal's canal within the modiolus. Nerve fibers reach the hair cells by traveling through the modiolus, and into the osseous spiral lamina, where they pass through holes in the lamina referred to as the habenulae perforatae. The nerve fibers are classified as type I and type II. Type I fibers are bipolar, of large diameter, and myelinated, and they constitute nearly 95% of the total number of fibers. Each type I fiber has a direct and independent synapse on the body of a single inner hair cell, and each inner hair cell is innervated by approximately 20 such fibers.[9,10] Type II fibers constitute the remaining 5%, and are smaller and may be myelinated or unmyelinated. Type II fibers synapse directly on the outer hair cells, with a single fiber diverging to form branches that synapse with multiple other outer hair cells.

The efferent auditory pathway originates from the olivocochlear bundle and provides central inhibitory modulation of hair cell activity via descending information. The olivocochlear bundle has about 1600 fibers, and these constitute the uncrossed olivocochlear bundle and crossed olivocochlear bundle.[11-15] These pathways originate from the medial superior olive (MSO) and lateral superior olive (LSO) regions on both sides. For the uncrossed olivocochlear bundle, the LSO projects many small-diameter, unmyelinated efferent fibers toward the ipsilateral inner hair cells, where they synapse with the afferent fibers. The MSO projects fewer myelinated fibers ipsilaterally that synapse directly on the outer hair cells. For the crossed olivocochlear bundle, the MSO projects large-diameter myelinated fibers to the contralateral outer hair cells, and the LSO projects a few unmyelinated fibers to the contralateral inner hair cell afferents. The fibers from the crossed olivocochlear bundle cross midline at the level of the fourth ventricle. To illustrate the pathways, Figure 128-5 shows a schematic example of the uncrossed olivocochlear bundle and crossed olivocochlear bundle innervation for the left organ of Corti.

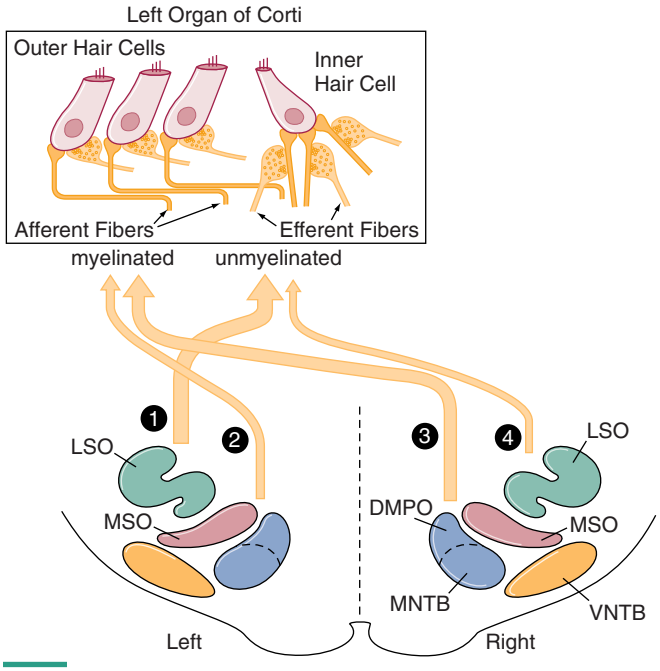

Figure 128-5. Illustration of the efferent uncrossed and crossed olivocochlear bundle pathways to the hair cells in the left organ of Corti. *Yellow* entities represent the efferent fibers and synapses. The arrow widths represent the relative amount of innervation. Uncrossed pathway: *1,* small-diameter fibers from left lateral superior olive (LSO; *green*) synapsing on left inner hair cell afferents; *2,* myelinated fibers from left medial superior olive (MSO; *pink*) to left outer hair cells. Crossed pathway: *3,* large-diameter myelinated fibers from right MSO to left outer hair cells; *4,* unmyelinated fibers from right LSO to left inner hair cell afferents. DMPO, dorsomedial periolivary nucleus; MNTB, medial nucleus of the trapezoid body; VNTB, ventral nucleus of the trapezoid body.

Central Auditory Pathways

Central auditory pathways involve all ascending and descending neuronal projections interconnecting the auditory nerve, brainstem, midbrain, thalamus, and cerebral cortex (Fig. 128-6). Most of the understanding of the anatomy, physiology, and function of these regions is inferred from animal studies. This section provides a broad overview of central auditory anatomy and may not entirely reflect the uniquely human condition. Many of the functions of these regions are inferred from animal behavioral or electrophysiologic studies, and the precise localization of human sound processing activities is not completely mapped. The reader should take away from this section a general understanding of central auditory anatomy and the complex interactions of sound processing pathways.

Cochlear Nerve

The cochlear nerve, a trunk of the cochleovestibular or eighth cranial nerve, contains afferent fibers transmitting auditory information from inner and outer hair cells to the brainstem. The cell bodies of these afferent neurons are located within the spiral ganglion of the cochlea. Spiral ganglion neurons are bipolar, with one process extending toward inner and outer hair cells and the other projecting to the brainstem. Approximately 90% to 95% of the traversing axons are large myelinated fibers, and the remaining 5% to 10% are thinner, unmyelinated axons.[16,17] The larger neurons are type I ganglion cells, which project from the inner hair cells. The smaller neurons are type II ganglion cells, which contact the outer hair cells. Both these cell types project to the cochlear nucleus, and their fibers form the cochlear nerve within the internal auditory canal and cerebellopontine angle.

The cochlear nerve is located anterior and inferior within the lateral internal auditory canal, and is separated laterally from the anterior-superior facial nerve by the transverse crest. Auditory nerve fibers entering the cochlea in this region are delicate, and care must be taken during acoustic neuroma surgery for hearing preservation to avoid lateral-to-medial traction on the nerve.[18] At the fundus, or lateralmost extent, of the internal auditory canal, the cochlear nerve is anterior to the vestibular nerves. As the trunk traverses the internal auditory canal, there is a 90-degree rotation of the complex so that the cochlear nerve lies inferior to the vestibular nerve trunk within the cerebellopontine angle. Although they join to form the cochleovestibular nerve proper, a plane of dissection generally remains apparent between the two trunks. The cochlear nerve may also appear to be a brighter white than the duller vestibular division. These features are important for identifying the proper nerve trunk during vestibular nerve section for intractable Meniere's disease.

The myelin of the cochlear and vestibular nerves transitions from peripheral Schwann to central myelin within the cerebellopontine angle. This transition zone has traditionally been thought to be the site of origin for most acoustic neuromas (i.e., vestibular schwannomas), but such an origin has been contested more recently.[19] The cochleovestibular nerve continues medially and enters the central nervous system at the pontomedullary junction. The root entry zone can be identified surgically within the foramen of Luschka after retraction of the flocculus and identification of the choroid plexus. This is the site of place-

ment of an auditory brainstem prosthesis along the lateral aspect of the cochlear nucleus.[20] The vestibular division enters the pontomedullary junction more medial than the cochlear division.

The olivocochlear bundle providing efferent innervation to the cochlea does not send fibers to the periphery through the cochlear division. Rather, the efferent innervation to the cochlea travels with the inferior division of the vestibular nerve. These fibers pass through the saccular ganglion and enter the spiral ganglion via the vestibulocochlear anastomosis of Oort.[21] Efferent fibers provide direct innervation of outer hair cells and indirect modulation of inner hair cells.

Cochlear Nucleus

All peripheral auditory information enters the central auditory system through the cochlear nucleus. Within the cochlear nucleus, initial auditory processing occurs, and fibers are distributed to higher brainstem centers. In most mammals, the cochlear nucleus forms a prominent bulge on the lateral surface of the brainstem. In humans, the cochlear nucleus is less conspicuous and is typically identified by its location along the floor of the lateral recess of the fourth ventricle.

The cochlear nucleus is traditionally segregated into ventral and dorsal subdivisions. These divisions are demarcated by the small granular cell domain, which may play a role in integrating nonauditory sensory information with auditory processes.[22] Such integration may explain the modulation of tinnitus in many individuals by jaw position or head turning.[23] The dorsal cochlear nucleus is typically laminar in organization and is more akin to the structure of the cerebellum than to other brainstem nuclei. It is less robust in humans than in other mammals, which typically have mobile pinnae and the dorsal cochlear nucleus may play a role in orienting to a sound source.[24] The dorsal cochlear nucleus has been implicated in several studies as a potential site for the generation of tinnitus.[25,26] The dorsal cochlear nucleus is tonotopically organized with low frequencies represented ventrolaterally and higher frequencies dorsomedially.[27]

The ventral cochlear nucleus is divided into anterior ventral and posterior ventral subnuclei, each with an individual tonotopic map.[16] These subnuclei have unique and shared neuronal subclasses that serve as the initial processors of auditory nerve information. Prominent spherical bushy cells, characteristic of the anterior ventral nucleus, send large-caliber axons to the olivary complex and function in sound localization.[28] The multipolar or stellate neurons, associated most with the posterior ventral cochlear nucleus, send multiple fine axons to several other brainstem centers, including the contralateral cochlear nucleus, the ipsilateral dorsal cochlear nucleus, and the contralateral inferior colliculus.[29] These cells likely play a role in encoding frequency and spectral shape, and sound intensity.[30] The octopus cells in the caudal regions of the posterior ventral cochlear nucleus may have similar functions.[31,32]

The axons of cochlear nucleus neurons project to other brainstem regions via the ventral, intermediate, and dorsal acoustic stria (see Fig. 128-6). The ventral acoustic stria, or trapezoid body, contains axons of spherical and globular bushy cells and traverses the medulla and pons to innervate the LSO, the MSO, the medial nucleus of the trapezoid body, and the inferior colliculus.[33,34] The intermediate acoustic stria contains octopus cell axons and projects to the ventral nucleus of the trapezoid body, LSO, and periolivary region. The dorsal acoustic stria transmits axons from dorsal cochlear nucleus fusiform and giant neurons to the central nucleus of the contralateral inferior colliculus.[35,36]

Superior Olivary Complex

The superior olivary complex (SOC), in the caudal aspect of the pons, is traditionally divided into three major subnuclei. These appear less distinct in human brainstems than in the brainstems of lower mammals. These subdivisions include the MSO, the LSO, and the medial nucleus of the trapezoid body. Small groups of neurons constituting the periolivary nuclei surround these and form the dorsomedial, dorsal, and dorsolateral periolivary nuclei. The periolivary group in humans is not as distinctly subdivided as in other mammals and appears disorganized with loosely arranged neurons.[37]

The SOC is the first central auditory center to receive binaural innervation, and it maintains the tonotopic organization seen in the cochlea and cochlear nucleus. Binaural innervation is indicative of the major role this nucleus plays in localizing sounds in space. Localization of sound is a combined comparison of interaural time delays by the MSO and interaural intensity differences by the LSO.[38,39] Additional roles of the SOC include sound detection and complex sound processing. The SOC also has an efferent limb providing feedback to the cochlear nucleus and cochlea.

Projections from the SOC entail ascending and descending pathways (see Fig. 128-6). The ascending fibers project via the lateral lemniscus to the nucleus of the lateral lemniscus and the inferior colliculus. This ascending pathway functions in sound localization. The descending pathway represents the olivocochlear bundle and provides efferent innervation to the cochlea hair cells (see Fig. 128-5). This descending pathway influences cochlea sensitivity or tuning through modulation of outer hair cell activity.[14,40] The integration of afferent and efferent activities makes the SOC potentially important in influencing signal-to-noise ratios and aspects of hearing in noise.

Lateral Lemniscus

The lateral lemniscus is the principal pathway by which medullary and pontine auditory nerve fibers reach the inferior colliculus. There are two subnuclei associated with this tract (i.e., ventral and dorsal) that receive differential innervation from the ipsilateral and contralateral cochlear nuclei and SOC subdivisions.[41] In some nonhuman mammals, a third subnucleus, the intermediate nucleus of the lateral lemniscus, has been identified. Most fibers from these nuclei innervate the central nucleus of the inferior colliculus, but minor tracts ascend to the superior colliculus and descend back to the SOC and trapezoid body. The dorsal lemniscal nuclei also send commissural fibers to each other from the contralateral lateral lemniscus. The lateral lemnisci are closely associated with the SOC and play a role in many of the same sound

localization and processing functions. The lateral lemniscus is also an important component of the acoustic startle reflex pathway, which includes the ventral cochlear nucleus.[42] These pathways through the lateral lemniscus correlate with aspects of the wave III to V interval of the auditory brainstem response.[43]

Inferior Colliculus

The inferior colliculus is a midbrain structure that receives extensive innervation from higher and lower brain regions. Almost all ascending and descending auditory pathways between the brainstem and forebrain synapse within the inferior colliculus.[44] Principal functions of the inferior colliculus involve sound localization, frequency determination, and integration of auditory with nonauditory systems.

The inferior colliculus is generally divided into three main neuronal groups: the central nucleus of the inferior colliculus, the cortex of the inferior colliculus, and the paracentral nuclei.[45] Each of these subdivisions is divided further into regions based on neuronal morphology and cellular organization. The central nucleus is the dominant region, and its structure is well conserved among species. There is a laminar organization, likely related to the tonotopic map, which subdivides the central nucleus into a pars lateralis, pars centralis, and pars medialis. Projections to the central nucleus of the inferior colliculus can be direct and monaural (from the contralateral cochlear nucleus), indirect and binaural (from the cochlear nuclei by way of the SOC), or polysynaptic (via the cochlear nuclei, SOC, and lateral lemniscus).

The cortex of the inferior colliculus is a laminar structure typically seen histologically to comprise four layers. This region forms a cap around the dorsal and caudal aspects of the inferior colliculus. Innervation to the cortex of the inferior colliculus is primarily from the forebrain and includes primary and secondary auditory cortex. These projections show tonotopic arrangement. There are few fibers to the inferior colliculus cortex from the lower brainstem, and typically only from cochlear nuclei. Surrounding nonauditory midbrain structures provide additional innervation to the cortex of the inferior colliculus. The paracentral nucleus of the inferior colliculus also receives nonauditory innervation, primarily from the somatosensory system.

The inferior colliculus also interacts with the proximate superior colliculus, which is associated with saccadic eye movements.[46] Ascending fibers from the subnuclei of the inferior colliculus all synapse in the medial geniculate body, where fibers are distributed to multiple auditory and nonauditory cortical structures. These tracts are likely the initial pathways for integrating auditory, somatosensory, and special sensory systems. These patterns of innervation argue for the multiintegrative function of the inferior colliculus.

Medial Geniculate Body

The medial geniculate body of the thalamus is the portal for all ascending auditory innervation to the telencephalon. Similar to other auditory centers, it is subdivided into several subnuclei—ventral, medial, and dorsal divisions.[47] Each of these divisions receives innervation from the nuclei of the inferior colliculus and descending fibers from the auditory cortex.

The ventral division of the medial geniculate body is secondarily organized into three distinct regions: the pars lateralis, pars ovoidea, and marginal zone. The pars lateralis is the dominant region and has a laminar appearance because of the orientation of its large bushy cells and intrinsic interneurons. These layers reflect an underlying tonotopic organization. The bushy cells project to layers III and IV of the auditory cortex, where the tonotopic map is recapitulated. Similar neuronal populations are found in the pars ovoidea and marginal zone, but with a less distinct laminar appearance.

The dorsal division of the medial geniculate body is a heterogeneous-appearing region comprising 10 subnuclei. The most basic description contains the dorsal, superficial dorsal, and deep dorsal nuclei, and the suprageniculate and posterior limitans nuclei. Inputs to the dorsal division include inferior colliculus and other thalamic nuclei. These auditory and nonauditory connections may play a role in attending to acoustic stimuli.

The medial division of the medial geniculate body contains some of the largest neurons in the geniculate body. Axons from these neurons project to all auditory cortical regions and many nonauditory centers. Innervation to the medial division has some auditory origin, but also nonauditory contributions from the vestibular nuclei and spinal cord. These varied interconnections may play a role in arousal to auditory stimuli.

Auditory Cortex

The principal human auditory cortex is located deep within the sylvian fissure on the superior surface of the temporal lobe. The auditory cortex consists of multiple defined tonotopically organized regions.[48] These include AI (primary), AII (secondary), the anterior auditory fields (AAF or A), the ventral auditory field (V), the ventral posterior auditory fields (VP), and the posterior auditory field (P). The primary auditory cortex is often referred to as AI (or Brodmann area 41), and the secondary cortex is referred to as AII (or Brodmann area 42). These regions lie within the transverse gyri of Heschl in continuity with the posterior aspect of the superior temporal gyrus (Fig. 128-7). These regions are structurally organized, similar to much of the cortex, into layers I through VI, each containing dominant populations of neurons and unique patterns of innervation and projection.

Numerous cortical association areas surround the primary auditory cortex. The posterior aspect of the superior temporal gyrus and the deeper planum temporale are known as Wernicke's area (left side), or area 22. Classically, this region has been viewed as a neural substrate for receptive language and is dominant on the left side in most humans. The enlarged left planum temporale has been thought to be a uniquely

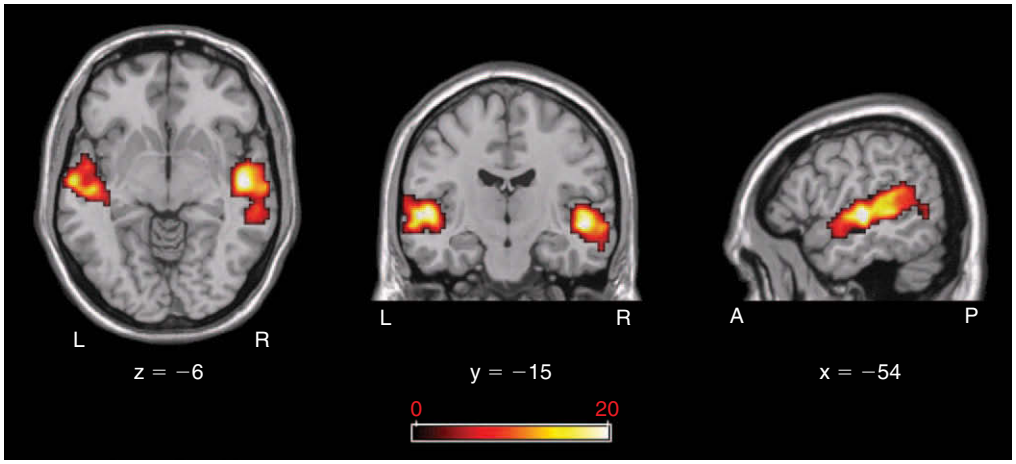

Figure 128-7. Functional MRI of the brain in a musician listening to music. The primary and secondary auditory cortex in both hemispheres shows strong activation. The brighter colors indicate more intense cortical activation. *(Copyright © 2008 C. Limb, MD. Published with permission.)*

human condition, but more recent evidence shows that the structural basis for this human trait is present in other apes.[49,50]

Just posterior to area 22, in the inferior parietal lobe, are the angular gyrus and supramarginal gyrus (areas 39 and 40). These cortical regions integrate auditory, somatosensory, and visual information. Higher orders of language integration, such as in reading and writing, may occur in these areas. Functional imaging studies also suggest that the angular gyrus may play a role in tinnitus perception.[51]

The arcuate fasciculus connects these association areas with the anteriorly located pars triangularis, which is part of the frontal operculum. This region of the inferior frontal gyrus is also known as Broca's area, or area 44 and 45. Similar to Wernicke's area, this region apparently is left hemisphere dominant and is important for expressive language, and the perception of musical syntax.[52]

Advances in functional imaging using functional magnetic resonance imaging (MRI), positron emission tomography, and magnetoencephalography have expanded the understanding of cortical processing of complex auditory information, such as music. Additional regions, such as the prefrontal cortex, cerebellum, and limbic system, may be important in music interpretation and production, including the processing of different musical features, such as dissonance.[53,54] There also seem to be segregated cortical pathways for the perception of musical elements such as melody and timber analogous to speech and the interpretation of verbal content versus the recognition of the speaker's voice.[55]

Reciprocal projections exist between the auditory cortex and lower auditory nuclei. Although not definitively identified in humans, three principal descending pathways to the thalamus, midbrain, and brainstem have been reported. The primary auditory cortex projects to other cortical regions and to the medial geniculate body.[56] Projections from cortex to SOC and inferior colliculus seem to contact neurons that feedback to higher centers.[57] Direct cortical projections to cochlear nucleus also have been reported in mammalian models.[58] These pathways may enable the cortex to modulate ascending auditory input.

Acknowledgments

The authors thank Dr. Charles Limb for providing a figure for, and review of, the auditory cortex section. The cochlear anatomy section was written by Dr. Christina Runge-Samuelson, and the central auditory pathway section was written by Dr. David R. Friedland.

CHAPTER ONE HUNDRED AND TWENTY-NINE

Physiology of the Auditory System

Wade Chien

Daniel J. Lee

Key Points

- The external ear funnels acoustic signals into the ear and plays an important role in sound localization, while the middle ear (including the tympanic membrane and the ossicular chain) matches the impedance between the air-filled external environment and the fluid-filled inner ear, or cochlea.
- A traveling wave is initiated on the basilar membrane as sound energy enters the cochlea.
- The basilar membrane maps frequency-specific information (tonotopic organization) and its displacement causes deflection of the stereocilia on hair cells, resulting in depolarization/hyperpolarization of the hair cells.
- Hair cells transduce mechanical energy (acoustic energy) to an electrochemical signal that is propagated as an action potential along the auditory nerve.
- Inner hair cells are innervated by type I auditory afferents and conduct sound information to the cochlear nucleus.
- Outer hair cells contract with depolarization and elongate with hyperpolarization to alter the mechanical properties of the basilar membrane.
- The auditory nerve carries information about which fibers are responding to sound, as well as the rate and timing pattern from each fiber.
- The cochlear nucleus is the first relay station for all ascending auditory information originating in the ear and receives inputs from the spiral ganglion cells through the auditory nerve.
- The auditory brainstem processes interaural timing and amplitude differences between ears to determine the location of the sound source.
- Binaural hearing improves auditory perception using three mechanisms: the head shadow effect, binaural squelch, and summation.
- The primary auditory cortex is located on Heschl's gyrus and is tonotopically organized. This region processes complex auditory signals to enable language comprehension.
- Descending pathways to the ear (auditory efferents) modulate the responses of the middle ear (acoustic reflex) and inner ear (medial olivocochlear reflex) to certain types of sounds.

A fundamental understanding of normal auditory physiology is the basis by which otolaryngologists can correlate structural changes with pathologic disturbances in the auditory system. Passive and active mechanisms in the auditory system work synergistically to provide sensitive hearing in humans. This chapter summarizes current knowledge of the exquisite mechanisms of sound and speech perception and processing by the peripheral and central auditory pathways.

Sound and Its Measurement

Sound is produced by a disturbance in particle density (whereby a particle is made up of many molecules of the sound-propagating medium) triggered by a sound-producing body, or sound source. If this disturbance in particle density travels through an elastic medium, such as air or fluid, sound propagation occurs. As a tuning fork (a sound source) is struck, it causes the air particles adjacent to it to vibrate. The vibration of these air particles causes other nearby air particles to vibrate, enabling sound propagation. The velocity of sound propagation in dry air is about 340 m/sec at room temperature, whereas in water, sound travels at around 1500 m/sec.

Simple harmonic motion provides the framework for understanding acoustic energy (Fig. 129-1). Simple harmonic motion is a periodic motion that undulates around a null point with equal amplitudes, similar to a sine function. The *frequency* of a simple harmonic motion is the number of cycles per second and is measured in *Hertz* (Hz). The *period* of a cycle is the inverse of its frequency ($1/f$), and represents the duration of a single cycle. The *amplitude* is the maximum amount of displacement from the null point in one direction. The sound produced by simple harmonic motion is called a *pure tone*. In the everyday environment, most sound sources do not produce sounds that follow simple harmonic motion. Any vibration that does not follow simple harmonic

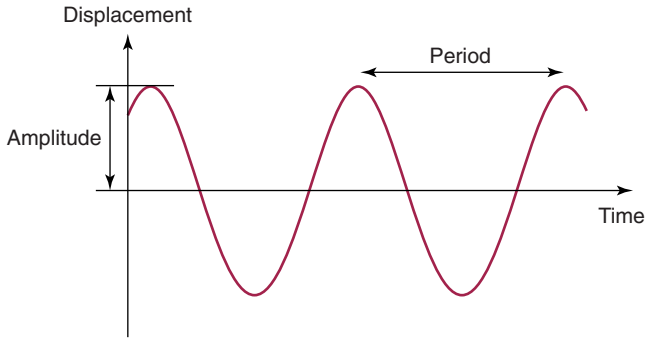

Figure 129-1. Simple harmonic motion. Simple harmonic motion is a periodic motion that undulates around a null point with equal amplitudes. The amplitude is the maximum amount of displacement from the null point in one direction. The frequency of a simple harmonic motion is the number of cycles per second, and is measured in Hertz (Hz). The period of a cycle is the inverse of its frequency ($1/f$), and represents the duration of a single cycle.

motion is said to be complex. If there is a repetitive periodic pattern to the complex vibration, it produces *tones*. If the complex vibration has no repetitive pattern, it results in *noise*.

One way to quantify sound is by its intensity, which is cumbersome to measure directly. Sound *pressure,* which is related to the square root of intensity, is relatively easy to measure, however, and is the most common way of quantifying sound. Sound pressure, which has units of *pascal* (Pa) (which is Newton per meter squared [N/m^2]), represents the amount of force that vibrating sound particles exert on a surface area.

Because the human ear is capable of perceiving a huge dynamic range of sound intensity (about 10^{12}-fold), a convenient way of expressing sound intensity is by taking the logarithmic ratio of two sound intensities (the numerator being the sound intensity of interest, and the denominator being a reference sound intensity) and multiplying by 10. This is called the *decibel scale*. The formula for determining decibels for sound intensity is: $dB = 10 \log_{10} J/Jr$, where J is the intensity of the sound of interest, and Jr is the intensity of reference.

Because pressure varies as the square root of intensity, it is necessary to square the pressures in the decibel formula when sound pressure is being used. The formula for determining decibels for sound pressure is $dB = 10 \log_{10} P^2/Pr^2 = 10 \log_{10} (P/Pr)^2 = 20 \log_{10} P/Pr$, where P is the sound pressure of interest, and Pr is the reference sound pressure. If the sound of interest has 10 times more pressure than the reference sound pressure, the sound of interest is 20 dB louder than the reference. If the sound of interest has 100 times more pressure, it is 40 dB louder than the reference. The most commonly used reference sound pressure is 20 µPa, which is referred to as *sound pressure level* (SPL). Another reference sound pressure that is occasionally used is *hearing level* (HL), which is the threshold sound pressure at a specific frequency (as measured in normal subjects); this threshold sound pressure varies across the frequency range.

Impedance

Impedance generally can be thought of as the impediment to movement. In the study of acoustics, impedance is defined as the ratio of the acoustic pressure over the volume velocity generated by the acoustic pressure. Imagine an acoustic stimulus striking an elastic membrane (e.g., the tympanic membrane); the greater the sound pressure of the acoustic stimulus, the larger the motion of the membrane, and the higher the velocities achieved by that motion. The exact relationship between the pressure of the acoustic stimulus and the membrane volume velocity is governed by acoustic impedance.

There are three components to acoustic impedance: stiffness, resistance (damping), and mass. If the membrane were stiffer than normal, the volume velocity generated by the acoustic stimulus would be decreased. Similarly, if the mass of the membrane were increased, one would also expect the volume velocity generated by the acoustic stimulus to decrease. In addition, a small amount of sound energy is lost because of the damping effect of the system. In a simple acoustic resonator, stiffness varies inversely with frequency and dominates the acoustic impedance at low frequencies, whereas the impedance of a mass increases with frequency and dominates at high frequencies. When the acoustic impedance is at its lowest point (i.e., at the frequency where the stiffness and mass components of the acoustic impedance cancel each other out), it is said that the system is in resonance.

External Ear

The external ear is composed of the pinna and the external auditory canal. The external ear funnels sound from the external environment into the ear. The peculiar shape of the pinna and the external auditory canal gives rise to specific resonant frequencies as these structures are struck by sound: the concha has a resonant frequency of around 5300 Hz, and the external auditory canal has a resonant frequency of around 3000 Hz. The external ear plays an important role in sound localization.

Sound localization is achieved by two major mechanisms: interaural time difference and interaural amplitude difference. Because the left and the right ears are located on opposite sides of the head, the amount of time it takes for a sound stimulus to arrive at each individual ear is governed by the distance of the sound source to that particular ear: the farther the distance, the longer it takes for the sound stimulus to arrive. The differences in the time arrival of the sound stimulus between the two ears can be used as a cue for sound localization. The differences in amplitude perceived by the two ears can also be used as a cue for sound localization.[1,2] This difference in amplitude is increased further by the "head shadow" effect: sound coming from one side is attenuated by the head as it travels to the contralateral ear. The head shadow effect in binaural hearing helps to improve the signal-to-noise ratio in adverse listening environments; one ear can be closer to the source of sound or speech, whereas the contralateral ear is exposed to the background noise. It has been shown that the interaural time difference is important for low-frequency sound localization, whereas the interaural amplitude difference is important for higher frequency sound localization.[3]

Middle Ear Mechanics

The middle ear is composed of the tympanic membrane, the ossicles (malleus, incus, and stapes), and the stapedius and tensor tympani muscles. As a sound stimulus enters the external auditory canal, it causes the tympanic membrane to vibrate. The malleus, which is coupled to the tympanic membrane, vibrates in response to the motion of the tympanic membrane. This causes the entire ossicular chain to vibrate, resulting in sound transmission to the inner ear via the stapes footplate. This pathway of sound transmission is referred to as *ossicular coupling*.[4] The ossicular chain has two synovial joints that are mobile: the incudomalleal and the incudostapedial joints.[5] The ossicular chain vibrates along an axis that projects through the head of the malleus and the body of the incus in an anterior-to-posterior direction (Fig. 129-2). The stapes, the smallest bone in the body, transmits the output of the middle ear into the inner ear through the oval window.

Because the inner ear is fluid-filled, if the sound stimulus strikes the inner ear fluid directly, most of the acoustic energy is deflected, as the impedance of fluid is much greater than the impedance of air. The pathway of sound transmission to the inner ear in the absence of the ossicular system is referred to as *acoustic coupling*.[4] It has been shown that the difference between ossicular coupling and acoustic coupling is about 60 dB, which is the maximal amount of hearing loss expected in patients with ossicular discontinuity.[6] The middle ear plays an important role in the process of "impedance matching" between the air-filled middle ear and the fluid-filled inner ear, allowing for efficient sound transmission. The most important factor in the middle ear's impedance matching capability comes from the "area ratio" between the tympanic membrane and the stapes footplate (see Fig. 129-2). The human tympanic membrane has a surface area approximately 20 times larger than

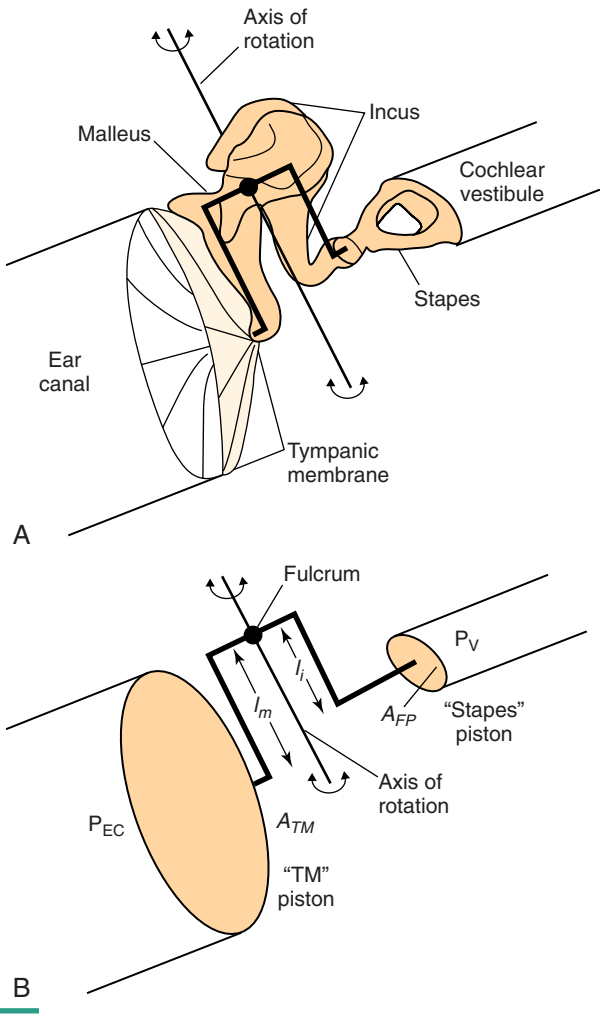

Figure 129-2. Schematic of the middle ear system. **A,** Motion of the ossicular chain along its axis of rotation. **B,** Concept of area ratio (ATM/AFP) and lever ratio (*lm*/*li*). AFP, area of the footplate; ATM, area of the tympanic membrane; *li,* length of the incus long process; *lm,* length of the manubrium; PEC, external canal sound pressure; Pv, sound pressure of the vestibule. *(From Merchant SN, Rosowski JJ. Auditory physiology. In: Glasscock ME, Gulya AJ, eds.* Glasscock-Shambaugh Surgery of the Ear. *5th ed. Ontario: Decker; 2003:64.)*

the stapes footplate (69 vs. 3.4 mm^2).[7] If all the force applied to the tympanic membrane were to be transferred to the stapes footplate, the force per unit area would be 20 times larger (26 dB) on the footplate than on the tympanic membrane.

A second mechanism for impedance matching is called the *lever ratio,* which refers to the difference in length of the manubrium of the malleus and the long process of the incus. Because the manubrium is slightly longer than the long process of the incus, a small force applied to the long arm of the lever (manubrium) results in a larger force on the short arm of the lever (incus long process). In humans, the lever ratio is about 1.31 : 1 (2.3 dB).[8] The combined effects of the area ratio and the lever ratio give the middle ear output a 28-dB gain theoretically. In reality, the middle ear sound pressure gain is only about 20 dB[9]; this is mostly due to the fact that the tympanic membrane does not move as a rigid diaphragm. At higher frequencies, it vibrates in a complex manner, with multiple areas that vibrate differently.[10] The effective area of the tympanic membrane involved with impedance matching is smaller than its total area. Nevertheless, the 20-dB middle ear sound pressure gain assists sound transmission from the air-filled middle ear into the fluid-filled inner ear.

Inner Ear Physiology

The inner ear is enclosed in a bony cavity called the *otic capsule*. It has two mobile windows: the oval and the round windows. The two important functions of the inner ear are hearing and balance. The portion of the inner ear that deals with hearing is the cochlea, and the portion of the inner ear that deals with balance is collectively known as the vestibular organs (semicircular canals, utricle, and saccule). The cochlea is shaped like a snail, and has a spiral configuration with two and a half turns (Fig. 129-3A). The center portion of the spiral is called the *modiolus*. The portion of the cochlea that is closest to the oval window is referred to as the base, whereas the portion of the cochlea that is farthest away from the oval window is referred to as the apex. The cochlea is a fluid-filled space with three compartments: scala tympani, scala media, and scala vestibuli (Fig. 129-3B). The scala tympani and the scala media are separated by the basilar membrane, and the scala media and the scala vestibuli are separated by Reissner's membrane. The scala tympani and the scala vestibuli join together at the apex of the cochlea to form the helicotrema.

The scala media contains the organ of Corti, which rests on the basilar membrane. Taken together, organ of Corti and the basilar membrane are also referred to as the cochlear partition. The organ of Corti has an arch at its center, called the arch of Corti, which is formed by the inner and the outer pillar cells. The inner hair cells are flask-shaped cells that rest on the side of the inner pillar cells, whereas the outer hair cells are cylindrical-shaped cells that rest on the side of the outer pillar cells. The human cochlea contains about 3000 inner hair cells that extend in a single row from the base to the apex; there are about 12,000 outer hair cells arranged in three or four rows. The hair cells derive their names from having hairlike projections on their apical surface. These hairlike projections are stereocilia, which play an important role in the signal transduction properties of the hair cells.

The scala vestibuli and the scala tympani are filled with perilymph, which has a similar composition to the extracellular fluid (high in sodium, low in potassium) (Fig. 129-4A). The scala media is filled with endolymph, which has a similar composition to the intracellular fluid (low in sodium, high in potassium).[11] The unique electrolyte composition of the scala media sets up a large electrochemical gradient, called the *endocochlear potential,* which is +60 to +100 mV relative to the perilymph (Fig. 129-5).[12] The maintenance of such a large electrochemical gradient is performed by the *stria vascularis,* which resides on the outer wall (away from the modiolus) of the scala media. The stria vascularis contains multiple active ion channels, and maintains the chemical composition of the endolymph and its positive electrical potential.[13]

As sound energy travels through the external and middle ears, it causes the stapes footplate to vibrate. The vibration of the stapes footplate results in a compressional wave in the inner ear fluid, which travels across the scala vestibuli, around the helicotrema, and out across the scala tympani toward the round window. An inward motion of the stapes causes an outward motion of the round window. As this compression wave travels across the scala vestibuli, however, the pressure in the scala vestibuli is higher than the pressure in the scala tympani. This sets up a pressure gradient, which causes the cochlear partition to vibrate.

von Bekesy[12] first described the vibration of the cochlear partition in cadaveric human cochleas. He showed that as the cochlear partition is deflected by the compressional wave created by the stapes footplate vibration, it sets up a traveling wave on the basilar membrane, which travels from the base of the cochlea to its apex (Fig. 129-6). von Bekesy[12] also found that the basilar membrane varied in its stiffness along its length, with higher stiffness near the base and lower stiffness near the apex. This property of the basilar membrane allows it to respond to various frequencies differently (i.e., the amplitude of the traveling wave peaks [resonates] at a specific place along the basilar membrane), with the higher frequencies at the base and the lower frequencies toward the apex. The basilar membrane is able to act as a series of filters, responding to specific sound frequencies at specific locations along its length. In other words, the basilar membrane is *tonotopically tuned* to different frequencies along its length. von Bekesy's

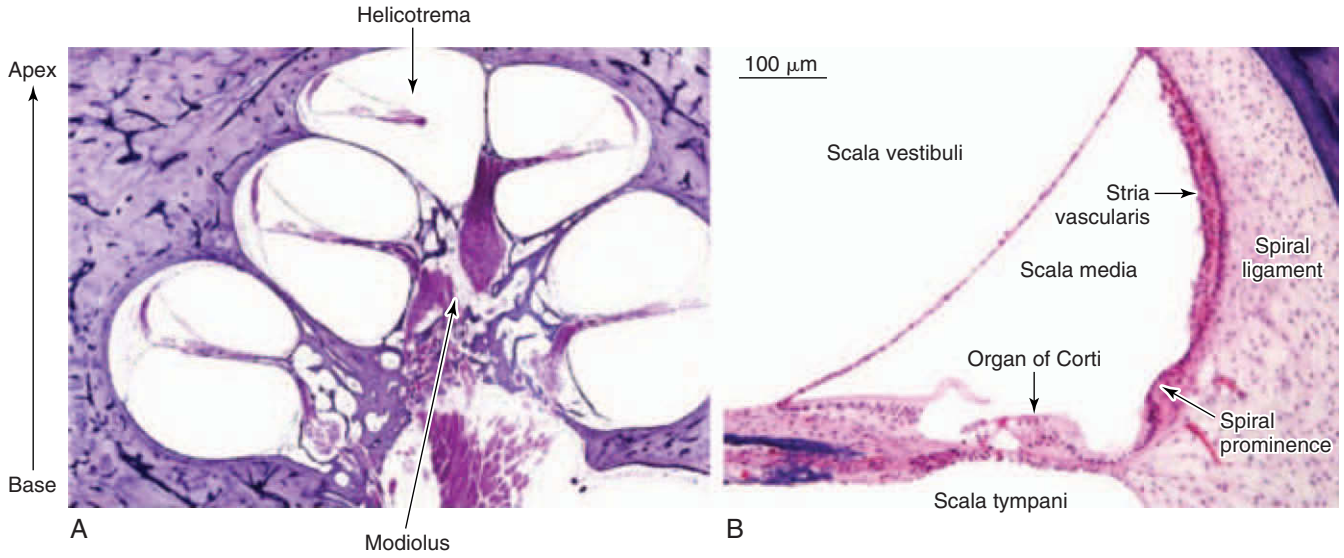

Figure 129-3. **A,** Histologic section showing normal human cochlea. The cochlea is shaped like a snail, and has a spiral configuration with two and a half turns. The center portion of the spiral is called the modiolus. The portion of the cochlea that is closest to the oval window is referred to as the base, and the portion of the cochlea that is farthest away from the oval window is referred to as the apex. (H&E stain.) **B,** Higher magnification of the histologic section in **A** showing the organ of Corti. The cochlea is a fluid-filled space with three compartments: scala tympani, scala media, and scala vestibuli. The scala tympani and the scala media are separated by the basilar membrane, whereas the scala media and the scala vestibuli are separated by Reissner's membrane. The scala tympani and the scala vestibuli join together at the apex of the cochlea to form the helicotrema. The scala media contains the organ of Corti, which rests on the basilar membrane. The organ of Corti and the basilar membrane together are sometimes referred to as the cochlear partition. The stria vascularis plays an important role in maintaining the electrochemical environment of the cochlea. (H&E stain.) *(Modified from www.temporalboneconsortium.org.)*

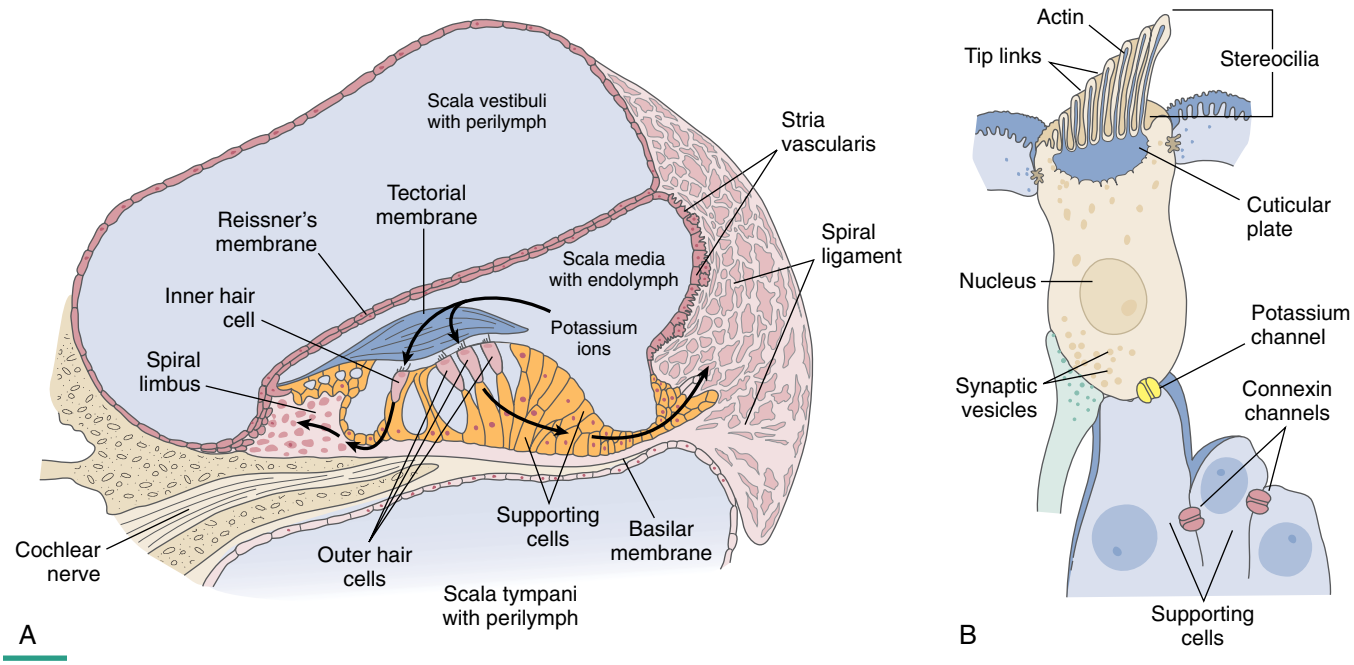

Figure 129-4. Mechanoelectrical transduction of the auditory signal depends on the recycling of potassium ions in the organ of Corti. **A,** Schematic cross-sectional view of the human cochlea. The scala media (cochlear duct) is filled with endolymph, and the scala vestibuli and tympani are filled with perilymph. The endolymph of the scala media bathes the organ of Corti, located between the basilar and tectorial membranes and containing the inner and outer hair cells. A high concentration of potassium in the endolymph of the scala media relative to the hair cell creates a cation gradient that is maintained by the activity of the epithelial supporting cells, spiral ligament, and stria vascularis. **B,** Hair cells contain stereocilia along the apical surface and are connected by tip links. The potassium gradient shown in **A** is essential to enable depolarization of the hair cell in **B** after influx of potassium ions in response to mechanical vibration of the basilar membrane, deflection of stereocilia, displacement of tip links, and opening of gated potassium channels. Depolarization results in calcium influx through channels along the basolateral membrane of the hair cell, causing degranulation of neurotransmitter vesicles into the synaptic terminal and propagation of an action potential along the auditory nerve, shown in *blue*. Gap junction proteins between the hair cells (potassium channel, *yellow*) and epithelial supporting cells (connexin channels, *red*) allow for the flow of potassium ions back to the stria vascularis where they are pumped back into the endolymph. *(From Willems PJ. Genetic causes of hearing loss.* N Engl J Med. *2000;342:1101-1109. Copyright © 2000 Massachusetts Medical Society. All rights reserved.)*

seminal work on cochlear mechanics earned him the Nobel Prize in Physiology or Medicine in 1961.

Although the cochlea is usually thought of as having two mobile windows (the oval and round windows), the possibility of a third mobile window has been proposed.[14] More recently, a select group of patients with an air-bone gap on audiologic testing (which is typically associated with middle ear pathology) who do not have any middle ear pathology on intraoperative exploration has been described.[15-17] It has been shown that the air-bone gap in this group of patients can be explained by a pathologic "third window" in the inner ear.[18] Perhaps the most well-studied example of this phenomenon is seen in superior semicircular canal dehiscence (Fig. 129-7; video clip available on website).

Patients with superior semicircular canal dehiscence often complain of autophony, aural fullness, sound-induced or pressure-induced vertigo, and hearing loss.[19-22] It is thought that the dehiscence in the superior semicircular canal acts as a third mobile window of the inner ear (in addition to the oval and round windows), shunting acoustic energy away from the cochlea, resulting in a decreased sensitivity to air-conducted sound and an air-bone gap seen on audiologic testing.[20,23-25] This third window is also theorized to decrease cochlear input impedance at the oval window, increasing the pressure gradient across the cochlear partition, and resulting in hypersensitivity to bone-conducted sound.[23] Repair, or plugging, of superior semicircular canal dehiscence in some cases results in improvement of the preoperative air-bone gap (see Fig. 129-7). The third window hypothesis has also been used to explain the air-bone gap associated with other temporal bone anomalies, such as large vestibular aqueduct syndrome and other inner ear malformations.[26-28]

As the cochlear partition is deflected in response to the compressional wave initiated by the stapes, it causes a shearing force between the stereocilia of the hair cells and the tectorial membrane. This shearing force causes a deflection of the hair cell stereocilia. The hair cell stereocilia are arranged in rows, and the rows are arranged in an orderly fashion by height (see Fig. 129-4B). The tip of each stereocilia is connected from one row to another by an elastic filament called the *tip link*.[29] It is thought that as the stereocilia is deflected toward the direction of the tallest row, it causes the tip links to stretch. The stretch of the tip links causes the opening of stretch-sensitive cationic channels located on the stereocilia (Fig. 129-8).

Because there is a large electrochemical gradient across the apical surface of the hair cells (with a large positive endocochlear potential on one side, and a large negative intracellular potential on the other side), the opening of these stretch-sensitive cationic channels on the stereocilia causes a large influx of cationic current, which leads to hair cell depolarization. As the stereocilia is deflected away from the tallest row, the tip links relax, decreasing the probability of ion channel opening; this leads to hyperpolarization of the hair cell.[30-32] The relationship between the degree of stereocilia deflection and hair cell depolarization or hyperpolarization is not symmetric or linear. Stereocilia deflection in the depolarization direction produces a greater response than deflection in the hyperpolarization direction (Fig. 129-9).[30] The deflection of the hair cell stereocilia and the resulting hair cell depolarization or hyperpolarization represents an important step in the signal transduction process of the hair cell (i.e., by converting a mechanical signal [inner ear fluid wave] into an electrochemical signal).

Because potassium is the major cation in the endolymph, it is believed that potassium current plays an important role in triggering the signal transduction process in hair cells. When inner hair cells are depolarized, voltage-gated calcium channels open.[33] These voltage-gated calcium channels are clustered in several "hot spots" along the basolateral surface of the inner hair cells, where synaptic contacts with primary afferent auditory nerve fibers are located.[34] The calcium current mediated by these voltage-gated ion channels are important for triggering neurotransmitter release across the synapse, which leads to activation of the auditory nerve fibers. The neurotransmitter involved in this process has not been definitively identified, but is believed to be a molecule closely related to glutamate.[35]

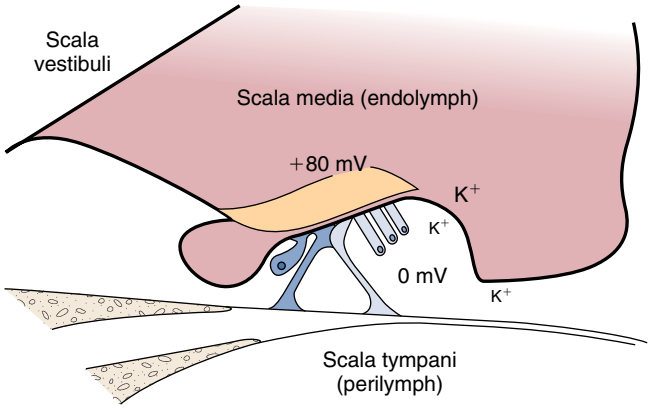

Figure 129-5. Schematic showing the electrochemical environment of the cochlea. The scala vestibuli and the scala tympani are filled with perilymph, which has a low potassium concentration. The scala media is filled with endolymph, which has a high potassium concentration. The unique electrolyte composition of the scala media sets up a large electrochemical gradient, called the endocochlear potential, which is about +80 mV relative to perilymph. The maintenance of such a large electrochemical gradient is performed by the stria vascularis. *(From Geisler CD.* From Sound to Synapse: Physiology of the Mammalian Ear. *New York: Oxford University Press; 1998:85.)*

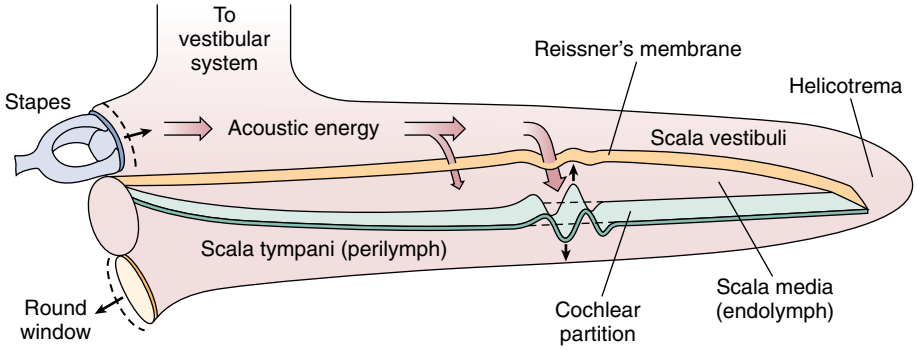

Figure 129-6. Schematic showing sound propagation in the cochlea. As sound energy travels through the external and middle ears, it causes the stapes footplate to vibrate. The vibration of the stapes footplate results in a compressional wave on the inner ear fluid. Because the pressure in the scala vestibuli is higher than the pressure in the scala tympani, this sets up a pressure gradient that causes the cochlear partition to vibrate as a traveling wave. Because the basilar membrane varies in its stiffness and mass along its length, it is able to act as a series of filters, responding to specific sound frequencies at specific locations along its length. *(From Geisler CD.* From Sound to Synapse: Physiology of the Mammalian Ear. *New York: Oxford University Press; 1998:51.)*

Superior semicircular canal dehiscence presenting as postpartum vertigo.* Otol Neurotol. *2006;27:756-768.)*

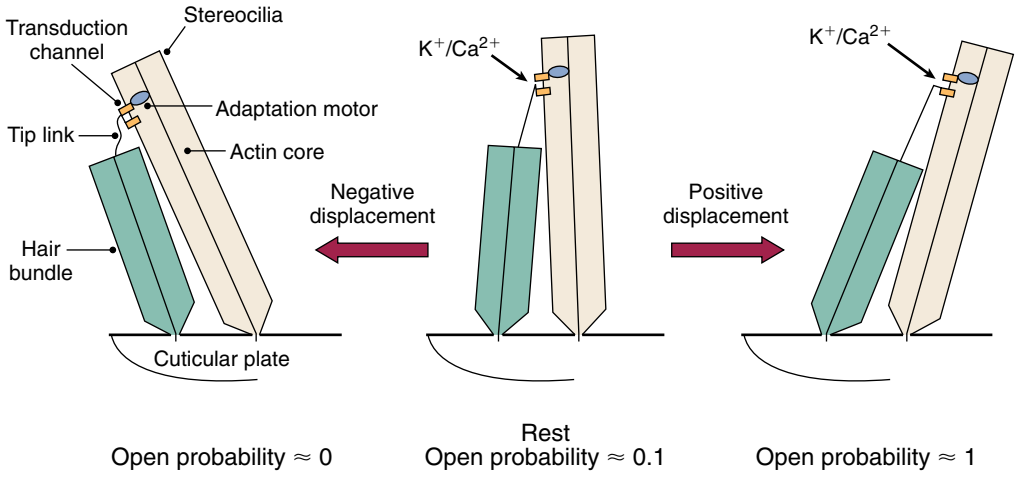

Figure 129-8. Schematic showing the role of tip links in hair cell signal transduction. It is thought that as the stereocilia is deflected toward the direction of the tallest row, it causes the tip links to stretch. The stretch of the tip links causes the opening of stretch-sensitive cationic channels located on the stereocilia. The opening of these stretch-sensitive cationic channels on the stereocilia causes a large influx of cationic current, which leads to hair cell depolarization. As the stereocilia is deflected away from the tallest row, it causes a relaxation of the tip links, which decreases the probability of ion channel opening. This leads to hyperpolarization of the hair cell. *(From Gillespie PG. Molecular machinery of auditory and vestibular transduction.* Curr Opin Neurobiol. *1995;5:449-455.)*

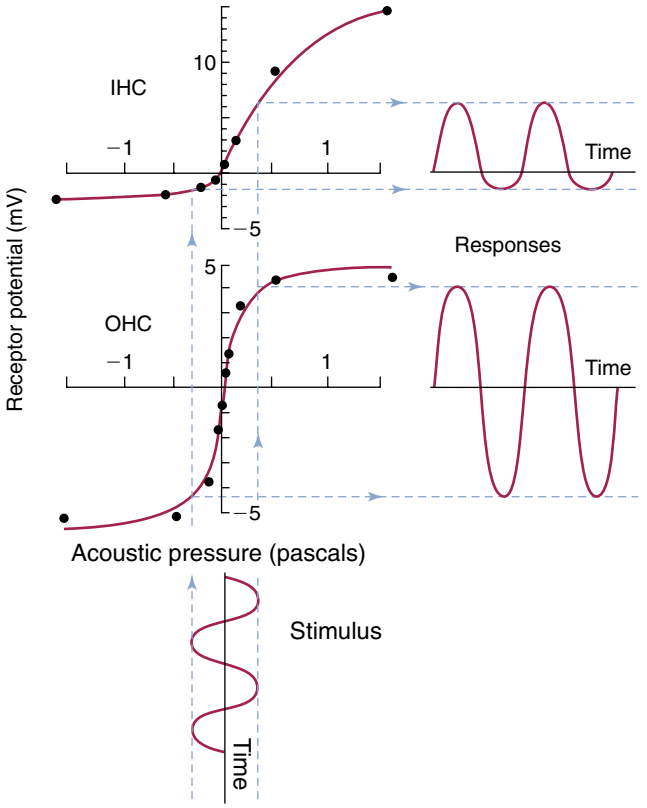

Figure 129-9. Generation of receptor potentials in inner hair cells (IHC, *upper panel*) and outer hair cells (OHC, *lower panel*) in response to a sound stimulus of 84 dB sound pressure level (SPL). The sound stimulus changes the receptor potential according to each hair cell's input-output curve *(left)*. The input-output curves for both types of hair cells are nonlinear. *(From Russell IJ, Cody AR, Richardson GP. The responses of inner and outer hair cells in the basal turn of the guinea-pig cochlea and in the mouse cochlea grown in vitro.* Hear Res. *1986;22:199-216.)*

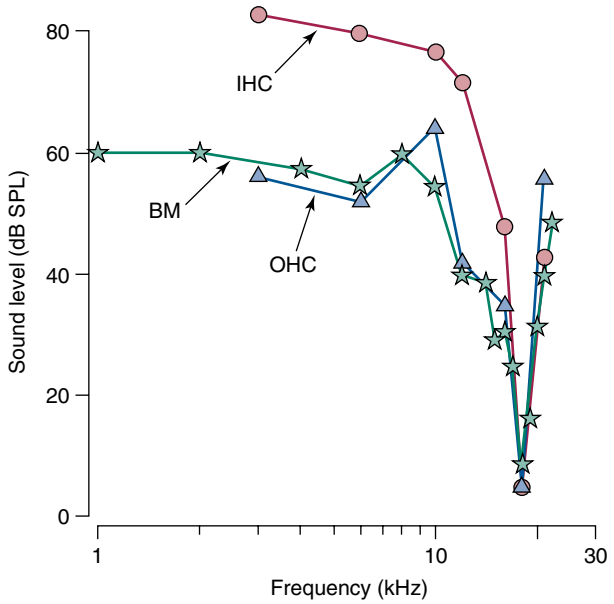

Figure 129-10. Tuning curves of the basilar membrane (BM) and the inner and outer hair cells (IHC and OHC) at a basal location in the guinea pig cochlea. The tuning curve plots the sound level required to produce a fixed level of response at a given location along the cochlear partition. The required sound level is lowest when the sound stimulus is at its characteristic frequency. The tuning curves for the basilar membrane and the inner and outer hair cells at the same location of the cochlear partition are very similar, indicating that the tonotopic arrangement of the basilar membrane is preserved in inner and outer hair cells. SPL, sound pressure level. *(From Russell IJ, Kossl M, Murugasu E. A comparison between tone-evoked voltage responses of hair cells and basilar membrane displacements recorded in the basal turn of the guinea pig cochlea. In: Manley GA, Klump GM, Koppl C, et al, eds.* Advances in Hearing Research. *Singapore: World Scientific; 1995:136-144.)*

In contrast to the inner hair cell, an outer hair cell can also change its length in response to voltage changes; it contracts with depolarization and elongates with hyperpolarization.[36] The molecular motor that is associated with rapid changes in outer hair cell length is a voltage-dependent, integral membrane protein called prestin.[37] The change in outer hair cell length in response to voltage changes is believed to add energy into the basilar membrane motion through a mechanical feedback scheme. In other words, the outer hair cell acts as a cochlear amplifier, augmenting the signals transmitted into the inner ear by the stapes vibration.[38] The importance of prestin in hearing is supported further by the finding that in animal studies in which prestin has been knocked out or altered, the hearing sensitivity and frequency selectivity are impaired.[39,40]

Because different regions of the basilar membrane are tonotopically tuned to specific frequencies, and because the hair cells reside on top of the basilar membrane, it is logical to assume that the hair cells from different regions are also tonotopically tuned to specific frequencies. The frequency tuning curves for outer and inner hair cells have been recorded in guinea pigs in response to various frequencies, and the hair cells in different regions along the basilar membrane are tonotopically tuned to specific frequencies that correspond to the tonotopic arrangement of the basilar membrane (Fig. 129-10).[41] The frequency to which a hair cell is most sensitive is called the *characteristic frequency*. As discussed subsequently, this tonotopic arrangement is essential for the processing of auditory information, and is preserved throughout the entire auditory pathway.

Auditory Nerve

When the mechanical vibration of the cochlear partition is transduced into electrochemical signals by the hair cells, the information carried by these signals is propagated by the afferent auditory nerve fibers into the brain for processing across neuronal stations and pathways. The afferent auditory neurons are bipolar in nature, sending peripheral processes to make contact with hair cells, while sending central projections to the auditory brainstem. Their cell bodies, also known as the spiral ganglion cells, are located in Rosenthal's canal. Humans have approximately 30,000 spiral ganglion cells.[42]

There are two types of spiral ganglion cells. Type I spiral ganglion cells are myelinated, and account for approximately 90% of all spiral ganglion cells. Each one of these type I cells sends a single peripheral process to form a single synapse with a single inner hair cell.[43,44] Type II spiral ganglion cells are unmyelinated, and account for approximately 10% of all spiral ganglion cells. Each one of these type II cells sends a peripheral process to form synapses with multiple outer hair cells. Each inner hair cell forms synapses with multiple type I spiral ganglion cells; each type II spiral ganglion cell forms synapses with multiple outer hair cells.

Through electrophysiologic recordings made in the guinea pig and in the cat, it has been shown that type I spiral ganglion cells can discharge spontaneously.[45,46] The spontaneous activity of these type I cells is believed to be mediated by neurotransmitter release from inner hair cells, and stops if there is a reduction in perilymphatic calcium levels (crucial for neurotransmitter release).[47] When the spontaneous discharge rates of different type I spiral ganglion cells were examined, it was discovered that type I cells have different spontaneous discharge rates (Fig. 129-11). The spontaneous discharge rate can be used to group the type I spiral ganglion cells into three categories: cells with high spontaneous activity (>18 spikes/sec), cells with medium spontaneous activity (0.5 to 18 spikes/sec), and cells with low spontaneous activity (<0.5 spikes/sec).[48]

The difference in spontaneous discharge rate of type I spiral ganglion cells is probably correlated with the diameter of the terminal axon,

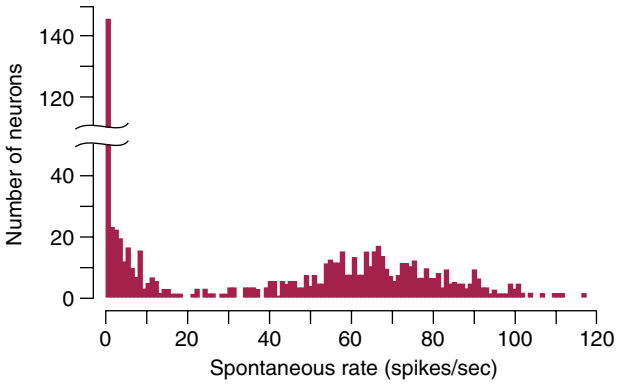

Figure 129-11. Histogram showing the distribution of spontaneous firing rates recorded from many type I afferent neurons in cats. The spontaneous discharge rate can be used to group the type I spiral ganglion cells into three categories: high spontaneous (>18 spikes/sec), medium spontaneous (0.5 to 18 spikes/sec), and low spontaneous (<0.5 spikes/sec). *(From Liberman MC. Auditory-nerve response from cats raised in a low-noise chamber.* J Acoust Soc Am. *1978;63:442-455.)*

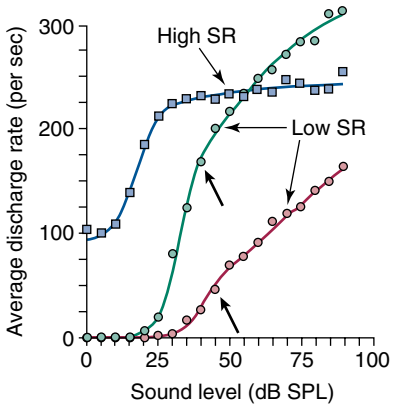

Figure 129-12. Response of three primary auditory neurons to tones of characteristic frequency with varying sound levels in the guinea pig. The single neuron with high spontaneous rate (SR) shows a low threshold and small dynamic range. In contrast, the two low-spontaneous neurons exhibit higher thresholds and larger dynamic ranges. SPL, sound pressure level. *(From Muller M, Robertson D. Shapes of rate-versus-level functions of primary auditory nerve fibres: test of the basilar membrane mechanical hypothesis.* Hear Res. *1991;57:71-78.)*

with high spontaneous neurons having a larger diameter, and low spontaneous neurons having a smaller diameter.[49] As the sound pressure increases over a certain level, the afferent neurons begin to discharge at a higher rate than the spontaneous rate. This sound pressure level is called the threshold. There is generally a monotonic relationship between the discharge rate of the afferent neurons and sound pressure, with neurons discharging at a higher rate as the sound pressure increases.[50] This relationship is a nonlinear one, however, because as the sound pressure increases over a certain level, the discharge rate of the afferent neurons begins to saturate. The difference between the sound pressures at threshold and at saturation is called the dynamic range of the afferent neuron.

It has been shown that the threshold and saturation, and the dynamic range of afferent neurons of various spontaneous rates are different, with the high-spontaneous neurons having lower threshold and saturation sound pressure levels than lower spontaneous neurons (Fig. 129-12). The low-spontaneous neurons also have a larger dynamic range.[51,52] These findings lead to the conclusion that the high-spontaneous neurons are important for detecting low-level sounds (because of their low threshold), whereas low-spontaneous neurons are important for signaling amplitudes at high level sounds (because of their large dynamic range).

The afferent auditory neurons are also tonotopically tuned, similar to the basilar membrane and the hair cells. The tuning curves of the basilar membrane, hair cell, and afferent neuron share many similar attributes. At a given location along the cochlear partition, the basilar membrane, the hair cells, and the afferent neurons all have the same characteristic frequency. As a sound stimulus enters the cochlea, its frequency components are analyzed by the basilar membrane as a series of filters. This frequency information is preserved through the hair cells and the auditory afferent neurons, and is transmitted to the central nervous system.

The threshold sound pressure for auditory neurons can be −10 dB SPL, which is equivalent to 7 μPa.[53] This sound pressure is so low that it produces ossicular chain vibration on the order of $^{1}/_{1000}$ the diameter of a hydrogen atom (approximately 10^{-13} m). The fact that such low sound pressure can be readily detected speaks to the incredible efficiency of the mammalian auditory system.

Auditory Brainstem and Midbrain

Cochlear Nucleus

The auditory nerve travels along the course of the internal auditory canal to terminate on the second-order neurons of the auditory system located in the cochlear nucleus. The cochlear nucleus is the critical first relay station for all ascending auditory information originating in the ear, and is located in the pontomedullary junction of the dorsolateral brainstem in humans (Fig. 129-13). The cochlear nucleus contains many cell types, each having unique somatic and dendritic characteristics.[54,55] These cell types display varying response properties to auditory stimulation[56-60] and project to different targets.[61-63]

The distribution of cell types subdivides the cochlear nucleus into its major subdivisions: the dorsal cochlear nucleus, the anterior ventral cochlear nucleus, and the posterior ventral cochlear nucleus. Each subdivision has a restricted population of cell types. The second-order neurons of the cochlear nucleus are tonotopically organized. The spatial representation of frequency-specific information in the cochlea is preserved in the cochlear nucleus.[64] Isofrequency lamina (sheets of neurons that have the same characteristic frequency) are distributed from dorsal to ventral across each major cochlear nucleus subdivision, and are seen in higher auditory nuclei.[65]

Inputs from auditory nerve drive multiple cell types in different subdivisions of the cochlear nucleus, with each cell type projecting centrally to different targets in the superior olivary complex, lateral lemniscus nuclei, and inferior colliculus. Because individuals with normal hearing use both ears, sound localization is accomplished by neural processing of intensity and timing cues from each ear in the auditory brainstem. The temporal and spectral features of sound originating in the ear are processed in the cochlear nucleus, and the cochlear nucleus is the origin of parallel pathways. These pathways that project to the auditory brainstem, midbrain, and cortex integrate information from the ear to determine (1) the identity of the sound source, (2) the intensity of the sound source, and (3) the location of the sound source.

The ventral cochlear nucleus contains many different cell types: (1) spherical bushy cells found primarily in the anteroventral cochlear nucleus (rostral), (2) globular bushy and multipolar cells found centrally, and (3) octopus cells found posteriorly (caudal). Spherical and globular bushy cells receive large auditory terminals with multiple synaptic specializations (end-bulbs of Held). This extensive contact allows the second-order neurons (bushy cells) to have primary-like responses to action potentials from the auditory nerve, preserving temporal and spectral information that is sent to higher auditory brainstem nuclei, the thalamus and, ultimately, the auditory cortex. End-bulbs of Held are vulnerable to sensory deprivation. Congenital deafness is associated with unambiguous changes to these large synaptic terminals. Specifically, the postsynaptic density is larger and dysmorphic in deaf animals compared with normal-hearing controls,[66,67] and these changes may be reversible with electrical stimulation using a cochlear implant.[68]

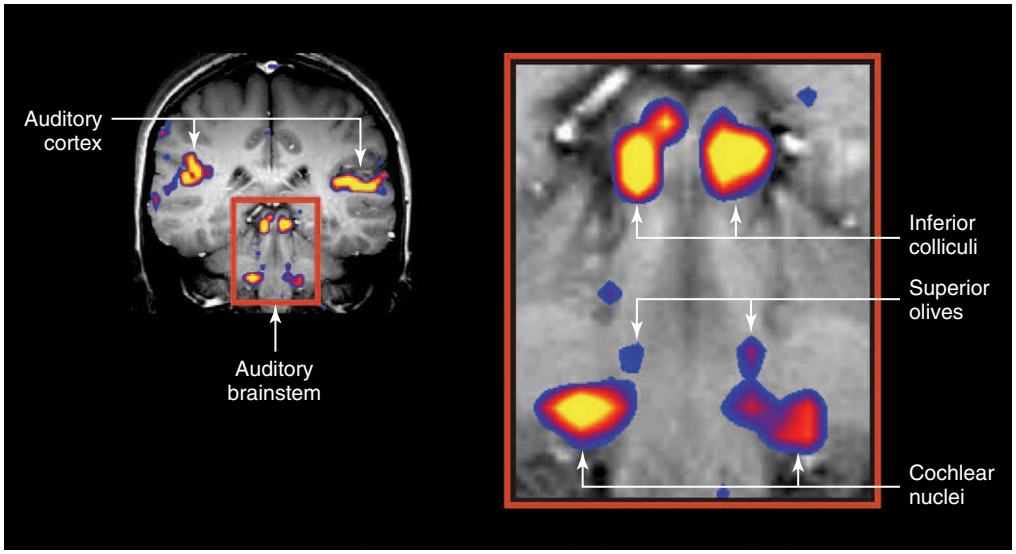

Figure 129-13. Functional magnetic resonance imaging showing the ascending pathways of auditory processing from the auditory brainstem to the auditory cortex. This figure shows activation of the cochlear nuclei (seen as areas of activation in the pontomedullary junction of the dorsolateral brainstem bilaterally), superior olives, inferior colliculi, and auditory cortex during bilateral acoustic stimulation in a normal-hearing adult patient. *(Image courtesy of Jennifer Melcher, PhD, and adapted from Hawley ML, Melcher JR, Fullerton BC. Effects of sound bandwidth on fMRI activation in human auditory brainstem nuclei.* Hear Res. *2005;204:101-110.)*

From the cochlear nucleus, three fiber tracts project auditory information to the contralateral inferior colliculus: the dorsal stria (also called the stria of Monaco), the intermediate stria (also called the stria of Held), and the ventral stria (also known as the trapezoid body). These fiber tracts collectively form the lateral lemniscus. Some fibers from the cochlear nuclei do not cross the midline and project to the ipsilateral inferior colliculus. There are also connections between the cochlear nuclei on both sides, which represent the most peripheral connections between the auditory pathways bilaterally.[69] The function of these connections is not well understood, however.

Superior Olivary Complex

The superior olivary complex is located medial to the cochlear nucleus in the caudal portion of the pons. It contains three main nuclei: the medial superior olive, the lateral superior olive, and the nucleus of the trapezoid body. The superior olivary complex serves as a relay station for auditory information from both ears, and some of the fiber tracts from the cochlear nucleus give off collaterals to the superior olive before forming the lateral lemniscus. Auditory information from both cochlear nuclei is integrated in the superior olivary complex; this region plays an important role in sound localization by analyzing interaural time and amplitude differences. Specifically, the medial superior olive receives inputs from the bushy cells of both cochlear nuclei, and is exquisitely sensitive to interaural time differences. In contrast, the lateral superior olive responds to interaural amplitude differences and receives excitatory inputs from the bushy cells of the ipsilateral cochlear nucleus and inhibitory inputs from the contralateral cochlear nucleus.[70]

The processing of auditory information from both ears by the brainstem nuclei not only allows for sound localization, but it also helps to enhance auditory perception by two additional mechanisms: binaural squelch and summation. *Binaural squelch* refers to the ability of the brainstem auditory nuclei to increase the signal-to-noise ratio of the incoming sound stimulus through information processing.[71] *Summation* refers to the fact that a sound signal received by both ears is greater in amplitude (by 3 dB) than the same signal received by a single ear.[72] This increase in perceptual loudness is thought to improve speech intelligibility in a noisy environment. Binaural squelch, summation, and the head shadow effect (see earlier section on external ear) are three mechanisms in binaural hearing that enhance auditory perception.[73] The superior olivary complex also plays an important role in the efferent pathways of the auditory system, which is discussed later in this chapter.

Lateral Lemniscus

The lateral lemniscus is formed by the three fiber tracts from the cochlear nucleus. It is one of the most prominent fiber tracts in the auditory pathway. On its way to the contralateral inferior colliculus, the lateral lemniscus sends multiple branches to terminate in the superior olivary complex, and to the dorsal and ventral nuclei of the lateral lemniscus.

Inferior Colliculus

The inferior colliculus is located in the midbrain just caudal to the superior colliculus. The inferior colliculus, similar to the cochlear nucleus, processes frequency-specific information along isofrequency lamina in the caudorostral dimension of the central nucleus.[74] The inferior colliculus receives projections directly from the cochlear nucleus and information about interaural time and amplitude differences from the medial superior olive and lateral superior olive. The inferior colliculus also integrates information from auditory and nonauditory sources. Anatomic and physiologic studies show that the inferior colliculus receives auditory inputs from the lateral lemniscus, the cochlear nucleus, and the superior olivary complex,[74,75] and projections from the somatosensory system,[76] and the visual and vestibular systems.[77] The inferior colliculus processes the information it receives and sends fibers to the medial geniculate body of the thalamus. The number of fibers from the inferior colliculus to the medial geniculate body is about 250,000, which is almost 10 times as many as the number of auditory nerves.[78] This increase in the number of nerve fibers at the level of the inferior colliculus indicates the substantial amount of signal processing that occurs in the central auditory system.

Thalamus and Auditory Cortex

Medial Geniculate Body

The medial geniculate body is the thalamic auditory relay center that receives auditory information from the inferior colliculus. It has three divisions: ventral, dorsal, and medial.[79] The ventral division of the medial geniculate body projects to the primary auditory cortex, and the dorsal division of the medial geniculate body projects to the auditory association cortex. The auditory processing performed by the medial geniculate body is greatly influenced, however, by an abundance of inputs from the auditory cortex that are believed to outnumber the projections it receives from the midbrain and lower auditory brainstem.[70] The medial geniculate body is thought to play an important

role in sound localization and processing of complex vocal communications, such as human speech.

Auditory Cortex

The main auditory portion of the cerebral cortex resides in the temporal lobe, close to the sylvian fissure. In this region, the two major centers for auditory processing are the primary auditory cortex and the association auditory cortex. The primary auditory cortex is located on the superior surface of the temporal lobe (Heschl's gyrus). This is also known as area A1, and corresponds to Brodmann's area 41. The auditory association cortex is also known as area A2, and corresponds to Brodmann's areas 22 and 42. It has been shown that the primary auditory cortex is tonotopically tuned, with high frequencies being represented more medially, and low frequencies being represented more laterally.[80] The primary auditory cortex is involved with integrating and processing complex auditory signals, including language comprehension. The auditory association cortex is located lateral to the primary auditory cortex, and it is part of a language reception area known as Wernicke's area. Functional imaging studies have shown that the auditory association cortex plays an important role in speech perception.[81,82] In addition, consonant perception deficits have been found in otherwise normal subjects when direct electrical interference is applied to the auditory association cortex,[83] further supporting the integral role that auditory association cortex plays in speech perception.

In addition to the primary auditory cortex and the auditory association cortex, auditory information from the subcortical structures also projects to other parts of the brain, such as the amygdala, which is a part of the limbic system.[84] This projection can help to explain why sounds such as music can evoke strong emotional responses.

Efferent Auditory System

The auditory brainstem not only projects to higher centers of auditory processing, but also provides efferent input to the ear via two major descending systems: (1) the middle ear muscle reflex pathways, and (2) the olivocochlear reflex pathways.

Middle Ear Muscle Reflex Pathways

The middle ear muscle reflex is another major feedback system to the auditory periphery. The pathways for the stapedius reflex to one side (ipsilateral side) are shown in Figure 129-14. The stapedius and tensor tympani muscles are the target organs of the middle ear muscle reflex, and are innervated by the efferent fibers originating in the motoneurons around and near the facial and trigeminal nerve nuclei. Activation of this neural pathway results in contraction of the middle ear muscles in response to specific sound stimuli. Contraction of the stapedius and tensor tympani muscles exerts forces perpendicular to the stapes and malleus to increase the impedance of the ossicular chain.[85]

The detailed pathway of the stapedial reflex arc is shown in Figure 129-14. Acoustic stimuli presented to either ear activate stapedius muscle contraction in both ears, similar to the consensual pupillary response to light. The reflex begins as afferent auditory input from the cochlea. The signal is transmitted along the auditory nerve to the cochlear nuclei. Interneurons that have not yet been identified (but may be located in the ventral cochlear nucleus)[86] project either directly or indirectly from the cochlear nuclei to the stapedius motoneurons (see Fig. 129-14). These central pathways are not completely understood at this point. Stapedius motoneurons project to the middle ear by way of the facial nerve to innervate the stapedius muscle (stapedial nerve). The stapedius muscle is attached to the posterior neck of the stapes capitulum; contraction stiffens the stapes suprastructure and increases middle ear impedance.

Acoustic impedance measurements have proven that the stapedius is the primary sound-evoked middle ear muscle.[87-89] In contrast to some animal models, in which the stapedius and tensor tympani contract in response to sound, the stapedius reflex is the dominant sound-evoked pathway in humans.[89,90] Two major functions of the stapedius reflexes have been proposed: (1) modulation of the middle ear impedance and attenuation of acoustic energy reaching the cochlea,[91-93] and (2) high-pass filtering of low-frequency sound (background noise) to prevent masking of speech frequencies. The function of the middle ear muscle reflex pathway seems to be protective; contraction of the middle ear muscles results in frequency-dependent sound attenuation in the presence of intense acoustic stimuli. This effect is more pronounced for low sound frequencies.[94,95] This frequency-specific attenuation of the middle ear muscle reflex supports the hypothesis that this reflex pathway preserves speech frequency information from masking by intense background noise, which is typically lower in frequency.[96-100] The stapedius muscle also contracts in response to internally or self-generated vocalization,[98] and may serve to prevent self-stimulation.

Electromyography of tensor tympani muscles has shown minimal electrical activity in response to sound presentation.[101-103] Patients who have a paralyzed stapedius muscle from facial palsy or a severed stapedius tendon from stapes surgery (and intact tensor tympani function) have absent middle ear muscle reflexes,[104] supporting previous observations that the tensor tympani plays a minor role in the middle ear muscle reflex pathway to loud sounds in humans. Measurable activity of the tensor tympani muscle seems to be associated with stimuli that cause a startle reaction.[94,100,105,106] Cortical input in addition to the auditory reflex pathway may help to modulate responses of both middle ear muscles.

The tensor tympani is a slender, feather-shaped muscle that is approximately 25 mm in length, lying in a bony canal above the eustachian tube.[88] It consists of short striated muscle cells that are arranged in parallel fibers. This arrangement permits considerable tension with minimal displacement.[88] The muscle arises from the cartilaginous portion of the eustachian tube and travels perpendicularly to insert at the neck of the manubrium of the malleus. Muscular contractions pull the malleus in an inward direction, stiffening the tympanic membrane and ossicles, and increasing the acoustic impedance.[88]

The tensor tympani is separated from the eustachian tube by a bony partition. The precise reason for this partition is unclear. von Bekesy[12] suggested that the partition prevented muscular vibrations from interfering with sound perception and acting as a mode of insulation. More than a third of the tensor tympani tendon contains elastic tissue, which dampens the ossicles during excessive stimulation and renders the muscular tractions more controlled.[88] Abundant amounts of fat are also found in the tensor tympani of humans, but the physiologic significance of this is uncertain.[88]

There is a dense concentration of motor and proprioceptive nerve fibers in the muscle that is innervated by the mandibular branch of the fifth cranial nerve. This nerve travels to the tensor tympani via the otic ganglion.[107,108] Motor fibers form an extensive and rich network on the muscle. These are thinner than other skeletal muscle nerves, but with shorter axons, still ensuring rapid conduction velocities.[107] Sensory input from the tensor tympani and the surrounding connective tissue is minimal. This is in contrast to extraocular or masticatory muscles,[109] which have rich afferent supplies. The postsynaptic regions are smaller compared with stapedial fibers, and have less mitochondrial activity in the motor end plates.[109]

The tensor tympani seems to respond to loud sound stimuli[104] and nonauditory inputs.[110] The middle ear muscles are anatomic antagonists but work synergistically to stiffen the ossicular chain, whereas the stapedius stiffens the stapes at the oval window of the cochlea, the tensor tympani exerts forces on the manubrium of the malleus, resulting in an inward deflection and stiffening of the tympanic membrane. The tensor tympani may play a protective role against loud acoustic stimuli and prevent overstimulation from self-generated vocalization or swallowing.[104,110] The multiple circuits that mediate these auditory and nonauditory functions are not fully understood, although we do know that activation of the tensor tympani reflex requires tensor tympani motoneurons, the common efferent limb of this circuit diagram.[111-113] The interneurons in the brainstem that project to tensor tympani motoneurons have not been identified, however, and the nonauditory sources that provide input to tensor tympani motoneurons are unknown.

The function of the tensor tympani muscle in humans is far from being understood. Several theories have been proposed to explain the auditory and nonauditory roles of the tensor tympani. Continued research of tensor tympani physiology is needed to help us understand this elusive muscle in greater detail.

Figure 129-14. Auditory efferent pathways. **A,** Stapedial reflex pathways. Only the pathways that activate contraction of the stapedius muscle in the ipsilateral ear are shown. Intense, low-frequency sound (or broadband noise) presented to the ipsilateral *(black pathways)* or contralateral *(gold pathways)* or both ears can trigger contraction of the ipsilateral stapedius muscle. After transduction of the auditory signal by the hair cells of the cochlea, the action potential is propagated along the auditory nerve (AN), and activates unidentified interneurons located in the ventral cochlear nucleus (CN).[86] Interneurons, either directly or indirectly, project from the cochlear nuclei to the stapedius motoneurons (*black* and *gold arrows*). Interneurons from the ipsilateral or contralateral CN synapse on stapedius motoneurons (*black* and *gold* terminals shown above). Efferent motor projections originating in stapedius motoneurons terminate on the stapedius muscle. The afferent inputs from the cochlea and efferent projections from the motoneurons to the middle ear muscles have been well characterized. The circuitry of the middle ear muscle reflex interneurons is not completely understood. **B,** Medial olivocochlear (MOC) reflex pathways that begin as sound in the ear and terminate on outer hair cells of the cochlea. Only the MOC pathways to one ear, the ipsilateral cochlea, are shown. Sound activates the outer and inner hair cells of the organ of Corti, giving rise to projections to the CN. These projections synapse on interneurons of the MOC pathways. These interneurons are believed to be multipolar cells found in the posteroventral cochlear nucleus.[130] These MOC reflex interneurons in the CN project across the midline to terminate on contralateral MOC neurons *(thick black arrow)*. These MOC neurons project axons back to the outer hair cells of the ipsilateral ear *(thin black lines)*. The MOC reflex pathway is also activated by contralateral sound to the ear *(gold pathways)*, giving rise to projections that cross the midline to innervate Contra MOC neurons *(gold stars)*. These MOC neurons project to the outer hair cells of the ipsilateral ear. *(**A** modified from Lee DJ, de Venecia RK, Guinan JJ Jr, Brown MC. Central auditory pathways mediating the rat middle ear muscle reflexes.* Anat Rec A Discov Mol Cell Evol Biol. *2006;288:358-369. **B** modified from Brown MC, de Venecia RK, Guinan JJ Jr. Responses of medial olivocochlear neurons: specifying the central pathways of the medial olivocochlear reflex.* Exp Brain Res. *2003;153:491-498.)*

Olivocochlear Reflex Pathways

There are two olivocochlear efferent pathways: medial and lateral olivocochlear pathways. The medial olivocochlear (MOC) fibers originate from the medial portion of the superior olivary complex, and travel along the vestibular nerve to the cochlea to innervate the outer hair cells. The lateral olivocochlear (LOC) fibers originate from the lateral portion of the superior olivary complex, and travel along the vestibular nerve to the cochlea to innervate the auditory nerves under the inner hair cells.[114] The MOC fibers are large and myelinated, whereas the LOC fibers are thin and unmyelinated.[115] The MOC pathway is much better understood than the LOC pathway because it is much easier to make electrophysiologic recordings on myelinated fibers.

The MOC and LOC neurons receive auditory inputs from the cochlear nucleus. MOC neurons are more sensitive to low-frequency sound information; LOC neurons are more responsive to higher frequency information. The ipsilateral MOC reflex is shown in Figure 129-14 and involves the following pathways: (1) sound activates the afferent auditory fibers, which innervate the interneurons in the ipsilateral posteroventral cochlear nucleus; (2) the interneurons of the cochlear nucleus innervate the contralateral MOC neurons; and (3) the contralateral MOC neurons send fibers to the ipsilateral cochlea, completing the pathway.[116] Electrophysiologic recordings from MOC neurons reveal that these neurons are sharply tuned and are tonotopically arranged, similar to the basilar membrane and the auditory nerves.[117,118] The tonotopic tuning of the MOC neurons continues back to the cochlea, with the MOC neurons innervating the region of the cochlea with similar characteristic frequency.[117-119]

The main function of the MOC pathway is to reduce cochlear responses by decreasing the gain of the cochlear amplifier. The MOC neurons achieve this by triggering hyperpolarization of the outer hair cells through an acetylcholine-mediated pathway.[120,121] The decreased cochlear amplifier gain in the presence of MOC stimulation is evi-

denced by the elevated threshold required for auditory nerve activation (level shift), and the blunting of the tuning curve at the characteristic frequency.[122,123] In the presence of background noise, the MOC pathway can increase auditory responses to transient sounds.[124-126] It is thought that the MOC pathway decreases the auditory responses to background noise, and more neurotransmitters are preserved for use in response to transient sounds. This effect is called MOC "unmasking."

The functions of the olivocochlear efferent pathways, especially the MOC pathway, are (1) to protect the ears from acoustic trauma, and (2) to discriminate transient sounds from background noise. Numerous studies support the notion that MOC pathway provides protection from acoustic trauma. In a study by Maison and Liberman,[127] the MOC systems in different animals were studied using otoacoustic emissions to classify them as weak, average, and strong. The animals were subjected to acoustic trauma. Animals with weak MOC systems were found to sustain the most damage in their hearing, whereas animals with strong MOC systems sustained the least damage. There have also been animal studies that support the important role the MOC pathway plays in discriminating transient sounds from background noise. It has been found that cats with cut olivocochlear fibers perform poorly on tasks involving formant discrimination or intensity discrimination of high-frequency tones in noise.[128,129] The role of the LOC pathway remains unclear at this time.

Conclusion

The normal auditory system provides humans with exquisitely sensitive binaural hearing for sound perception and speech understanding; it is able to decipher complicated acoustic signals with enormous dynamic and frequency ranges and process them in a way that is understandable to us. As the acoustic signal enters the ear, it is first transformed into a mechanical signal by the middle ear, which plays a crucial role in impedance matching. This mechanical signal is transmitted to the inner ear, where its frequency components are analyzed by the basilar membrane. The signal, which is embedded in the traveling wave of the basilar membrane, is transformed again into electrochemical form by the hair cells. This signal is propagated by the afferent auditory neurons as action potentials to auditory brainstem, midbrain, thalamus, and auditory cortex for further processing. In addition to the afferent pathway, the auditory system has two major efferent pathways that prevent acoustic overstimulation and enhance speech discrimination in background noise.

Although a clearer picture of the mechanics of the human auditory system is starting to emerge, many unanswered questions still remain. Continued research on the anatomy and physiology of the peripheral and central auditory systems using animal models and clinical research will help to clarify the exquisite mechanisms of hearing in humans.

CHAPTER ONE HUNDRED AND THIRTY

Anatomy of the Vestibular System

Anna Lysakowski

Key Points

- The labyrinth develops from the otic placode, which invaginates to become the otic pit, and then pinches off to form the otic cyst or otic vesicle.
- The vertical canals are oriented at 45 degrees with regard to the sagittal plane, and the horizontal canal is tilted upward anteriorly about 30 degrees from the horizontal plane.
- Scarpa's ganglion has two parts, the superior ganglion and the inferior ganglion. The former gives rise to nerves supplying the superior (anterior) and horizontal crista and the utricular macula; the latter supplies the posterior crista and the saccular macula.
- The blood supply to the vestibular labyrinth is the labyrinthine artery, which has two branches: anterior vestibular artery, supplying the superior and horizontal ampullae and the utriculus, and common cochlear artery, which divides into the proper cochlear artery and the vestibulocochlear artery. The latter splits into a cochlear branch and the posterior vestibular artery, which supplies the posterior ampulla and the sacculus.
- Hair cells are embedded in a matrix of supporting cells, and form tight junctions with the supporting cells, dividing the labyrinth into endolymphatic and perilymphatic compartments.
- Hair cells have a staircase arrangement of actin-filled stereocilia, anchored in a cuticular plate, on their apical surface with a single kinocilium that defines the morphologic polarization for the hair cell.
- Hair cells make synaptic contacts with their afferents by means of ribbon synapses. Vestibular afferents are of three types: calyx afferents, which enclose one or more type I hair cells; bouton afferents, which contact type II hair cells; and dimorphic afferents, which receive synaptic contacts from both types of hair cells. Efferents contact afferents and type II hair cells.
- Calyx afferents are found in the central (striolar) region of the crista (macula). Bouton afferents are found in the peripheral (extrastriolar) region of the crista (macula). Dimorphic afferents are found throughout the sensory epithelium.
- Vestibular afferents give rise to two branches in the vestibular nuclei: rostral branch projecting to the superior and medial vestibular nuclei, and the cerebellum, and caudal branch projecting to the inferior and medial vestibular nuclei, and to the ventrolateral part of the lateral vestibular nucleus.
- The vestibular nuclei are divided into four main subdivisions—superior, medial, lateral, and inferior vestibular nuclei—and several minor cell groups.
- The superior and medial vestibular nuclei project to the oculomotor complex and are involved in the vestibuloocular reflex. The medial vestibular nucleus also gives rise to the medial vestibulospinal tract, which projects to oculomotor and neck muscles, for the vestibulocollic or cervicovestibuloocular reflexes.
- The lateral vestibular nucleus contains giant Deiters' cells that give rise to axons in the somatotopically organized lateral vestibulospinal tract, which projects to ventral horn cells in the cervical and lumbar spinal cord.

The vestibular system is the system of balance and equilibrium. It consists of five distinct sensory organs: three semicircular canals, which are sensitive to angular accelerations (head rotations), and two otoliths, which are sensitive to linear accelerations (e.g., motion in a vehicle or an elevator). This chapter describes the anatomic basis for these functions.

The *semicircular canals* are arranged as a set of three orthogonal sensors (Fig. 130-1)—that is, each canal is at approximately right angles to the other two. Each canal is maximally sensitive to rotations that lie in the plane of that canal. The result of this arrangement is that the three canals can uniquely specify the direction and amplitude of any arbitrary head rotation. Each of the canals acts as an integrating accelerometer; the necessary stimulus for the canal is an angular acceleration, but the information that is encoded by the firing of the afferent nerve fiber is more closely related to angular velocity. Finally, the canals are organized into functional pairs wherein both members of the pair lie in the same plane. Any rotation in that plane is excitatory to one of the members of the pair and inhibitory to the other. Although in the horizontal system the two horizontal canals form a functional pair, the situation is more complex in the vertical system. Here, the anterior canal on one side is parallel and coplanar with the posterior canal on the opposite side; for example,

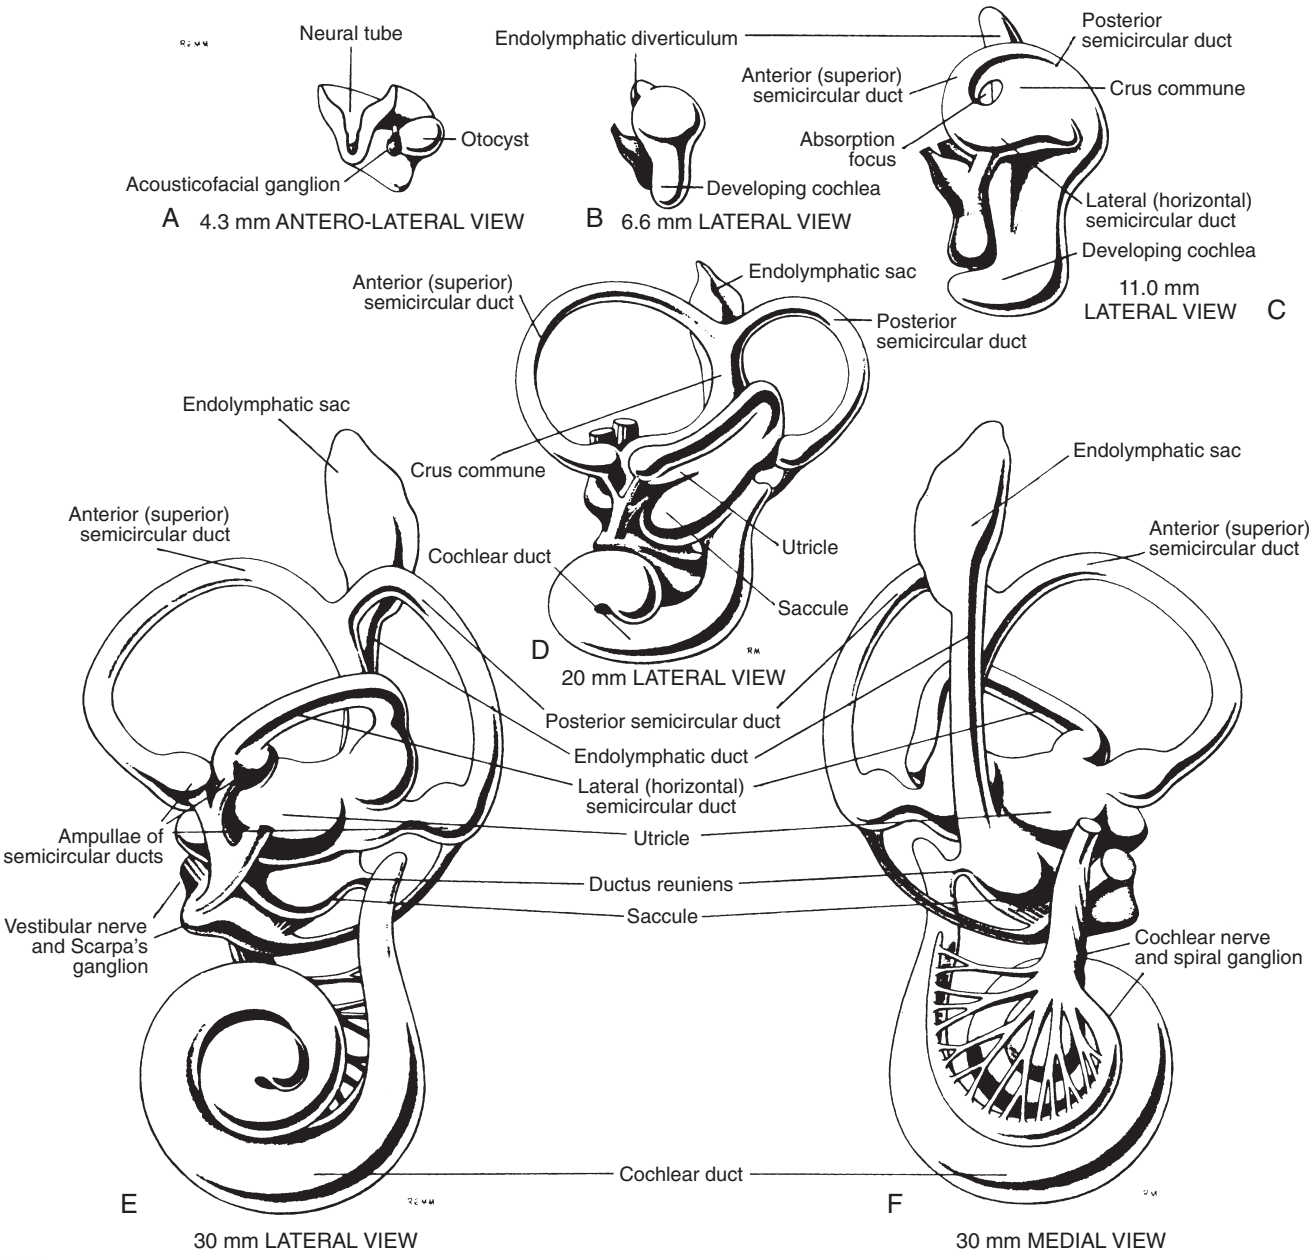

Figure 130-1. Development of vestibular apparatus in humans. **A,** Embryo of 4.3 mm (approximately 23 days old). **B,** Embryo of 6.6 mm (approximately 30 days old). **C,** Embryo of 11 mm (approximately 41 days old). **D,** Embryo of 20 mm (approximately 50 days old). **E** and **F,** Embryo of 30 mm (approximately 56 days old). See text for details. *(Modified from Williams PL, Warwick R.* Gray's Anatomy. *36th ed. Philadelphia: Saunders; 1980.)*

the right anterior canal and the left posterior canal form a functional pair.

Because the primary vestibular afferent fibers exhibit a substantial resting firing rate (60 to 80 spikes per second in mammals), each canal is able to report rotations in either its excitatory direction (by increasing its firing rate) or its inhibitory direction (by decreasing its firing rate). This observation explains why it is possible to function reasonably well after the loss of one labyrinth.

The vestibular system forms the basis for many fundamental reflexes: the vestibulocollic reflex (head stabilization), vestibulospinal reflex (control of upright posture) and vestibuloocular reflex (retinal image stabilization). The last of these, the vestibuloocular reflex, has been studied far more extensively than the others and is the best understood; this reflex forms the basis for most clinical testing (e.g., calorics, rotation tests). See also Chapters 163 and 164 for clinical applications.

This chapter describes the anatomy of the vestibuloocular reflex in some detail, but without exploring every possible aspect. Many of the details that are described have been obtained from experiments in animal species, principally the cat and monkey. Nevertheless, the information is applicable to humans because the vestibular system has changed little during the evolution of vertebrates.

Embryology of the Vestibular Apparatus

The development of the inner ear is a complex process that starts at the beginning of the 4th week and is completed at about 25 weeks of gestational age. By that time, the vestibular apparatus has achieved adult form and size. A brief description of this process of development in human embryos follows. Further details can be found by consulting more detailed references.[1-3] An excellent description of the molecular aspects of development can be found in Post,[4] and a review by Kelley[5] discusses these molecules in relation to potential hair cell regeneration (see also Chapters 1 and 2).

When the human embryo reaches the seven-somite stage (about 22 days), surface ectoderm overlying the future site of the inner ear (at

about the level of the first occipital somite) thickens to form the *otic placode*. The otic placode invaginates into the mesenchyme, forming an otic pit. At about 30 days, the otic pit becomes pinched off, forming the *otic vesicle* or *otocyst* (see Fig. 130-1). Concurrently at about 4 weeks, a portion of the neural crest migrates to the vicinity of the otic vesicle and becomes the acousticofacial ganglion. The geniculate ganglion soon migrates away from this cluster of neurons, leaving the vestibulocochlear ganglion in close proximity to the otic vesicle.

Within 1 or 2 days after formation of the otic vesicle, its more medial portion, the *endolymphatic diverticulum,* becomes distinguishable from the lateral *utriculosaccular chamber*. This chamber differentiates by a constriction of its middle into (1) a utricular chamber that gives rise to the *utriculus* and the *semicircular ducts,* and (2) a saccular chamber that gives rise to the *sacculus* and the *cochlea*. The utricular chamber differentiates first by a rapid expansion into three diverticula. At about 35 days, the centers of these diverticula fuse together and break down, leaving spaces around the perimeter that become the three semicircular ducts. The superior semicircular duct forms first, at about 6 weeks, with the posterior and lateral ducts forming soon afterward in that order. Dilations of one end of each of the semicircular ducts become the ampullae. The ampullar ends and the opposite ends of the ducts remain connected to the utriculus.

The saccular chamber differentiates by expansion and coiling of the cochlear duct. This duct becomes separated from the sacculus by a narrowing of the duct at its dorsal end to form the *ductus reuniens*. While morphogenesis proceeds within the otocyst, histogenesis of the sensory epithelium is also occurring. The arrival of afferent endings in the epithelium precedes hair cell differentiation.[6,7] In the 3rd week, a common macula, or specialized neuroepithelium, appears. Its upper part becomes the utricular macula and crista ampullaris of the superior and lateral semicircular ducts, and its lower part becomes the saccular macula and crista ampullaris of the posterior semicircular duct. At 9 weeks, the hair cells in the vestibular end organs are well differentiated, and they exhibit typical synapses with nerve endings. The maculae reach adult form at about 14 to 16 weeks; the cristae, at about 23 weeks; and the organ of Corti, at about 25 weeks. The mesoderm surrounding the membranous labyrinth becomes the bony otic capsule, or *bony labyrinth*. The *membranous labyrinth* is suspended in fluid (perilymph) within the bony labyrinth by a loose connective tissue termed *periotic tissue*.

Overall Organization of Labyrinth: Relationship to Skull and Cochlea

The vestibular apparatus is enclosed within a bony labyrinth, the vestibule, in the petrous portion of the temporal bone. The vestibular end organs include three semicircular canals, each oriented in a different plane, and two maculae, one roughly in the horizontal plane (the utriculus) and one in the vertical plane (the sacculus). There are two vertical semicircular canals, the anterior (also known as the superior) and posterior canals, and one horizontal (also known as the lateral) canal. The vertical canals are oriented roughly at 45 degrees in relation to the sagittal plane, and the horizontal canal is tilted upward about 30 degrees anteriorly from the horizontal plane (Fig. 130-2). The five vestibular end organs, along with the cochlea, are contained within an endolymph-filled membranous labyrinth (the endolymphatic space), which is itself contained in the perilymph-filled bony labyrinth (the perilymphatic space) (Fig. 130-3).

The vestibule is situated between the internal auditory meatus anteromedially and the middle ear cavity laterally (Fig. 130-4). The entrance to the mastoid antrum (the *aditus ad antrum*) is just lateral to the horizontal semicircular canal. The cochlea sits anterior to the vestibule and is connected to the vestibule by the narrow ductus reuniens (Fig. 130-5; see Fig. 130-3). Posterior and lateral to the vestibule are the mastoid air cells. Directly medial is the posterior cranial fossa, into which the endolymphatic duct and sac extend beneath the dura.

The seventh (facial and intermediate) and eighth (vestibulocochlear) cranial nerves emerge from the brainstem laterally at the cerebellopontine angle. They enter the vestibule and cochlea from the internal auditory meatus (see Fig. 130-4), located medial to a point midway between the cochlea and vestibule. The facial nerve lies anterior and dorsal to the vestibulocochlear nerve. The two nerves separate just inside the meatus, and the facial and intermediate nerves continue laterally in their own canal, past the vestibule. When past the vestibule, the facial nerve makes a 90-degree turn inferiorly to exit the temporal bone through the *stylomastoid foramen*. The vestibulocochlear nerve splits into a vestibular division, which turns posteriorly to supply the vestibule, and a cochlear division, which turns anteriorly to supply the cochlea.

The vestibular (Scarpa's) ganglion sits at the bottom of the internal auditory meatus. It has two parts, the superior vestibular ganglion and the inferior vestibular ganglion (see Fig. 130-5). Large ganglion cells in the superior and inferior ganglia provide afferent innervation to the central regions of the cristae and maculae, and small ganglion cells innervate the peripheral regions of these end organs (the regional specialization within the end organs is discussed in more detail subsequently). A nerve branch is associated with each ganglion. The superior (or anterior) vestibular nerve supplies the anterior and horizontal cristae and the utricular macula. The inferior (or posterior) vestibular nerve supplies the posterior canal and saccular macula. There are also a few small branches that anastomose between the larger divisions of CN VIII. One such small branch is Voit's anastomosis, which runs from

the superior vestibular nerve to the anterosuperior part of the sacculus. Another is the vestibulocochlear (Oort's) anastomosis, which runs from the inferior vestibular nerve to the cochlear nerve and carries cochlear efferents (see later). In addition, some intermediate nerve fibers cross to the vestibular nerve proximal to the superior vestibular ganglion, and others cross back to the intermediate nerve distal to Scarpa's ganglion. It has been suggested that this facial-vestibular anastomosis carries parasympathetic innervation to the vestibular labyrinth; for details on these and other small fiber connections, see Lindemann.[8]

Efferent Innervation of Peripheral Vestibular Apparatus

The efferent supply to the vestibular end organs arises from a small group of about 200 neurons lateral to the abducens nucleus and the genu of the facial nerve, the so-called *group e* (see later).[9] These neurons project ipsilaterally and contralaterally (Fig. 130-6). The contralateral pathway crosses the midline at the level of the facial genu and joins the ipsilateral pathway; both pass ventral to the vestibular nucleus. At this point, they are joined by cochlear efferents originating from the superior olivary complex (olivocochlear bundle). All of the efferents enter the vestibular nerve, coursing through the middle of the nerve in a small distinct bundle. At the end organs, these few fibers branch profusely to innervate the entire sensory epithelium. More recent work suggests that the ipsilaterally projecting efferents supply the central regions of the crista, whereas the contralaterally projecting efferents supply the peripheral zone.[10] The efferent fibers terminate as highly vesiculated boutons, making synaptic contacts with hair cells and afferent fibers.[11,12] For an excellent review of the neurochemistry of the vestibular efferent system, see Goldberg and colleagues.[13]

Autonomic Supply of Peripheral Vestibular Apparatus

Postganglionic sympathetic fibers from neurons in the superior cervical ganglion also innervate the vestibular end organs. They are of two types: perivascular and nonvascular. The nonvascular sympathetic fibers run among the myelinated afferent fibers. The terminals of these nonvascular sympathetic fibers are found as free endings near the cells of Scarpa's ganglion, distal to the ganglion and underneath the sensory epithelium. They do not seem to penetrate the basement membrane into the sensory epithelium and do not seem to have a direct effect on the hair cells or afferent fibers.[14] Their functional role remains unexplored, along with the functional role of any parasympathetic innervation of the vestibular sensory epithelium.

Blood Supply to Vestibular End Organs

The main blood supply to the vestibular end organs is through the internal auditory (labyrinthine) artery, which arises most often (45%) from the anterior cerebellar artery, superior cerebellar artery, or basilar artery, according to a radiographic study by Wende and coworkers.[15] Shortly after entering the inner ear, the labyrinthine artery divides into two branches: the anterior vestibular artery and the common cochlear artery (Fig. 130-7). The anterior vestibular artery provides the blood supply to most of the utriculus and the superior and horizontal ampullae, and some blood to a small portion of the sacculus. The common cochlear artery forms two divisions, the proper cochlear (or spiral modiolar) artery and the vestibulocochlear artery. The latter divides into a cochlear ramus and a vestibular ramus, also known as the posterior vestibular artery. The posterior vestibular artery is the source of the blood supply to the posterior ampulla, the major part of the sacculus, and parts of the body of the utriculus and horizontal and superior ampullae.

Anatomy of End Organs

At the dilated end of each semicircular duct is the ampulla. It contains the neuroepithelium (crista ampullaris), the cupula, supporting cells, connective tissue, blood vessels, and nerve fibers. The crista is a saddle-shaped, raised section of the wall that extends across the floor of the ampulla at right angles to its long axis. The crista has been found to be divided into central (near the apex) and peripheral (on the slope) zones based on the morphology and physiology of vestibular afferents supplying the different regions (see later).[16,17] The shape of the crista facilitates maximal packing of the specialized mechanoreceptor hair cells.

The hair cells and the supporting cells are modified columnar epithelial cells that have microvilli on their apical surfaces. In the hair cells, many of these microvilli are elongated to form stereocilia, which

Bethesda, MD: American Physiological Society; 1984: 977-1031.)*

are grouped in an organ pipe–like arrangement (Fig. 130-8). In addition, each hair cell has a single long kinocilium, a true cilium showing the 9 + 2 arrangement of microtubules. This kinocilium is longer than the stereocilia and eccentrically located, imparting a certain polarization to the hair cell that has important functional implications (see Chapter 163). In the cristae, the kinocilium on each hair cell is located on one end of the cell (Fig. 130-9). In the horizontal cristae, the kinocilia are located on the side of the hair cell that is closest to the utriculus. In the vertical cristae, the kinocilia are located on the side of the hair cell furthest from the utriculus, the canalicular side. The entire hair bundle extends upward into the cupula (Fig. 130-10).

The cupula is a gelatinous mass, consisting of mucopolysaccharides within a keratin meshwork,[18] which extends from the surface of the cristae to the roof and lateral walls of the membranous labyrinth, forming a fluid-tight partition. There is a distinct subcupular space in the region of the cupula overlying the apex of the center of the crista (see Fig. 130-10). This subcupular space is believed to provide space for freedom of movement and more sensitive responses to endolymph flow for the stereocilia on the hair cells in the central zone. The space may be artifactual and due to fixation methods commonly used to prepare tissue for histology. The specific gravity of the cupula is approximately 1, which is about the same as that of the endolymph.[19] This matching of the specific gravity of the cupula and the endolymph is necessary to prevent the cupula from floating upward in certain head positions and causing an enduring nystagmus. Disruption of this match in specific gravity is likely the cause of postalcoholic nystagmus.

A torsion pendulum model is used to describe the mechanics of cupular and endolymph displacement.[20] For a description of the mathematic details of the response of canal afferents, see Goldberg and Fernández.[21] More details are also given in Chapter 163.

Similar to the cristae ampullares, the maculae of the utriculus and sacculus consist of neuroepithelium, supporting cells, blood vessels, and nerve fibers. The utricular macula is oriented in the horizontal plane, and the saccular macula is oriented in the vertical plane (Fig. 130-11). Cilia from the hair cells in both maculae extend upward into their respective otolithic membranes (Fig. 130-12)—gelatinous membranes analogous to the cupula. In the upper surface of the otolithic membranes, the otoliths (or otoconia) are embedded. Otoliths are inorganic crystalline deposits composed of calcium carbonate or calcite.[22] They vary in size from 0.5 to 30 µm, with most being about 5 to 7 µm.[8] The specific gravity of the otolithic membrane is much higher than that of the endolymph, about 2.71 to 2.94.[19] Within the otolithic membrane is the striola,[23] a specialized central region that has a snowdrift-like appearance. The striola is identifiable as a thin stripe running down the center of the otolith membranes of both maculae. In the striola, the otoliths are very small (about 1 µm), and the thickness of the otolithic membranes is either reduced, as in the utricular macula, or increased, as in the saccular macula. These regional differences in the otolithic membranes are paralleled by morphologic and physiologic differences in the afferent fibers supplying the hair cells in the underlying sensory epithelium.[24-26]

The kinocilia on the hair cells in the maculae are also dynamically polarized, but the pattern of polarization is much more complex than in the cristae (see Figs. 130-9 and 130-11). In the utricular macula, the kinocilia are oriented so that they point toward the striola, whereas in the saccular macula, the kinocilia point away from the striola. Because both maculae are curved areas, and the striolae are curved lines, the arrangement is so complex (see Fig. 130-11) that static head tilts in any direction cause some hair cells to be excited and others to be inhibited in one or both of the otolithic organs. The stimulus is encoded by means of stimulation of hair cells in the appropriate sector of the macula.

The otolith organs are sensitive not only to gravity, but also to other linear acceleration forces, such as forward motion and bobbing movements of the head during walking. Static head tilts are represented by a vector and the afferent response predicted by a trigonometric function based on the tilt angle. One would expect a linear model based on this simple relationship; however, there is a response asymmetry in that the excitatory response is larger than the inhibitory response. Consequently, the equation describing this force-response relationship is by necessity nonlinear (for more mathematical details, see Fernández and Goldberg[27,28]).

Cellular Morphology of Vestibular Sensory Epithelium

The sensory epithelium is composed of several different elements: hair cells, supporting cells, afferent nerve fibers and their synaptic terminals, and efferent nerve fibers and their synaptic boutons. Two basic cell types are present within the sensory epithelium: supporting cells and hair cells (Fig. 130-13). Supporting cells extend from the basement membrane to the apical surface. Their nuclei are usually found just above the basement membrane and below the hair cells. In sections taken tangential to the apical surface, several supporting cells can be seen to form a ring around an individual hair cell. The supporting cells themselves contain well-developed Golgi complexes, many mitochondria, and occasional lipid droplets. The upper part of the supporting cells contains large numbers of round or ovoid granules. These secretory granules are likely responsible for the formation of the cupula and otolithic membrane.[29,30]

Hair cells generally contain a bundle of stereocilia attached to their apical surface and grouped in a staircase arrangement. These stereocilia are densely packed with longitudinally oriented actin filaments that extend into the hair cell and are anchored in a thickened region near the apical surface, termed the *cuticular plate*. The cuticular plate is a dense filamentous meshwork of randomly oriented actin filaments that fills up the area just under the apical surface of the cell except for the region of the kinocilium. A basal body and many large vesicles are usually in the region of the kinocilium. Hair cells are surrounded by supporting cells, as mentioned earlier, and form tight junctions and desmosomes with the supporting cells, separating the endolymphatic space, in which endolymph bathes the stereocilia above the cells, from the perilymphatic space below the apical surface. Another general feature that applies to hair cells is that they are presynaptic to the afferent nerve fibers that they contact. Hair cells make synaptic contacts by means of synaptic specializations termed *synaptic ribbons* or *bars,* electron-dense structures with synaptic vesicles clustered around them.

Synaptic Morphology of Vestibular Afferents

Hair cells are of two types, type I and type II, defined by the presence or absence of a calyx, or chalice, a specialized type of large afferent ending that completely surrounds the cell except for the near-apical and apical surfaces (see Fig. 130-13). Type I hair cells are flask-shaped cells surrounded by a calyx ending. Usually, a calyx surrounds a single type I hair cell. In this case, the calyx ending is termed a *simple calyx ending*. Sometimes one calyx surrounds two to four type I hair cells (Fig. 130-14); this is termed a *complex calyx ending*. Complex calyx endings are much more common in the central zone (or striola) than in the periphery (or extrastriola). Histologically, the existence of complex endings is a criterion that can be used to define the central zone.

The ratio of type I to type II hair cells is approximately 1:1, and this ratio changes very little from the central to the peripheral zone, based on studies in which rodents have been used to quantify cell distributions.[31,32] More recent work in the crista of the squirrel monkey has shown, however, that although the total number of hair cells is similar to rodents, the ratio of type I and type II hair cells in the central zone is increased from 1:1 to about 5:1 in primates compared with rodents.[33] This ratio may reflect the relative importance of type I hair cells for primates. The same is not the case, however, for the monkey otolith organs, in which type II hair cells outnumber type I hair cells by 2:1.[34]

Type II hair cells are cylinder-shaped cells that are contacted at their basal surfaces by numerous afferent and efferent synaptic boutons.

Afferent boutons contain mitochondria and few vesicles and receive synaptic contacts from the hair cell. They transmit the impulse centrally to the vestibular nuclei and are postsynaptic to the hair cell. Efferent boutons contain many vesicles and smaller mitochondria and vesicles than those found in afferent boutons. They form synapses with hair cells and afferents, and transmit impulses from the efferent group of neurons located in the brainstem. It has long been assumed that hair cells from different regions had approximately the same number of afferent boutons contacting them, and that each bouton formed about the same number of synapses with a given hair cell. More recent ultrastructural work[12,34] has shown that there are regional variations in the synaptic innervation of type II hair cells (see Fig. 130-14). Type II hair cells in the periphery (or extrastriola) make synaptic contact with many afferent boutons, each of which receives one synapse from the adjacent hair cell. Type II hair cells in the central zone (or striola) make synaptic contact with relatively few afferent boutons, but make multiple contacts with each of these. In addition, type II hair cells in the central zone make synaptic contacts with the outer surface of the calyx endings surrounding type I hair cells, a type of synapse rarely found in the peripheral zone.

Synaptic Morphology and Function of Vestibular Afferents

More recent morphologic and physiologic work on vestibular afferents[16,17,24-26,33,35] has defined, structurally and functionally, specialized subregions within the sensory epithelium (loosely analogous to the fovea and periphery of the retina): the central and peripheral zones of the vestibular sensory epithelium. These studies have involved experiments in which vestibular afferent nerve axons were impaled with microelectrodes; characterized electrophysiologically using responses to galvanic, rotational, and linear acceleration stimuli; and injected with horseradish peroxidase used as an intracellular dye. The horseradish peroxidase–filled afferent nerve fibers were recovered histologically, their position within the sensory epithelium was reconstructed, and their nerve terminals and axons were drawn. In this manner, these investigators were able to define morphologically three types of afferent endings—pure calyx (or chalice) endings, bouton endings, and dimorphic endings (which contained calyx and bouton terminals) (Figs.

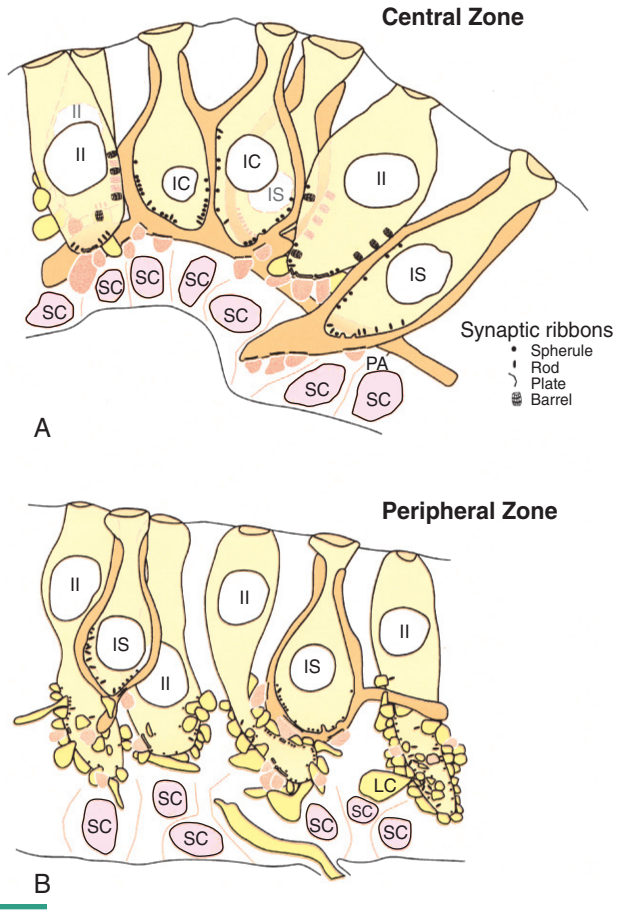

Figure 130-14. Regional variations in synaptic innervation of type I and type II vestibular hair cells. Schematic based on electron micrographs taken from a chinchilla superior crista. **A,** This portion of the central zone contains three type II hair cells (II) and four type I hair cells, including two in a complex calyx (IC) and two others, each in a simple calyx (IS). Supporting cell (SC) nuclei are seen at the bottom. Efferent boutons are shaded *black,* and afferent boutons are *unshaded*. Calyx endings are shaded *orange,* as is the parent axon (PA) running from right to left and giving rise to the complex calyx. Hair cells are wider and calyces are thicker than in the peripheral zone. There are fewer afferent boutons per type II hair cell in the central zone, but each central bouton makes multiple ribbon synapses. Type II hair cells in the central zone also synapse with the outer faces of neighboring calyx endings. Synaptic ribbons occur in different shapes (see key on figure). Efferent synapses are made with type II hair cells, with calyx endings, and with other afferent processes. **B,** Four type II hair cells (II) and two type I hair cells (IS) are shown from the peripheral zone. Hair cells and calyces are thinner, and there are many more afferent boutons per type II hair cell. Most afferent boutons contact one ribbon synapse. Complex calyx endings and outer face ribbons are rare in the periphery. Efferent innervation appears similar in the two regions. *(From Lysakowski A, Goldberg JM. A regional ultrastructural analysis of the cellular and synaptic architecture in the chinchilla cristae ampullares.* J Comp Neurol. *1997;389:419-443.)*

130-15 and 130-16)—and to determine that the distribution of these three types was segregated within the sensory epithelium.

These three morphologic types of afferents fell into two physiologic types that were also segregated within the sensory epithelium. Pure calyx endings had a very irregular discharge pattern and were insensitive (low gain) in response to sinusoidal head rotation. Calyx endings were found only in the central region. Bouton and dimorphic endings were distributed along a continuum in which discharge regularity and response dynamics were linearly correlated; that is, bouton endings were very regularly discharging and had low sensitivity to sinusoidal head rotation, whereas dimorphic endings could vary from very regular to very irregular in discharge rate, and from very low gain to very high gain response dynamics. Bouton endings were always found near the periphery. Dimorphic endings were found throughout the sensory epithelium, but irregular dimorphic endings were found in the central zone, and regular dimorphic endings were in the peripheral zone. The functional classification of vestibular afferents into regularly and irregularly discharging afferents, which correlates with numerous other physiologic and morphologic features,[13,36] has proved useful in understanding peripheral and central terminations, as discussed subsequently.

Central Pathways of Vestibular System

Terminations of Vestibular Nerve in Brainstem

The vestibular nerve enters the brainstem at the ventrolateral aspect of the pontomedullary junction in close proximity to the cochlear and facial nerves, which accompany it to the internal auditory meatus. After

Relation between afferent response properties and peripheral innervation patterns in the utricular macula.* J Neurophysiol. *1990;63:791-804.)*

entering the brainstem, the fibers of the vestibular nerve course dorsally and medially, passing between the inferior cerebellar peduncle and the descending tract of the trigeminal nerve, and enter the vestibular nuclei. On entering the nuclei, most vestibular fibers give rise to two branches in the vestibular nuclei, one rostral and one caudal (Fig. 130-17).[37] The rostral branch projects to the superior and medial vestibular nuclei, and sends a collateral branch to the cerebellum. The caudal branch projects to the inferior and medial vestibular nuclei and to the ventrolateral part of the lateral vestibular nucleus. Regularly discharging vestibular afferents, described in the previous paragraph, terminate on small to medium-sized vestibular nuclear neurons, whereas irregularly discharging afferents terminate on medium-sized to large vestibular nuclear neurons (see Fig. 130-17).[38] There are two major projection sites in the brain—the vestibular nuclei and the cerebellum.[39] No primary vestibular afferents cross the midline.

Projections of Vestibular Nerve to Cerebellum

It has been estimated that about 70% of primary vestibular afferents[40] terminate by means of mossy fibers in the granular layer of the most caudal lobules of the cerebellar vermis, specifically in the uvula and nodulus. This region of the cerebellum is thought to be involved in coordinating movements of the head and eyes. Purkinje cells in the posterior vermis project either to the fastigial nucleus or to the vestibular nuclei. The fastigial nucleus is the deep cerebellar nucleus that receives collateral projections from primary afferents in addition to inputs from the vermis.[41,42] Another region of the cerebellar cortex that projects directly to the vestibular nuclei, the cerebellar flocculus, does not seem to receive significant direct inputs from the vestibular nerve, although it does receive secondary inputs.[43]

Anatomic Subdivisions of Vestibular Nuclei

The vestibular nuclei have been classically divided into four main regional subdivisions[44-46]—superior, medial, lateral, and inferior vestibular nuclei—and several minor cell groups (Fig. 130-18). The superior vestibular nucleus (of Bechterew) is located dorsally and rostrally in the vestibular complex. It can be subdivided into a central region that contains many medium-sized neurons and a peripheral region that contains mostly smaller cells. The superior vestibular nucleus is involved in vestibuloocular reflex pathways. Neurons in this nucleus fire in relation to eye movements and head movements (see Chapter 163), and a prominent efferent projection of this nucleus is to the oculomotor nucleus via the medial longitudinal fasciculus. This tract is particularly important in the control of the vestibuloocular reflex.

The lateral vestibular nucleus (of Deiters) can be subdivided on anatomic and functional grounds into two subnuclei: the dorsal lateral vestibular nucleus (or Deiters' nucleus) and the ventral lateral vestibular nucleus. The dorsal lateral vestibular nucleus contains the many giant cells of Deiters that give rise to the lateral vestibulospinal tract, and the ventral lateral vestibular nucleus contains medium-sized neurons that give rise to vestibuloocular pathways, the medial vestibulospinal tract, and vestibulothalamic pathways. The two subdivisions of the lateral vestibular nucleus also differ in regard to their afferent

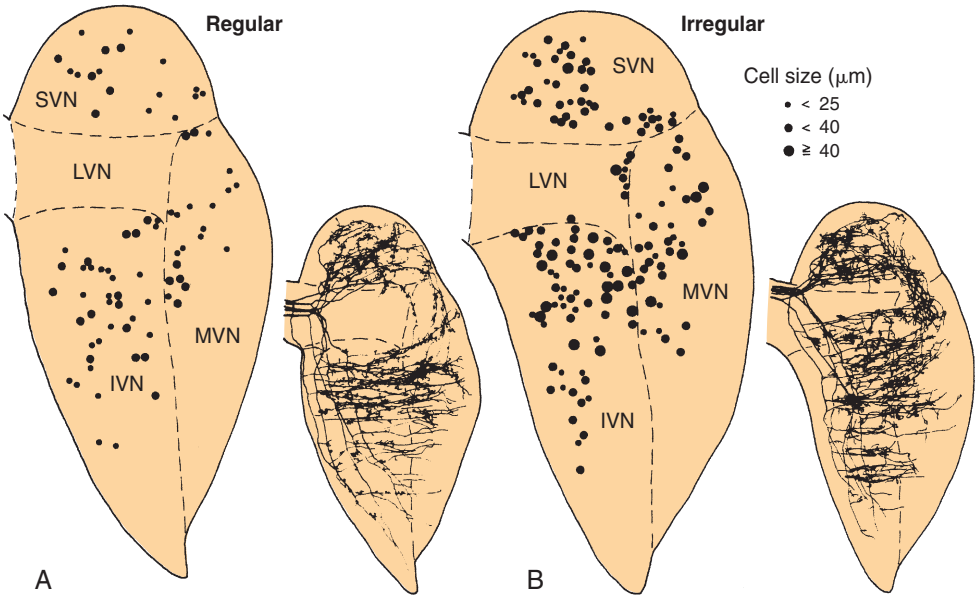

Figure 130-17. Central terminations of regularly **(A)** and irregularly **(B)** discharging canal fibers in vestibular nuclei. IV, LV, MV, SV, inferior, lateral, medial, superior vestibular nuclei. *(From Sato F, Sasaki H. Morphological correlations between spontaneously discharging primary vestibular afferents and vestibular nucleus neurons in the cat.* J Comp Neurol. *1993;333:554-566.)*

inputs (see later). There is a somatotopic representation within the lateral vestibular nucleus,[47] such that the anterior and superior part of the nucleus supplies the cervical cord, whereas the posterior and inferior part supplies the lumbosacral cord. The lateral vestibulospinal tract terminates directly on the ventral horn cells either directly or indirectly by means of interneurons. This tract is particularly important for vestibulospinal and vestibulocollic reflexes.

The medial vestibular nucleus (of Schwalbe) extends rostrocaudally in the brainstem from the level of the abducens nucleus to the hypoglossal nucleus. It is bounded medially by a functionally related nucleus, the nucleus prepositus hypoglossi, and laterally by the inferior vestibular nucleus. More recent studies indicate that the medial vestibular nucleus can be subdivided into a rostral magnocellular region and a parvocellular region and a caudal region with small to medium-sized neurons.[39,48] The rostral medial vestibular nucleus, similar to the superior nucleus, contains many neurons that project to the oculomotor nuclei and whose firing behavior is related to eye movements.[49-51] Little is known about the functions of the caudal region of the medial vestibular nucleus, although many of the cells in this region seem to project to the cerebellum.[52] The medial vestibular nucleus also gives rise to the medial vestibulospinal tract, which descends in the medial longitudinal fasciculus to terminate on interneurons in the cervical spinal cord, and ascends to terminate in the eye motor nuclei. This tract is particularly important for cervicovestibuloocular reflexes.

The inferior (or descending) vestibular nucleus merges rostrally with the ventral lateral vestibular nucleus and extends most caudally in the vestibular complex. This region of the vestibular nuclei is one of the primary recipients of vestibular afferents that innervate the otolithic organs.[53] Some of the cells in this nucleus contribute to the vestibulospinal pathways, but the major projections from this area seem to be to the cerebellum and reticular formation.

The minor cell groups associated with the vestibular nuclei have been named alphabetically in lower case letters: cell groups f, l, x, y, z, and e. Cell group f is a caudal subdivision of the descending vestibular nucleus, consisting of medium-sized cells. Cell group l is a small group of medium-sized cells at the caudal and lateral border of the lateral vestibular nucleus, adjacent to the restiform body. It can be distinguished from the many giant cells of Deiters in the nucleus. In addition, most of its projections are to the spinal cord below T1.[47] Cell group z is not properly included in the vestibular nuclei. It is located in the caudal part of the vestibular complex, and it receives its primary input from fibers that travel in the spinal dorsal columns; its cells contribute to ascending somatosensory pathways to the thalamus.

Cell groups x and y are important functional subdivisions of the vestibular nuclei. Cell group x is also located in the caudal part of the vestibular complex. This area receives a prominent input from the spinal cord, and it projects to the cerebellum. The y group is located caudal and lateral to the superior vestibular nucleus and has a dorsal boundary with the lateral vestibular nucleus and a ventral boundary with the inferior cerebellar peduncle. The dorsal and ventral parts of the y group of cells seem to be functionally different. The ventral part of the y group consists of small fusiform neurons that receive inputs from vestibular afferents that innervate the sacculus.[53] The dorsal part of the y group contains larger neurons and is traversed by a fiber tract, termed the *floccular peduncle,* which passes from the cerebellar flocculus to the vestibular nuclei. Many of the cells in the dorsal part of the y group seem to be functionally related to the flocculus and to eye movement control, particularly eye movements in the vertical plane.[54]

Cell group e (also see Fig. 130-6) is associated with the vestibular nuclei, but contains neurons projecting out to the labyrinth instead of receiving primary afferents. There is some suggestion, however, that it may receive collaterals of primary afferents, which would constitute a type of feedback circuit. It is located at the ventromedial aspect of the rostral medial vestibular nucleus, and it contains the cells that give rise to the efferent pathway from the brain to the vestibular end organs.[9]

Organization of Vestibular Nerve Inputs to Vestibular Nuclei

The vestibular nerve terminates in virtually all parts of the vestibular nuclei.[53] The details of the terminations of the afferents that innervate individual vestibular end organs are not yet completely known, but cells whose activity is related primarily to otolith function have been found mainly in the dorsal lateral and inferior vestibular nuclei. In contrast, cells whose activity is primarily related to semicircular canal function have been found mainly in the superior, medial, and ventral lateral vestibular nuclei. Although the results of physiologic studies suggest that afferents that innervate different vestibular end organs do not synapse directly on the same cells in the vestibular nuclei,[55] the activity of individual cells in the vestibular nuclei is not always clearly related to a single end organ.[56] This finding suggests that there is some func-

tional convergence of inputs from different end organs in some vestibular nuclear cells.

Some neurons in the vestibular nuclei do not receive direct inputs from the vestibular nerve. One example is a group of cells that respond preferentially to stimulation of the contralateral vestibular nerve (see later).[57,58] The head movement sensitivity of most of the cells in the vestibular nuclei depends on bilateral activation of the vestibular end organs. Removal of one vestibular nerve typically reduces the head movement sensitivity of vestibular nuclear neurons approximately in half,[59] which suggests that commissural pathways between the vestibular nuclei contribute significantly to the physiologic sensitivity of vestibular nuclear neurons.

Four physiologic types of neurons are found in the vestibular nuclei.[57,58] These are described briefly here. Type I neurons are excited, whereas type II neurons are inhibited, by ipsilateral rotations of the head. The former receive ipsilateral input from primary afferents, whereas the latter receive either contralateral or commissural input. Type III neurons are excited by both directions of rotation, whereas type IV neurons are inhibited by either type of rotational acceleration. Type I neurons are the most common; there are also numerous type II neurons. Type III and type IV neurons are rare. Figure 130-19 shows a vestibular type I neuron in the medial vestibular nucleus that has been characterized morphologically and physiologically and projects to the abducens nucleus and other targets.[60]

Vestibular commissural pathways arise from every part of the vestibular nuclei except the dorsal lateral vestibular nucleus.[48,61] Although there is a tendency for a particular region of the vestibular nuclei to project heavily to its contralateral counterpart, there is also considerable divergence in the commissural pathways to other parts of the vestibular nuclei (Fig. 130-20). Functionally, the commissural pathways between the vestibular nuclei seem to play an essential role in the ability to compensate for unilateral vestibular lesions.[62] Because most vestibular nuclear neurons fire spontaneously even when the head is not moving,[49] and because most vestibular functions are organized bilaterally, an imbalance between the spontaneous firing rate of one vestibular nucleus compared with the other results in the central perception of head movement and dysfunctional operation of reflex pathways (e.g., ocular nystagmus is usually produced when the vestibular nuclei are unilaterally damaged). The vestibular commissural pathways seem to play an important role in maintaining the balance in the output of the two sides.

Other Inputs to Vestibular Nuclei

The vestibular nerve is not the only source of input to the vestibular nuclei. Many regions of the brainstem and the cerebellum also project to the vestibular nuclei. Most of the nonvestibular inputs arise from the flocculonodular lobe of the cerebellum,[63] from the fastigial nucleus,[64] and from regions of the brainstem in the vicinity of the vestibular nuclei, although the vestibular nuclei also receive inputs from the spinal cord and from nuclei located in the midbrain and caudal diencephalon.

Although the function of each source of nonvestibular afferents to the vestibular nuclei is not completely known, the physiologic responses of vestibular nuclear neurons have been clearly shown to be affected by behaviors and stimuli not related to vestibular nerve activity. Perhaps the most common nonvestibular input to the vestibular nuclei is an input from the visual system. Most vestibular nuclear neurons that are sensitive to head movements are also sensitive to movements of the visual world; that is, they are sensitive to optokinetic stimuli.[65] The semicircular canals are insensitive to low-frequency (<0.05 Hz) movements of the head. The visual system is capable of detecting extremely low-frequency movements of the visual scene, however. The brain uses visual information to supplement the information obtained from the labyrinth. The anatomic pathways by which the visual optokinetic signals reach the vestibular nuclei have not been completely worked out, but several midbrain pretectal nuclei (in particular, the nucleus of

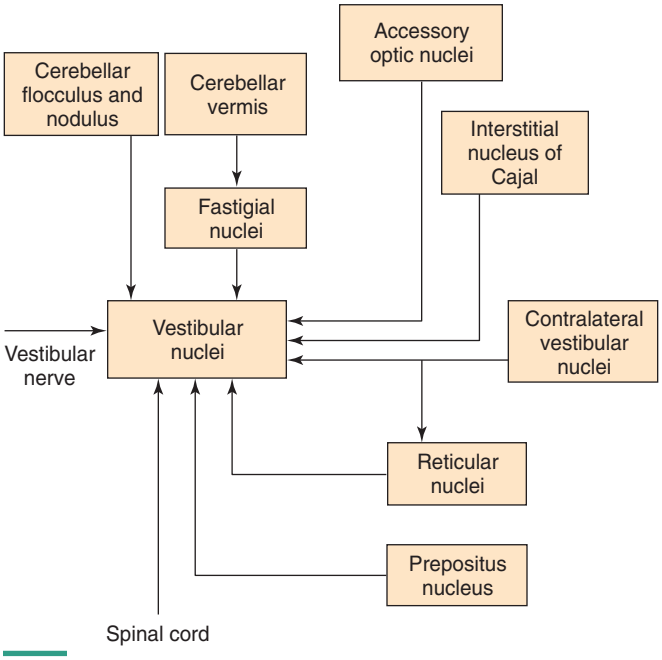

Figure 130-21. Afferent pathways to vestibular nuclei. See text for details. *(Schematic courtesy of Robert McCrea.)*

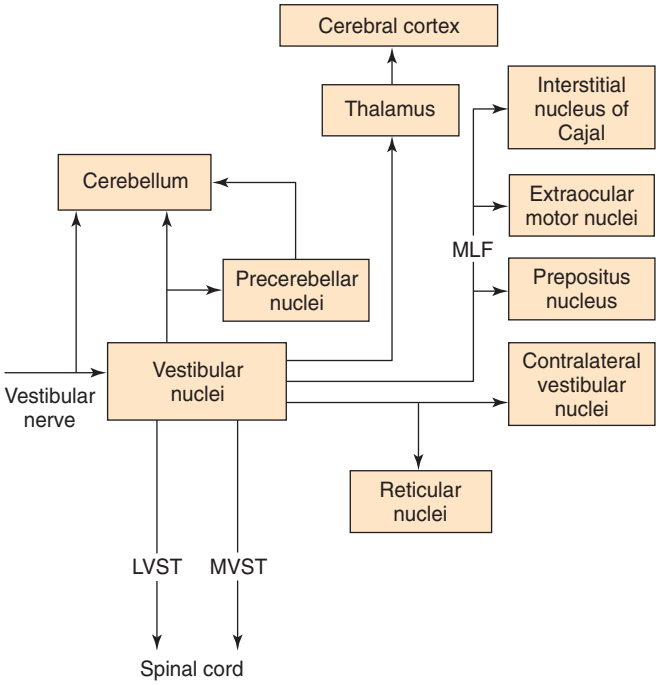

Figure 130-22. Efferent connections of vestibular nuclei. See text for details. LVST, lateral vestibulospinal tract; MLF, medial longitudinal fasciculus; MVST, medial vestibulospinal tract. *(Schematic courtesy of Robert McCrea.)*

the optic tract and the accessory optic nuclei) seem to play an essential role. These midbrain nuclei do not project directly to the vestibular nuclei themselves; rather, they project to other brainstem nuclei. These other nuclei project to the vestibular nuclei (e.g., the prepositus nucleus[66]) or to regions of the cerebellum that project to the vestibular nuclei (e.g., visual signals reach the cerebellum via the inferior olive[67] and the pontine nuclei[68]).

Pathways from the cerebellum to the vestibular nuclei not only contribute to the visual responsiveness of vestibular nuclear neurons, but also are essential for adaptive modification of the head movement sensitivity of vestibuloocular pathways and compensation for unilateral vestibular lesions. The cerebellar flocculus is particularly important for adaptive modification of vestibuloocular reflex pathways.[49,69] The Purkinje cells in this region of the cerebellar cortex are sensitive to optokinetic visual stimuli and to movements of small visual targets on the fovea.[70,71] When eye movements produced by vestibuloocular pathways fail to stabilize images on the retina, the Purkinje cells of the flocculus change their firing rate and modify the head movement sensitivity of some of the vestibular nuclear neurons that project to the extraocular motor nuclei.

As noted earlier, many of the neurons in the superior, medial, and ventral lateral vestibular nuclei change their firing rate during eye movements even when the head is not moving and the vestibular nerve activity is unchanging. In a study by Chen-Huang and McCrea,[72] the size of the utricular signal traveling to the oculomotor nucleus in the ascending tract of Deiters depended on the fixation distance. This finding implies the existence of an important neural multiplier system in the vestibular nuclei, and not a simple disynaptic relay between the utricle and the oculomotor nucleus. Vestibular nuclear neurons that project to the extraocular motor nuclei fire during steady fixation, saccadic eye movements, and ocular smooth pursuit.[73,74] The vestibular nuclei apparently contribute to the generation of each of these oculomotor behaviors. The regions of the brain that provide these oculomotor-related inputs include the prepositus nucleus,[75] the interstitial nucleus of Cajal,[76] and the pontine and medullary reticular formation.[77]

The spinal cord, particularly the cervical spinal cord, is another important source of nonvestibular afferents to the vestibular nuclei. The neurons in the dorsal lateral vestibular nucleus that project to the spinal cord also receive inputs from the spinal segments to which they project.[78] Neurons in the medial and ventral lateral vestibular nuclei that project to the extraocular motor nuclei receive inputs from the cervical spinal cord.[79] These inputs are probably important for mediating the cervical ocular reflex, which is a reflex that can help the vestibuloocular reflex to stabilize gaze during head movements, particularly when the labyrinth is damaged. These pathways provide a possible explanation for the nystagmus often seen after neck injury.

There are other nonvestibular inputs that are functionally important but whose anatomy is poorly defined. It is likely that some vestibular nuclear neurons receive inputs related to central autonomic functions and behavioral state (e.g., alertness). Several observers have noted that the spontaneous firing rate and sensitivity to eye and head movements of many vestibular nuclear neurons are profoundly reduced during slow wave sleep or reduced alertness despite the fact that vestibular nerve activity is apparently unaffected. The central anatomic pathways that mediate these effects are unknown. The major afferent connections to the vestibular nuclei are summarized in Figure 130-21.

Efferent Projection Pathways from the Vestibular Nuclei

The vestibular nuclei project to numerous regions of the brainstem, cerebellum, and spinal cord. In addition, the vestibular nuclei are highly interconnected. The intrinsic connections of the vestibular nuclei are not limited to the commissural pathways described earlier, but also include connections between the various vestibular nuclei on the same side of the brain.[48,61]

Figure 130-22 provides an overview of the major vestibular efferent projections. All of the vestibular nuclei except the dorsal lateral vestibular nucleus contain neurons that project to the cerebellum. The cerebellar vermis, the flocculonodular lobe, and the fastigial nucleus are the regions of the cerebellum to which these vestibulocerebellar pathways project.[80] These are the regions of the cerebellum that are thought to be involved in coordinating movements of the axial musculature, the head, and the eyes. The output of the cerebellar cortex is organized in parasagittal efferent strips.[81] There is an efferent parasagittal cortical strip in the vermis that projects to the neurons in the dorsal lateral vestibular nucleus that gives rise to the lateral vestibulospinal tract. Another efferent strip in the vermis projects to the fastigial nucleus. Strips in the cerebellar cortex of the flocculonodular lobe project to the neurons in the superior, medial, and lateral vestibular nuclei that give rise to the vestibuloocular reflex pathways.[69] There are reciprocal con-

nections between the vestibular nuclei and regions in the cerebellum that receive vestibular inputs.

The medial, superior, and ventral lateral vestibular nuclei give rise to major bilateral efferent projections to the regions of the brainstem involved in controlling eye movements.[82-84] The vestibular nuclei give rise to an important set of reflex pathways involved in the vestibuloocular reflex. The axons that make up these pathways usually join the medial longitudinal fasciculus near the abducens nucleus.

The function of the vestibuloocular reflex is to stabilize vision during head movements. This stabilization is accomplished by moving the eyes at the same speed as the head, but in the opposite direction. The vestibuloocular reflex pathways are organized reciprocally such that the motor neurons that innervate each extraocular muscle receive excitatory and inhibitory inputs from the vestibular nuclei. For more details on vestibuloocular reflex function, see Chapter 163.

A second major efferent vestibular pathway that aids in gaze stabilization is the medial vestibulospinal tract. This pathway originates from cells in the medial and ventral lateral vestibular nuclei and projects bilaterally in the medial longitudinal fasciculus to the ventral horn of the cervical spinal cord. Approximately half of these cells also contribute to the vestibuloocular reflex pathways via axon collaterals.[85] The medial vestibulospinal tract functions to stabilize the head on the shoulders by generating neck muscle contractions that resist passive movements of the head.[86]

The lateral vestibulospinal tract plays an important role in maintaining postural balance. This pathway arises from cells in the dorsal lateral vestibular nucleus and projects ipsilaterally to the ventral horn of the spinal cord, as far as the lumbar enlargement. The cells in the dorsal lateral vestibular nucleus are particularly sensitive to tilting of the head. The lateral vestibulospinal tract is tonically active and provides a powerful tonic excitatory synaptic input to postural extensor motor neurons. With unilateral labyrinthine lesions, the tonic excitatory input to ipsilateral postural extensors is reduced, particularly when visual cues are absent, and there is a tendency to fall toward the side of the lesion.

Vestibulothalamic pathways arise from cells in the ventral lateral vestibular nucleus and project to thalamic regions that border and include the ventral posterolateral, ventral posteromedial, and ventral lateral nuclei of the thalamus.[87-89] The vestibular nuclei also project to another thalamic nucleus, the ventral lateral geniculate nucleus.[90] This nucleus is adjacent to the dorsal lateral geniculate nucleus, and has anatomic connections that suggest it is involved in visual processing. Presumably, vestibulothalamocortical pathways play a role in the conscious perception of vertigo, or of self-motion, in the absence of visual stimulation.

CHAPTER ONE HUNDRED AND THIRTY-ONE

Anatomy and Physiology of the Eustachian Tube

Robert C. O'Reilly

Isamu Sando

Key Points

- The eustachian tube is involved in pressure equalization, mucociliary clearance, and middle ear protection.
- The principal dilator of the eustachian tube is the tensor veli palatini muscle.
- Anatomic changes in the tube with growth and development include increased length and diameter, increasing tubal angle, change in cellular composition of tubal cartilage, and increased efficiency of tubal opening.
- Tubal function can be adversely affected by viral and bacterial infections, adenoid disease, craniofacial anomalies, neoplasm, genetic predisposition, sinonasal disease, and gastroesophageal reflux.
- Current tubal function tests have limited prognostic value.

Since Eustachius first described the anatomy of his eponymous tube in 1563, understanding of its function in healthy and diseased ears has continued to evolve.[1] An anatomic connection between the middle ear space and the nasopharynx was recognized, but the role played by the eustachian tube was unclear. Although this connection was initially thought to be an organ of respiration, later observers realized that it was vital to the health of the tympanic membrane and middle ear as a whole. Pioneering otologists including Toynbee, Politzer, and Bezold developed a paradigm that held that the eustachian tube regulates and modulates the pneumatic status of the middle ear and mastoid to maintain the appropriate milieu for optimal sound transmission by the tympanic membrane and ossicular chain.

Initial concepts regarding the physiology of tubal function were found to be too simplistic. New information has led to a model of the eustachian tube as an "organ" because of its complex anatomy, function, and interdependent relationship with surrounding structures.[2] A comparison of early otology texts with contemporary work reveals an evolution of the study of tubal function from limited therapeutics applied directly to the tube to an attempt to understand and modify intrinsic and extrinsic pathologic influences on its function.

Embryology and Postnatal Development

The eustachian tube is derived from the first pharyngeal pouch.[3] The endoderm lining the tubotympanic sulcus invaginates between the first and second arch mesoderm to form the tubotympanic recess. The recess expands to form the tympanic cavity and the mastoid antrum. The osseous portion of the tube forms from the petrous and squamous parts of the temporal bone and the greater wing of the sphenoid bone. The cartilaginous tube has at least two discrete centers of chondrification.[4] In patients with cleft palate, there is often a deficiency in the development of the lateral lamina.[5]

The muscles associated with the tube are the tensor veli palatini (TVP), dilator tubae (DT) (which is the medial bundle of TVP muscle),[6] tensor tympani (TT), levator veli palatini (LVP), and salpingopharyngeus. These muscles appear early in development and form from the mesenchyme of the first (mandibular) arch together with the muscles of mastication.[7] The TVP, DT, and TT are innervated by the mandibular branch of the trigeminal nerve, whereas the LVP is innervated by the vagus nerve.[8] The TVP and DT change position during intrauterine development to form a more acute angle with the tube, particularly at the upper portion of the lateral lamina.[7,9,10]

The eustachian tube is patent during embryologic development, allowing for free flow of amniotic fluid into the middle ear space.[11] Early patency explains the occasional finding of keratin and lanugo hairs in the middle ear cleft in infants, and may limit the ability to detect otoacoustic emissions during newborn hearing screening. It is conceivable that this route of entry of squamous epithelium may produce a congenital cholesteatoma, although the more likely mechanism seems to be epidermoid formation from the ectoderm of the first pharyngeal cleft.[12]

The most rapid development of the petrous and squamous portions of the temporal bone occurs in the first 2 years of life, and eustachian tubal development parallels this.[13] Tubal length progresses from 17.5 mm in infants to reach an adult length of 37.5 mm. The length and area of the entire lumen increase more than twofold when comparing adults with young children, although the ratio of the cross-sectional diameter of the lumen to tubal length remains constant.[7,14,15]

The length of the osseous portion of the tube triples during development, whereas the cartilaginous tube increases 1.6-fold.[16] The cartilaginous (nasopharyngeal) portion of the tube is three times as large in adults as in children, and the cross-sectional area, and presumably the efficiency of the dilatory muscles, increases with age.[17,18]

More significantly, with an increase in cartilage size, there are important changes in cellular composition and shape with aging that result in a less "floppy" tube in adults compared with children. The cartilage cell density decreases in the midcartilaginous portion, and intercellular elastin, present in the hinge region between the medial and lateral laminae, is far more abundant in adults than in children. The

medial lamina develops more than the lateral lamina, and when viewed in cross section, the lateral lamina and lateral wall of the tube develop a greater "S" shape. These changes allow for more efficient tubal recoil.[14,19-22]

Other anatomic changes lead to an improvement in the efficiency of tubal function. During growth, there is a shift in the orientation of the cartilaginous portion to the osseous portion of the tube. When viewed from above, the long axis of the tube describes a greater curve with the increasing inferior and lateral movement of the cartilaginous tube. This augments middle ear protection.[16] Additionally, the angle of insertion of the dilatory muscles (DT) becomes more perpendicular to the cartilaginous tube, and the tube becomes more dependent relative to the middle ear cleft.[23] All these elements may play a part in the decreased incidence of otitis media with age.[15]

Anatomy

The function of the eustachian tube in pressure equalization, middle ear protection, and clearance can be understood only when its anatomic subtleties are appreciated. The tube is located in the skull base and connects the anterior portion of the middle ear cleft with the nasopharynx. Its anatomic course brings it close to many critical structures. The general shape of the eustachian tube can be described as two cones joined at their apices. It comprises an osseous, intratemporal portion and a cartilaginous, nasopharyngeal portion. These describe a gentle outward curve when viewed from above as it extends from the middle ear to the nasopharynx (Fig. 131-1).[7]

In adults, the osseous portion accounts for less than one third of the length of the tube, and the cartilaginous portion constitutes more than two thirds of the length, even if the central (junctional) region is considered part of the osseous tube.[15,16] The orifice of the tube in the middle ear originates in the anterior mesotympanum (protympanum), with the mouth of the tube above the level of the floor of the middle ear. The orifice is not dependent, unless the head is tilted forward. It is triangular to oval in shape with a diameter of 5 mm × 3 mm and marks the entrance to the osseous tube.[24] This portion of the tube progresses anteromedially to its isthmus portion along its longitudinal section of the petrous portion of the temporal bone.[25] The petrous bone surrounds most of the osseous portion of the tube except for a part of the lateral wall that is surrounded by the sphenoid bone (Fig. 131-2).[7] Because of the rigid walls in this anatomic segment, the lumen is always patent, unless obstructed by mucosal thickening or debris.

The osseous portion of the eustachian tube lies close to several structures (Fig. 131-3). The glenoid fossa of the temporomandibular joint is lateral and inferior to the osseous tube, the middle fossa dura lies superior, and the internal carotid lies medial. The medial wall of the tube is composed of two parts: a posterior labyrinthine portion and an anterior carotid portion.[26] The horizontal segment of the petrous carotid artery is capped by thin bone (see Fig. 131-2). This bone has been found to be dehiscent in 2% of normal adult specimens and exceptionally thin in 22.2%.[27,28] Distance between the bony wall and anterior tympanic anulus was found to be an average 4.9 mm. The TT runs just lateral to the midthird of the cochlea. Its semicanal can be found above the osseous tube on the nasopharyngeal side, but runs more medially as it approaches the middle ear. The average distance from the lumen of the tube to the dura of the middle fossa is 3.6 mm.[24] All these structures are in jeopardy when the tube is surgically manipulated, and caution must be exercised when removing disease from the lumen.

Approximately 33% of patients have pneumatization of the petrous apex, and the osseous tube can be variably surrounded by peritubal air cells. Computed tomography (CT) has revealed that in 92% of patients, these cells can open directly into the osseous tube anterior to its tympanic orifice. This opening may play a role in persistent cerebrospinal fluid rhinorrhea after cerebellopontine angle surgery despite packing of the tympanic orifice of the tube.[29]

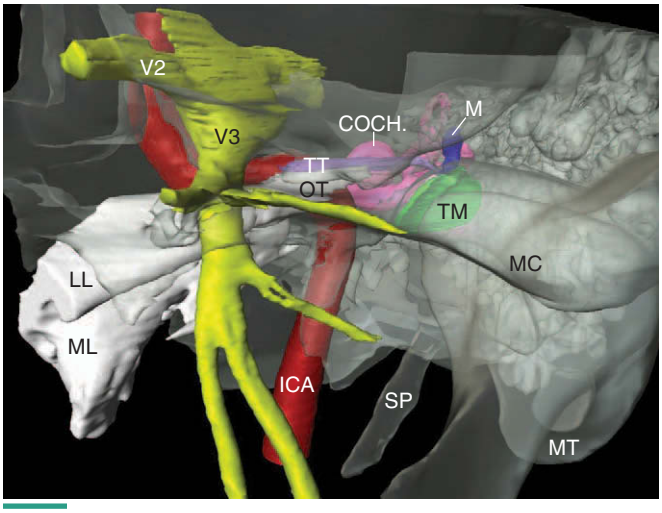

Figure 131-3. Lateral view of the left eustachian tube showing the relationship to adjacent structures. Figure 131-4. Photomicrograph of cross section of junctional portion of the eustachian tube. The eustachian tube cartilage (ETC) is suspended by the superior tubal ligament in the sulcus tubarius (STU). In this portion of the tube, the cartilage covers only the superior aspect of the lumen. The levator veli palatini muscle (LVP) originates from the inferior surface of the petrous apex. ICA, internal carotid artery; MMA, middle meningeal artery; TT, tensor tympani muscle. *Top,* Superior. *Right,* Medial. *(From Sando I, Ikui A, Sudo M. Microscopic sectional anatomy with 3-D reconstruction of the temporal bone. In: Janecks IP, Tiedemann K, eds.* Skull Base Surgery, Anatomy, Biology, and Technology. *Philadelphia: Lippincott-Raven; 1997:151-159.)*

The osseous portion of the tube progressively narrows as it approaches the cartilaginous portion. Small endoscopes 0.8 mm in diameter are able to pass through this region.[30] At its most anterior tip, the fibrocartilage of the cartilaginous tube extends slightly into the lumen of the bony canal. This area has been called the isthmus; however, it is not the narrowest part of the tube. Histopathologic studies measuring the circumference of the internal lining and the cross-sectional area of the tube have revealed that the narrowest portion of the tube in the closed and in the fully open positions lies in the proximal cartilaginous tube. Sando and coworkers[15] proposed that the divisions of the eustachian tube be reclassified as osseous (lumen surrounded by bone), cartilaginous (lumen surrounded by cartilage), and "junctional" (lumen surrounded by bone and cartilage) (Fig. 131-4).

The cartilaginous portion of the tube has a complex shape reflecting the nuances of its function (Fig. 131-5). It is composed of two distinct rhomboidal plates when viewed from the side, with a large medial lamina and a much smaller lateral lamina. These are joined at the apical hinge region. In three dimensions, the cartilage is bell-shaped with a largest transverse diameter of 9 mm. When viewed from the nasopharynx, the fibrocartilage is in a distinct "crook" shape with the longer arm located medially. Its projection into the nasopharynx is covered by a layer of respiratory mucosa and is distinctly seen on nasopharyngoscopy as the torus tubarius. Although the laminae are principally composed of fibrocartilage, the hinge region contains an abundance of elastic cartilage allowing for efficient tubal opening (Fig. 131-6). The nasopharyngeal opening of the eustachian tube lies opposite the lateral aspect of the choana behind the posterior end of the inferior turbinate. It is partially protected from nasal airflow. This location makes blind cannulation of the tube challenging.

At the skull base, the cartilaginous tube is fixed superiorly to a shallow depression in the bone of the greater wing of the sphenoid (sulcus tubarius). Laterally, it is held in place by the medial pterygoid plate. This base of support prevents vertical and rotational movement of the pliable cartilage during opening. The angle the tube forms with the Frankfort horizontal plane has previously been estimated in infants and children, using gross anatomic measurements, to be approximately 10 degrees. As the skull and midface expand vertically, and the hard and soft palates descend, this angle increases to 45 degrees in adults.[3] Imaging studies have revealed these angles in a Japanese population to

be approximately 20 degrees in infants and children and 27 degrees in adults, with adult angles reached at approximately 7 years of age.[31]

The adenoid pad occupies the area between the nasopharyngeal openings of the tubes. A depressed space medial to each torus forms the fossa of Rosenmüller, an area of particular interest in the diagnosis of nasopharyngeal carcinoma (Fig. 131-7). This fossa extends posterolaterally and superiorly to the area behind the midportion of the tube. The distance between the deepest part of the fossa and petrous apex was found to be only 4 mm.[32] Above this lies the foramen lacerum, a hiatus between the sphenoid and petrous bones, through which nasopharyngeal tumors may spread intracranially.

The muscles that allow for opening of the cartilaginous tube are arranged in a complex fashion. The principal and perhaps only dilator of the tube is the tensor TVP. It is composed predominantly of fast-twitch muscle fibers, but also contains slow-twitch fibers to maintain tone.[18] This muscle has several distinct segments. The main body of the muscle originates in the base of the skull at the angular spine of the sphenoid and the scaphoid fossa at the root of the medial pterygoid plate. It progresses in a lateral and anteroinferior direction to curve around the hook of the hamulus.[15] As it becomes tendinous, it fans out to insert into the aponeurosis of the soft palate and posterior edge of the hard palate. Secondary attachments in the maxillary tuber and the palatoglossal arch may be important in preserving muscle function after infraction of the hamulus during cleft palate repair surgery.[33]

The TVP is said to have three anchoring points on which it isometrically contracts: the pterygoid hamulus, Ostmann's fat pad, and the medial pterygoid muscle (Fig. 131-8).[34] The fibers roughly parallel the plane of the lateral lamina of the cartilaginous tube. An additional segment of the TVP originates from the area of the hamulus and projects more perpendicularly to this plane. It attaches to the short lateral lamina of the cartilaginous tube and to a condensation of connective tissue lateral to the tubal wall and a portion of Ostmann's fat pad.[35,36] This segment has been termed the DT and may be a separate muscle.

The TVP also is prolonged superomedially to form the muscle belly of the tensor tympani. The TVP continues in a posteromedial direction through the semicanal to emerge into the middle ear cleft through the cochleariform process; in middle ear surgery, this serves as a convenient marker for the first genu of the facial nerve in its tympanic segment. The tendon of the TT attaches to the medial aspect of the

handle of the malleus. Occasionally, this tendon must be divided to release the malleus during ossiculoplasty. Spasm of the TT can create a fluttering of the tympanic membrane and a "popping" tinnitus; this produces characteristic oscillations on open bridge tympanometric measurements. Although division of the TT tendon can relieve this condition, the otologist must be aware that the stapedius muscle may also be responsible.

Less important dilators of the cartilaginous tube include the levator veli palatini (LVP) and the salpingopharyngeus muscles. The LVP originates from the petrous apex. Here it lies medial to the tube, but its anterior segment is immediately inferior to the floor of the tube, separated by connective and fatty tissue.[15,16] It inserts in a radiating fashion into the nasal surface of the soft palate. The LVP has been observed to facilitate tubal opening by elevating the floor of the tube and moving the medial lamina toward the midline during contraction. The salpingopharyngeus attaches to the edge of the cartilaginous tube medially and is directed inferolaterally. Its role in tubal function remains speculative. Swallowing, yawning, and clenching teeth may activate all these muscles.[37]

The histology of the tubal lumen is vital to its action. The bony canal is lined by a prolongation of the low cuboidal, ciliated mucosa of the middle ear. After the junctional region is passed, the mucosa transitions to pseudostratified, ciliated, columnar epithelium identical to the epithelium lining the upper respiratory tract.[38] The density of ciliated and goblet cells gradually increases in a distal and inferior direction.[39,40] Within the cartilaginous tube, the floor of the triangular-shaped lumen is different than the walls. The floor contains an abundance of mucus-producing goblet cells and is heavily rugated; in the upper half of the tube, the walls contain far fewer goblet cells and are generally smooth. It has been suggested that the lower half of the tube is principally involved with clearance of the mucociliary blanket, whereas the upper half is important to pressure equalization and gas exchange.[15]

Mucosa-associated lymphoid tissue is found submucosally throughout the eustachian tube and is particularly prominent around the inferior half of the cartilaginous tube.[41] This tissue may be a factor in luminal obstruction when inflamed. The lateral mucosal wall is bounded laterally by a collection of adipose tissue termed Ostmann's fat pad.[42,43] This tissue represents one segment of a collection of adipose tissue around the tube and is in the shape of a cone with the base anterior. During conditions of metabolic stress, loss of this fat results in an abnormally patulous eustachian tube.

The arterial supply to the osseous tube consists of a branch of the accessory meningeal artery called the tubal artery and the caroticotympanic arteries arising from the internal carotid artery. The superior tympanic artery, which originates from the middle meningeal artery, supplies the TT. The deep auricular and pharyngeal arteries from the internal maxillary artery, the ascending palatine artery, and the ascending pharyngeal artery supply the cartilaginous tube. The venous drainage generally parallels the arterial supply with the pterygoid venous plexus of particular importance.[44,45] Manipulation and air insufflations of the eustachian tube can result in intracranial complications owing to intracranial venous anastomoses, proximity of the internal carotid artery, and potential osseous dehiscence of the skull base.[46-50]

Physiology

The proper and efficient functioning of the eustachian tube is vital to the health of the ear. The tube is said to have several functions related to the middle ear, including pressure equalization, mucociliary clearance and "drainage," and protection from the influences of the nasopharyngeal environment and loud sounds. Understanding of tubal function and the ability to measure its function accurately continues to evolve.

Pressure Equalization

In its resting state, the cartilaginous tube is closed at its nasopharyngeal orifice. As pressure external to the middle ear cleft changes with fluctuations in atmospheric pressure and during nonphysiologic pressure alterations (e.g., airplane flight, diving in water), it must open to equalize middle ear pressure to ambient pressure. This opening allows for a state conducive to efficient sound conduction through the tympanic membrane and ossicular chain. This pressure equilibration is also accomplished by bidirectional gas exchange and transudation of fluid.[51]

During swallowing, the muscles that dilate the eustachian tube are activated; this occurs during a pause in respiration in the expiratory phase.[51] As the soft palate is elevated and seals the nasopharynx, the TVP isometrically contracts providing a base of support for the DT. This muscle pulls on the lateral lamina and the connective tissue lateral to the tube. The superior half of the tube is typically C-shaped at rest. With lateral movement of the lateral lamina, owing to the hinge action between the laminae where the elastin fibers are in abundance, it becomes more circular in cross section.[3,14,52] The medial lamella remains relatively rigid, and the sequence of muscular contraction allows for concerted tubal opening and flow of gas. Because the cartilaginous tube extends slightly into the osseous tube between the semicanal of the TT and the tubal lumen, there is no crimping of the tube during dilation. Other mechanisms that can initiate tubal opening include yawning, sneezing, and, in some patients, forced pressurization by swallowing with a closed glottis (Toynbee maneuver) or with insufflations of air (politzerization).

Slow-motion videoendoscopy has revealed four steps in tubal opening: (1) palatal elevation with medial movement of the lateral pharyngeal wall and medial rotation of the medial lamina (initiation of opening of the distal cartilaginous tube presumably by the LVP), (2) lateral movement of the lateral wall with dilation of the orifice laterally and vertically, (3) propagation of dilation of the tubal lumen from distal to proximal by the TVP/DT, and (4) opening of the proximal cartilaginous tube adjacent to the junctional region with formation of a round to crescent-shaped lumen.[53] During this event, the tube remains open for 0.3 to 0.5 second, but is open much longer during yawning.[51] In normal individuals, the eustachian tube fully opens once or twice hourly.[54]

To be fully opened, the dilatory muscles must overcome the intraluminal surface tension generated by the apposition of the mucosal surfaces. Surfactant protein B, similar to that obtained in bronchoalveolar lavage, has been identified in the secretory granules of surface cells lining the eustachian tube. The ability of surfactant to reduce the opening pressure in the eustachian tube has been shown experimentally.[55-58] The surface tension in the normal eustachian tube is typically 58 mN/m, but is elevated in serous and mucoid otitis media.[56,59] Tubal surface tension is also influenced by the amount and composition of tubal secretion. This is under control of the autonomic nervous system, and increased parasympathetic transmission has been shown to impair tubal opening.[60]

Tubal closure depends on adhesion of the intraluminal mucous blanket, elastic forces of the supporting tissues, and hydrostatic pressure of venous blood.[51] The position of Ostmann's fatty tissue in the posterolateral half of the tube enables it to assist in restoring the tube to its closed position.[61]

According to the classic theory of eustachian tube dysfunction suggested by Politzer in the 19th century, the gas contained in the middle ear/mastoid system tends to be absorbed into the bloodstream by the capillaries of the middle ear/mastoid mucosa when the tube is hermetically sealed.[62] This was termed the "hydrops ex-vacuo" model. Although under normal conditions the middle ear maintains a very slight negative pressure a few millimeters of H_2O lower than the nasopharynx, unless the tube periodically opens, the absorption of gas would result in a large negative pressure differential.[63] Mechanical obstruction of the tube or impaired opening of the tube predisposes to middle ear pathology. In histologic specimens of patients with otitis media, the cross-sectional area of the tubal lumen tends to be smaller than in patients without otitis media, particularly in the osseous portion.[64] This is due to a combination of submucosal inflammatory infiltrates and an increased density and hyperplasia of goblet cells.[65]

The continuity of the middle ear cleft to the volume of gas in the mastoid air cell system is likely to be important in pressure equalization. Bluestone and colleagues[66] described a "flask" model in which the volume supplied by the mastoid air cell system acts as a buffer protecting against abrupt pressure changes and reflux of nasopharyngeal secretions into the middle ear. A well-developed mastoid air cell system facilitates maintenance of normal middle ear pressure, although the

mastoid mucosa is unlikely to be important in gas exchange because of its paucity of submucosal blood vessels. More likely, the mastoid mucosa acts as a simple pressure reservoir according to Boyle's law.[67] The mastoid air cell system is often found to be hypoplastic in patients with chronic ear disease, although it has not been determined whether this is a result of or a contributor to this disease.[68,69]

Bidirectional gas exchange in the middle ear also facilitates maintenance of ambient pressure. The gas composition of the middle ear is similar to venous blood. This similar composition reflects a bidirectional exchange in middle ear homeostasis; otherwise, the gas composition would more closely resemble air. Under conditions of mucosal inflammation, this process is disturbed. Dilation of the mucosal vessels leads to increased perfusion. Nitrogen clearance into the blood may exceed the rate that may be balanced by eustachian tube ventilation. A vacuum is created, and, at negative pressures less than 100 mm H_2O, it is possible to develop a transudation of serum in the middle ear.[67]

Proponents of the "classic" theory of eustachian tube function have focused on the opening capability of the tube; however, other investigators have suggested that a failure of closure of the eustachian tube under normal physiologic conditions is to blame for middle ear pathology.[51] Experimental observations show that middle ear tympanometric pressures are positive after sleep or time spent in the supine position, and cannulation of the eustachian tube in an animal model leads to an egress of gas from the middle ear. Specifically, carbon dioxide preferentially diffuses from the bloodstream into the middle ear, and nitrogen contained in air is sequestered in the middle ear because of its slow diffusion into the bloodstream. Hypoventilation with increasing serum carbon dioxide levels (during sleep) can lead to a positive middle ear pressure that moves to a slight negative gradient when the person is erect and breathing normally. Based on this observation and others that in most cases of otitis media the eustachian tube is not found to be physically obstructed, otitic conditions may reflect an abnormally compliant eustachian tube. With sniffing, the tube would be susceptible to opening, and evacuation of the middle ear gas would produce negative pressure.[51,70]

Mucociliary Clearance and Drainage

Clearance of the middle ear cleft depends on programmed movement of the mucous blanket out of the eustachian tube. The middle ear mucosa and respiratory epithelium of the tube are covered with cilia that transport the mucous blanket from the tympanic orifice of the tube toward the nasopharynx. The morphology of the cartilaginous tube reflects this function. The dependent floor of the tube involved in clearance is rich in goblet cells and is corrugated; the superior portion of the tube involved with ventilation/pressure equalization is smooth and lacks mucus-producing cells.

Mucus of the tube is composed of a thick, more superficial, gel phase and a thin sol phase. The cilia move in the sol phase with their tips contacting the overlying gel phase, propelling the mucous blanket. Surfactant potentiates the movement of the gel over the sol phase.[56,71,72] Mucins are high-molecular-weight glycoproteins and constitute the major component of the mucous secretions.[73] Nine human mucin genes have been identified, and their expression is epithelium specific. They lubricate the epithelial surface, and trap bacteria and viruses. Mucin genes, particularly *MUC5AC,* have been found to be upregulated in otitis media.[74] The periciliary fluid is provided by serous epithelial cells and a group of integral membrane proteins called aquaporins that facilitate the passage of water through cell membranes.[75]

The tympanic opening of the tube lies above the level of the floor of the hypotympanum. Tube transport is an active process that is not gravity dependent. Material instilled through tympanic membrane perforations in humans and experimentally placed in the middle ear cleft of animals is actively cleared into the nasopharynx.[76-78]

Disturbance of this mechanism leads to a propensity to develop otitis media. This propensity is particularly apparent in conditions such as primary ciliary dyskinesia, in which otitis media is almost universal.[79-81] The viscosity of the mucus, as determined by the ratio of its component materials, is important to ciliary beat frequency. Conditions of hyperviscosity, such as those found in sinusitis, middle ear effusions, and cystic fibrosis, lead to reduction in beat frequency and efficiency of mucociliary clearance.[56,82,83]

Impairment of ciliary action by upper respiratory viruses is intrinsic to the development of otitis media. After viral damage, ciliated cells may take 1 month to regenerate.[84] Bacterial infection also leads to compromise of mucociliary clearance through the release of endotoxins and the stimulation of injurious inflammatory pathways.[85-88] This process disrupts middle ear protection and has been shown experimentally. Nasopharyngeal radiographic tracers enter the middle ear cleft of children with otitis media, but not children who are otologically normal.[76,89] Physiologically, this "reflux" up the eustachian tube is less difficult when the tympanic membrane is perforated because the middle ear and mastoid gas "cushion" is removed.[2]

Middle Ear Protection

In the resting state, the middle ear is protected from the bacterial environment of the nasopharynx by the closed orifice of the cartilaginous tube and innate protective mechanisms present within the tube. This protection is particularly important because the bony portion of the tube remains permanently open.

The middle ear space typically is sterile and has very few immunocompetent cells.[90] It develops an immune response only after inflammation has occurred. When bacterial organisms reach the middle ear space, the cascade of inflammatory events leads to migration of immunocompetent cells (lymphocytes) and antigen-presenting cells (macrophages). Local immunologic mechanisms and normal bacterial flora in the nasopharynx assist in protection from bacterial pathogens. Secretory IgA from the nasopharyngeal immune system and possibly antigen-specific IgA in breast milk reduce nasopharyngeal colonization with pathogens that are typically present, but in small numbers (*Streptococcus pneumoniae,* nontypable *Haemophilus influenzae,* and *Moraxella catarrhalis*).[91] The ratio of commensal organisms (viridans streptococci) to potential pathogens in a healthy subject is greater than 5 : 1 and helps to down-regulate the spread of the pathogens.[92]

Respiratory viruses can disrupt tube bacteriology. Viruses have been shown to predispose to otitis media by (1) releasing cytokines and inflammatory mediators in the nasopharynx causing tubal dysfunction, (2) increasing nasopharyngeal colonization with bacterial pathogens, and (3) altering the host immune response through immunosuppression of cell-mediated immune response.[93]

Sterility of the middle ear space is also guarded by molecules of innate immunity secreted by the tubal mucosa.[73] Antimicrobial molecules that function through various mechanisms are all actively secreted into the tubal lumen.[73] These include lysozyme (muramidase that creates cell wall disruption), lactoferrin (iron-binding glycoprotein that acts synergistically with immunoglobulins), beta defensins (antimicrobial peptides that increase permeability of cell walls), and colectins (oligomeric polypeptide chains that bind microbial carbohydrates assisting phagocytosis). Additionally, cellular proliferation in the lymphatic tissue associated with the tube (mucosa-associated lymphoid tissue) plays an important role in the local immune response. Lymphocyte trafficking into the middle ear during inflammation has been shown.[90,94]

Surfactant proteins found in the eustachian tube lining may play a more important role in host defense than eustachian tube opening. They are apparently prophagocytic and anti-inflammatory.[56] Surfactant is a mixture of mostly phospholipids and one of four surfactant proteins (surfactant protein A through D) that are tissue-specific.[95] The most abundant surfactant protein in the eustachian tube is SP-A, produced in the tubal floor.[96] The primary role of surfactant protein A seems to be mucosal defense through facilitation of phagocytosis. The principal role of surfactants in antimicrobial defense may be as releasing agents and antiadhesives.[56,97]

Sound protection is also an important function of the eustachian tube. Sound pressure generated by the glottis can reach a high level in the pharynx and oral cavity, and would be transmitted directly through the tube into the middle ear unless the tube remained sealed. The tube also is involved in sound protection from loud noises in the external auditory canal that impinge on the tympanic membrane. It has been

shown experimentally that these sounds lead to a coordinated contraction of the stapedius, TT, TVP, and DT muscles. This muscle contraction causes the middle ear cleft, mastoid, and nasopharynx to form one continuous cavity assisting in dissipation of sound pressure. This muscle contraction also seems to be a generalized response to noxious stimuli.[37,98]

The eustachian tube is involved in sealing the middle ear from nasopharyngeal airflow. The nasopharyngeal orifice of the eustachian tube is directly in the intranasal respiratory stream, but autophony and an audible movement of the tympanic membrane with breathing occur only when the tube is abnormally patulous. In this condition, otoscopy reveals synchronous movement of the tympanic membrane with respiration and swallowing. There is no widely accepted or definitive treatment for a patulous eustachian tube. Therapeutic initiatives have included application of caustics to the torus tubarius to promote tubal closure, section of the TT muscle, occlusion of the osseous tube, and myringotomy tube placement.[99-102] Endoscopic examination of the patulous eustachian tube has revealed a scaphoid defect in the superolateral surface of the orifice of the cartilaginous tube. This area has been termed the "tubal valve," and relief of autophony has been achieved by submucosal graft implantation to restore convexity.[103]

Eustachian Tube Dysfunction

Under nonphysiologic pressure changes, such as ascent or descent in an airplane, hyperbaric oxygen treatment, or diving in water, the function of the eustachian tube is stressed. When the condition change involves a decrease in ambient pressure relative to the middle ear (ascent in an airplane or from a dive), the eustachian tube opens readily, and "overpressurized" middle ear gas passively opens the tube, assisting in active dilation during swallowing. During descent, if the tube is not frequently opened, it may "lock" from increasing negative pressure in the middle ear. This can induce barotrauma with resulting middle ear effusion, with the possibility of hemorrhage (hemotympanum), tympanic membrane rupture, and perilymph fistula. Delayed barotrauma may occur in a diver who descends using pure oxygen because this would be principally concentrated in the middle ear. On ascent, the oxygen diffuses into the circulation more rapidly than it can be replaced by inhaled nitrogen, setting up a middle ear gas deficit and negative pressure.[67]

Tubal opening is adversely affected by the supine position because it results in engorgement of the pterygoid venous plexus and protrusion of the lateral wall of the eustachian tube toward the lumen.[104] This can be a diagnostic clue in a patient with an abnormally patulous tube because typically symptoms are relieved or improved by lying flat. The importance of the peritubal venous system can be dramatically shown in patients receiving hemodialysis. Although they can develop dysfunction of the eustachian tube through ossification of the medial lamina and Ostmann's fat pad, a patulous condition has been noted to develop after hemodialysis, presumably from a decrease in extraluminal hydrostatic pressure.[105,106]

In adults with eustachian tube dysfunction, abnormalities in lateral wall movement have been documented. The most common pathologic finding is mucosal edema of the lateral wall resulting in inadequate lateral excursion. Other observed pathologies include inadequate or abnormal muscular movements and disorganization or absence of the typical dilatory wave.[107] Attempts have been made to correlate the degree of dynamic dysfunction with manometric studies and severity of middle ear disease.[108]

The pathophysiology of otitis media most certainly relates to dysfunction of the eustachian tube and failure of middle ear pressure regulation, despite controversies regarding the exact mechanisms. Middle ear effusions have been produced by viral inoculation of the nasopharynx and paralysis of the tubal muscles.[109-110] Generally, tubal dysfunction can be mechanical from intraluminal (middle ear pathology, inflamed mucosa, polyps) or extraluminal (hypertrophic adenoids, nasopharyngeal neoplasm) blockage, or can be functional (inability to dilate the tube actively).[111] Both mechanisms may coexist and may lead to a relative middle ear negative pressure. Depending on its severity, this negative pressure may result in atelectasis and vasodilation of the tympanic membrane.

Although only a minimal decrease in middle ear pressure has been experimentally measured under these conditions, it is sufficient to produce an effusion. In serous otitis media, this effusion has the characteristics of an inflammatory exudate.[63,112] Over time, nasopharyngeal bacterial contamination of the effusion can result in recurrent acute otitis media. It has been postulated that the mucous produced in this inflammatory state obstructs the lumen of the eustachian tube and is held in place by the negative middle ear pressure. A myringotomy relieves the negative pressure and allows the plug to be propelled into the nasopharynx.[67] Although inflammation progresses from the eustachian tube to the middle ear cleft, and resolution of inflammation follows an opposite course, the degree of mucosal inflammation in the middle ear does not always parallel the degree of inflammation in the lumen of the eustachian tube, and studies have shown that rarely is the eustachian tube completely, intraluminally blocked in otitis media.[111,113-115] Shambaugh and Glasscock[116] have described the clinical appearance of the phases of otitis media: the negative pressure "hyperemic phase" followed by the exudative and suppurative phase. If the tubal function improves, a phase of resolution ensues in which the remaining serous effusion slowly resolves. Persistence of eustachian tube dysfunction can lead to persistent serous effusion (serous otitis media) or proteinaceous concentration in the effusion (mucoid otitis media) with the possibility of irreversible atelectasis, contraction, and adhesion of the tympanum.

Anatomic changes relevant to pressure equalization and middle ear protection occur with aging and likely account for a difference in susceptibility to otitis media. The ability to equilibrate negative middle ear pressure is less efficient in children than adults, and the protective function of the tube seems to be compromised in children.[117,118] The shorter length of the tube, its more horizontal orientation, and relative compliance of the cartilaginous portion allow it to be forced open by nasopharyngeal pressure. The shallower alignment of the tube counteracts gravitational forces and theoretically makes mucociliary clearance less efficient. An infant feeding in the supine position is susceptible to nasopharyngeal pooling and retrograde flow. These anatomic points do not seem to account completely for the susceptibility to otitis media, however. Although the angle and length of the eustachian tube have been found on CT studies to be more horizontal, shorter, and straighter in children than in adults, no differences were found in these parameters between children with and without otitis media.[31]

Other important influences on tubal function and susceptibility to otitis media have been identified, including adenoidal hypertrophy, allergy, sinonasal disease, craniofacial anomalies such as cleft palate and Down syndrome, neoplasm, extraesophageal reflux, and genetic predisposition.[119] Hypertrophic adenoids may extrinsically compress the nasopharyngeal orifice of the tube, and may act as a bacterial reservoir in cases of chronic infection (Fig. 131-9). Hyperplasia of the lateral portion of the adenoid pad adjacent to the torus tubarius seems to be particularly important in this phenomenon.[120] Patients with a large adenoid pad and shallow nasopharynx are predisposed to middle ear effusion and negative middle ear pressure.[121] Adenoidectomy has been shown to improve manometric measures of eustachian tube function and diminish needed myringotomies in children.[122,123] The removal of a source of chronic infection may be more important than direct effects on tubal function.[124] With advancing age, the volume of the adenoid tends to regress, modifying its effect on the patency of the eustachian tube.

Nasal allergy may affect tubal function through mucosal inflammation. Four mechanisms of action have been proposed with varying levels of proof: (1) targeting of middle ear mucosa in the allergic reaction, (2) eustachian tube obstruction by mucosal edema, (3) inflammatory obstruction of the nose and nasopharynx, and (4) insufflation or reflux of allergic nasopharyngeal secretions into the middle ear.[125]

In a patient with cleft palate, persistence of eustachian tube dysfunction and susceptibility to otitis media seem to be related to anomalies in the course and insertion of the TVP and the shape and development of the cartilaginous tube. Anomalies include a poorly developed lateral lamina that does not describe the typical "S" shape with the lateral tubal wall and an abnormal attachment of the TVP to this lamina (Fig. 131-10).[5,20,126] In some patients with cleft palate, the abnormal position of the LVP causes the muscle to occlude rather

than open the tube during contraction.[127] Of patients with cleft palate, 96% have middle ear disease, and nearly 50% require more than one set of myringotomy tubes.[128] Tubal dysfunction does not improve with repair of the cleft despite the fact that there is a trend toward improvement with age. Improvements in tubal function after cleft repair seem to be contingent on the integrity of the pterygoid hamulus and the TVP.[34]

In patients with neoplasms of the nasopharynx, eustachian tube function can be disturbed by occlusion of the nasopharyngeal orifice of the tube and, more commonly, by direct invasion of malignant cells into the paratubal muscles causing functional obstruction (Fig. 131-11).[129-131] In either case, unilateral serous otitis media should raise suspicion of a mass lesion in the nasopharynx. Eustachian tube dysfunction and serous otitis media commonly persist after surgical resection and radiation therapy of the nasopharynx.[132,133]

Extraesophageal reflux seems to play a role in the pathophysiology of otitis media through disruption of eustachian tube function. Animal experiments of simulated extraesophageal reflux have produced clinically apparent eustachian tube dysfunction. Additionally, pepsin, a gastric, proteolytic enzyme, has been identified in the middle ear space of patients with otitis media.[134-136]

There apparently is a hereditary component to eustachian tube dysfunction. Racial differences in the prevalence of otitis media have been documented notably in Native American and Inuit populations.[45] In a prospective study of monozygotic and dizygotic same-sex twins and triplets, the correlation of the proportion of time with middle ear effusion between sibs was consistently higher in the monozygotic twins and triplets.[137] It is unclear if the hereditary factors are purely anatomic, such as mastoid pneumatization or eustachian

tube anatomy, or also include intrinsic immunologic protective mechanisms.[138-140]

Assessing Function of the Eustachian Tube

The clinical utility of eustachian tube function tests is currently limited. None are uniformly able to determine the adequacy of tubal function in candidates for surgical closure of a tympanic membrane perforation or to assess the risk of otitis media in candidates for myringotomy tube placement.[141] Perhaps the shortcoming is that these tests involve nonphysiologic conditions.[51] The results of single tubal function tests have been found to have low prognostic value because of pronounced intraindividual variability.[142] Often, "normal" subjects cannot equilibrate middle ear pressure during eustachian tube function, but they do not have signs or symptoms of otologic disease.[143,144]

Generally, tubal function tests are of two types: tests that measure passage of air through the tube, and tests that measure active muscular opening of the tube.[46] Tympanometry is an adjunct measure that determines the flow of acoustic energy through the middle ear system (immitance testing) and indirectly measures eustachian tube function by determining the relative middle ear pressure. Tympanometry can be used during tests of tubal function to determine objectively middle ear pressure changes.

Tests that measure airflow through the tube include inflation and deflation tests. The Politzer test involves placement of a rubber reservoir with a nasal tip into the nostril while occluding the contralateral nostril. When the patient swallows or phonates, with elevation of the palate, air is forced into the nasal cavity. In the Valsalva test, the patient pinches the nose and attempts to exhale with a closed mouth forcing air into the tube.

The Toynbee test is performed similarly, but involves a swallow while the nose is occluded. The Toynbee test is considered positive if an alteration in middle ear pressure is measured by tympanometry before and after the test (in an intact tympanic membrane) or during the test (in a perforated tympanic membrane). An expansion of the Toynbee test that may be performed in an ear with an intact tympanic membrane is the nine-step inflation-deflation tympanometric test developed by Bluestone.[145] This test involves measurements of the patient's ability to equilibrate applied positive and negative pressures with swallowing. It gives useful information about tubal function when positive, although even normal children can have trouble performing the test.[145]

The forced opening test may be performed in a patient with a perforated tympanic membrane and involves placement of positive pressure in the external canal. The pressure is recorded continuously, and the pressure is increased until a sudden decrease occurs when the tube opens ("opening pressure"). In healthy ears, a slight positive pressure remains ("closing pressure"). This test may also be performed with the patient swallowing (forced response test) with the resistance to airflow through the tube measured during the resting condition (passive resistance) and at the moment of swallowing (active resistance).[51]

The active opening of the tube can also be measured by sonotubometry. A constant sound is applied to the nostril, while a microphone in the external auditory canal measures the transmitted sound pressure. The sound levels are measured with the patient swallowing. An increase in sound pressure in the ear canal of 5 dB or more is considered indicative of tubal opening.[146] Advantages of this measure include assessment of tubal function under physiologic conditions without externally applied pressure and the ability to perform it with an intact tympanic membrane. Continuous middle ear pressure measurements can also be performed for long periods, but these require a perforated tympanic membrane and the use of a wearable measuring unit with a stable measuring system.[147]

Treatment of Eustachian Tube Dysfunction

Since Armstrong reintroduced Politzer's concept of myringotomy with insertion of pressure-equalizing tubes, this procedure has become commonplace in the treatment of eustachian tube dysfunction.[148,149] In a systematic review, oral and topical intranasal steroids alone or combined with antibiotics were found to hasten the resolution of otitis media with effusion in the short-term, but there was no evidence of long-term benefit.[150] More recently, surgery targeting mucosal edema impairing function of the cartilaginous tube has been successful. Laser and microdébrider removal of tissue from the "posterior cushion" overlying the medial lamina has been shown to improve tubal function.[151-153] Extreme care must be taken to stay superficial to this lamina, however, to prevent injury to the underlying carotid artery.

CHAPTER ONE HUNDRED AND THIRTY-TWO

Neural Plasticity in Otology

Robert V. Harrison

Key Points

- Neural plasticity underlies many clinical events in otolaryngology. Adaptation to a vestibular insult, rehabilitation after hearing loss, and auditory learning after a cochlear implant all are mediated by "neural rewiring."
- In the studies described, changes to the pattern of peripheral input in the auditory system always have an effect on central neural organization. Cochlear hearing loss does not imply simply cochlear dysfunction, but a change in the whole ascending auditory pathway up to and including cerebral cortex. After a period of deafness, many functional and structural changes occur in the auditory brain. In part, these can be reversed by stimulation with a hearing aid or cochlear implant.
- Neural plasticity is age-related. Maximum change or compensation can be expected in early development. For interventions such as a cochlear implant or hearing aid for a congenitally deaf child, the earlier the intervention is applied, the better. This imperative requires the early detection and diagnosis of hearing loss, such as afforded by universal neonatal hearing screening.

For centuries, much has been known about neural plasticity, but that precise term has not always been used to describe the phenomenon. Otologists have observed recovery of vestibular and auditory function after inner ear insult, calling these processes "adaptation" or "rehabilitation." Clinicians have observed the significant progress achieved in speech understanding and language development in hearing-impaired children fitted with an auditory prosthesis. This process has simply been called learning to hear.

It has been recognized for a long time that whatever the lesion or disease, a recovery of function is better achieved in infants than in adults. Otologists now use terms such as "age-related plasticity" and "critical period" to express the notion that, during early development, neural plasticity is greater and has more potential than in a more mature brain. Many examples also exist of how the adult brain maintains a high degree of neural plasticity; this is manifest in the learning and memory mechanisms that humans have throughout life. What is most different between the developing brain and the mature brain is, however, the ability of the former to recover function after serious lesions or sensory deficits.

Increased awareness about neural plasticity has been fueled by many basic science experiments, which have illustrated clearly how the neural networks in the brain reorganize after various manipulations of sensory input. This body of work has been paralleled by even more basic level studies on the neuronal and synaptic mechanisms that can mediate the plastic changes. Scientific reductionism has not stopped there, for we now enter the era of genomics, which promises to explain, among other things, how genes control neurotransmitter synthesis and secretion from presynaptic sites, and the synthesis and distribution of ion channels of the postsynaptic cell membrane. In this chapter, we do not consider mechanisms at this molecular level of organization; the focus is on cellular and systems level physiology.

In this chapter, we review some examples of neural plasticity as they pertain to the auditory system. These examples are laboratory experiments and clinical studies that illustrate neural plasticity at work. For the most part, we concentrate on the auditory system. This system, following perhaps in the wake of pioneering studies in visual and somatosensory systems, has provided much direct knowledge about the neurophysiology of plasticity. This chapter does not specifically consider the plasticity in the vestibular system. Plastic change in this system, as manifest in the recovery of balance function after peripheral lesions, is well known to clinicians, and there is extensive literature on the plasticity of the vestibular ocular reflex in human and animal experiments. Although we do not consider these in detail, behind the specialized complexity of all sensory organs there lies a brain, whose neural elements tend to follow similar rules, independent of their source of excitatory input. In this sense, the examples of auditory system plasticity given in the following sections and the discussion of basic mechanisms are as relevant to the vestibular system as they are to any other sensory system.

In the following sections, we carefully define what we mean by plastic change in otology. We discuss different types of plasticity and introduce the important distinction between developmental plasticity and adult plasticity. We then consider in detail experimental studies that serve to illustrate key aspects of plasticity in the auditory system. This is followed by a review of some important underlying mechanisms of plasticity. We consider these mechanisms at a systems physiology level, and at more basic cellular and subcellular levels. The review is far from exhaustive, and can be supplemented by other key studies[1-8] and the more comprehensive textbooks listed under Suggested Readings. In the final section, we discuss what this new knowledge about sensory system plasticity means to the otologist or hearing health care professional.

Definition of Plasticity

A broad definition of *plasticity,* as it pertains to otology, is the inherent ability of the auditory (or vestibular) system to modify or reorganize. The term "plasticity" is used to cover a wide spectrum of phenomena, and it can mean different things to different people. Consider the variety of experimental methods that have been used to reveal plastic change in the auditory system. Various anatomic studies have established that plasticity relates to physical change in the brain. Some of the earliest observations made, including the pioneering work of Levi-Montalcini,[9] were of the anatomic changes to auditory pathways after experimental lesions to the inner ear. In such studies, cell counts, axonal pathway changes, and alterations to neural structure were observed to

follow partial or total auditory deafferentation. Further examples of anatomic studies of plasticity in the auditory system are given in a subsequent section.

The research literature also contains many physiologic studies in which short-term or long-term change in central auditory system function has been observed after experimental manipulations to auditory input. In this chapter, many of these studies are presented in detail. The methods for the evaluation of plasticity of auditory function include various electrophysiologic studies in animal models (see later sections) and in humans,[10,11] and functional neuroimaging methodologies. The latter include positron emission tomography, functional magnetic resonance imaging, and magnetoencephalographic studies.[12,13]

Finally, myriad behavioral studies have monitored hearing performance change after some manipulation of auditory input. These studies range from systematic, well-controlled psychophysical experiments, to clinical outcome studies, to simple post-treatment observations of patients. In regard to this last category, any clinician who has noted an improved sensory function, over time, in a patient with a hearing (or vestibular) loss, or a performance change after some intervention, has observed neural plasticity in action.

Time Course of Plastic Change

The term "plasticity" is currently used in auditory neuroscience to describe phenomena that differ considerably in their time courses. Plasticity is used to describe changes to the auditory system occurring very rapidly, over a span measured in minutes, and much longer term changes over weeks, months, and years. As an example of acute plasticity, auditory neuron receptive fields (excitatory and inhibitory frequency tuning curves) have been observed to change within 10 minutes after induction of cochlear lesions or partial deafferentation.[14,15] It is reasonable to suppose that short-term plastic change reflects small-scale neural alterations, with subtle synaptic modifications to existing neural networks. With such acute observations, initial stages of plastic change may have occurred, but it is unclear whether these changes would be consolidated in the longer term (see the section on basic mechanisms of plastic change).

More extensive auditory system reorganization seems to occur over a longer time course. Numerous studies show a modification of central tonotopic mapping as a result of cochlear lesions or partial deafferentation.[16-21] In these studies, the time course of plastic change apparently is completed over many weeks. In such cases, underlying synaptic strengthening seems to be consolidated. Sometimes very extensive reorganization is observed, which suggests that long-term processes, such as new axonal growth and synaptogenesis, have occurred. To use a computer analogy, short-term plasticity might be considered to be software changes, whereas long-term changes might also include hardwiring modifications.

Age-Related Plasticity

Perhaps the most important factor to consider when reviewing studies relating to plasticity is the age, or rather the developmental state, of the subject. As shown in subsequent examples, reorganization of tonotopic maps after cochlear lesions is significantly different when experimental manipulation is done in the neonate compared with the adult animal. There are numerous other examples of age-related plasticity in the auditory system. Perhaps the most familiar to the otologist is the performance of a congenitally deaf child provided with a cochlear implant at an early age compared with a deaf child implanted at a much later age.[22] Studies such as this and other clinically related aspects of auditory system plasticity are explored in the final section of this chapter, where we consider what all this new knowledge about plasticity means to the practitioner.

Experiments Showing Plastic Change in Otology

Over the past few decades, a large body of experimental evidence has accumulated showing that the central auditory brain develops and is maintained under the influence of the patterns of neural excitation that originate at the ears. It is definitely not the case that we have a central auditory nervous system and independent inner ear sensory organs. Not only does the cochlea send acoustically related signals to the central system, but also these activity patterns seem to promote initially the development and then the maintenance of the central system. The functions of the periphery and central components are intimately linked, and this is most evident during an early developmental period, when alterations of central neural wiring patterns can result from abnormal sensory input.

Historical Background

Two pioneering studies drew attention to the notion that early sensory input has a crucial role in central brain development. These two experiments paved the way for many modern studies of sensory brain plasticity. The seminal study was in the developing chick auditory system by Levi-Montalcini,[9] who documented the anatomic changes to central auditory pathways after the otocyst of the chick embryo was removed or damaged. In later, seemingly unrelated studies, Wiesel and Hubel[23,24] showed that visual cortical wiring responsible for ocular dominance columns is disrupted in cats if, during an early postnatal period, the animals have had visual input from one eye only (i.e., after neonatal monocular deprivation).

These seminal experiments were followed by many others in visual, somatosensory, vestibular, and auditory systems. In otologic research, numerous studies revealed the considerable anatomic changes that result from neonatal ablation of one cochlea. These changes include loss, or pathologic change, to neurons in brainstem and midbrain,[25-27] and, importantly, the formation of novel innervation patterns, particularly from the cochlear nucleus on the normal side to more central nuclei.[28,29]

From a clinical perspective, such unilateral ablation studies highlight the importance of bilateral input during early development, and, by extrapolation, a balanced input from both ears. This is an important "normal condition" for auditory development. One could speculate that central auditory development could be more normal with a symmetric, mild to moderate sensorineural hearing impairment than with a very asymmetric loss.

Other relevant studies were made in other sensory systems. The visual experiments by Wiesel and Hubel[23,24] have already been mentioned. In addition, work in the somatosensory system pointed the way to analogous experiments in the auditory system. The reorganization of somatosensory maps in cortex after damage or partial deafferentation of the sensory inputs was initially shown after whisker removal in young rodents,[30] and after peripheral nerve damage or digit removal in developing and adult animals.[31-33] These experiments were significant because they noted reorganization of the cortical somatotopic maps, which can be considered, as Merzenich and associates[32] would say, the "mainline functional organization" of this sensory system. These studies also showed that deafferented cortical areas (i.e., no longer receiving input from the periphery) become connected to areas corresponding to the border of the peripheral lesion. In terms of cortical space, these border areas become overrepresented. As discussed in the following sections, there are considerable similarities between the somatosensory data and data from analogous experiments in the auditory system.

Reorganization of Central Tonotopic Maps after Cochlear Lesions

The main experimental studies I have chosen to illustrate "plastic change in otology" are those in which central tonotopic map reorganization occurs after lesions are made to the cochlea. These experiments show how peripheral activity patterns can influence the establishment and maintenance of central frequency maps. Analogous to the central somatotopic projections mentioned previously, tonotopic maps can be considered the mainline organizational feature of the auditory system. In the auditory system, the topographic order of afferent neurons is well maintained from the sensory epithelium of the cochlea up to the cortex.[34,35] Strictly speaking, we should refer to this projection system as "cochleotopic," analogous to the similarly organized retinotopic visual system and the somatotopic pathways of the somatosensory system. The interchangeability of "cochleotopic" and "tonotopic" is possible because of the place coding of sound frequency along the

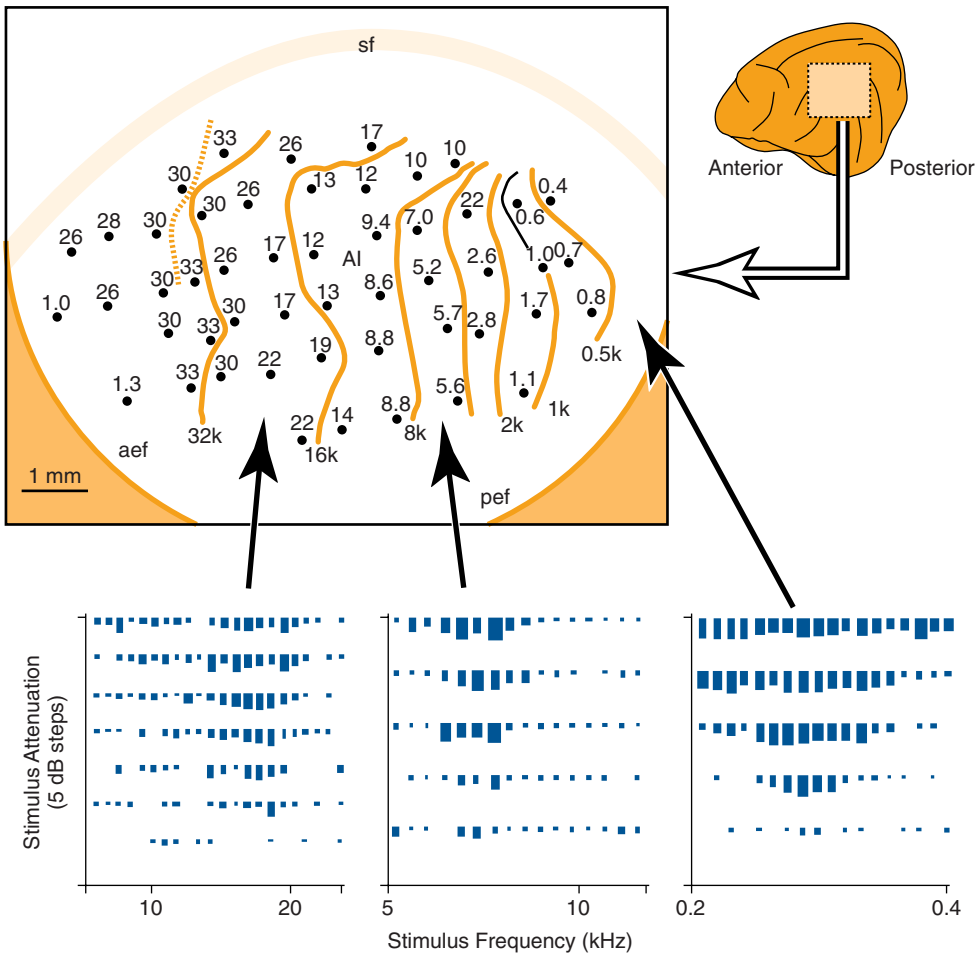

Figure 132-1. Tonotopic map in normal cat auditory cortex (AI) as determined by multiple microelectrode recordings. At each indicated electrode position, the frequency tuning of neural units is determined from receptive field raster plots as indicated (*lower panels,* three example neurons). The best frequency of response, or characteristic frequency, is indicated on the tonotopic map in kHz. Isofrequency contours shown are at octave intervals. aef, anterior ectosylvian fissure; pef, posterior ectosylvian fissure; sf, sylvian fissure. *(Adapted from Harrison RV, Nagasawa A, Smith DW, et al. Reorganization of auditory cortex after neonatal high frequency cochlear hearing loss.* Hear Res. *1991;54:11-19.)*

cochlear length. Some caution is advised, however, on the interchangeability of these terms when considering systems having pathologic cochleas; under such conditions, considerable distortion of the normal place coding of sound frequency is possible.

To set the scene for the experimental studies that follow, let us consider the normal cochleotopic (tonotopic) mapping at the level of the auditory midbrain and cortex. Figure 132-1 shows a tonotopic map in the primary auditory cortex of a cat, as determined by recording from cortical neurons at several sites.[18] Each data point indicates the microelectrode recording site, and the sound frequency to which neurons respond best is indicated in kilohertz. The lower panels of Figure 132-1 indicate how the response of (three) individual neurons is analyzed. Each raster shows the response (spike count) to stimuli of different frequency and intensity combinations. The isofrequency contours that are drawn through the cortical map are plotted at octave intervals. Similar microelectrode recording techniques were used to determine tonotopic maps in the inferior colliculus of the midbrain. Such a map from a normal chinchilla is shown in Figure 132-2A.[16]

Tonotopic Map Reorganization in a Developmental Model

Figure 132-3 shows two examples of cortical tonotopic maps in cats treated shortly after birth with the ototoxic aminoglycoside amikacin.[18] This treatment resulted in basal cochlear hair cell lesions. Amikacin was given systemically, and cochlear lesions were bilaterally symmetric. Histologic evaluation in subject A showed that the basal region of the cochlea was totally damaged (inner and outer hair cell loss), but in more apical areas, above the 6- to 8-kHz region, a normal sensory epithelium was present. This is consistent with the auditory brainstem response (ABR)–derived audiogram showing normal tone pip evoked ABR thresholds up to the high-frequency cutoff slope. The cortical tonotopic map for this subject is characterized by a normal representation of low frequencies, but the cortical region that has been deprived of normal input by the partial cochlear deafferentation now contains neurons that are all tuned to 6 to 8 kHz (shown as the shaded area). The boundary region of the cochlear lesion is abnormally overrepresented in terms of cortical space.

In subject B (see Fig. 132-3B), the results are more revealing. In this kitten, the cochlear lesion was more extensive, with a severe basal lesion, but also with scattered hair cell loss up to apical regions. This is reflected in the ABR audiogram that gradually slopes down across all frequencies measured. This kitten also developed a cortical frequency map in which there was a very large isofrequency area (shown as a shaded area) where all neurons have common 6.6-kHz frequency tuning. In addition, the low-frequency region of the tonotopic map is severely distorted compared with normal (compare with Fig. 132-1). It seems that a reduced or abnormal stimulus-driven activity pattern from cochlear areas more apical to the main lesion has had an influence on normal map development.

Cortical Frequency Map Reorganization in Adult Subjects

The experimental results shown in Figure 132-3 were from studies in which the cochlear lesions were induced in neonates.[18] Qualitatively,

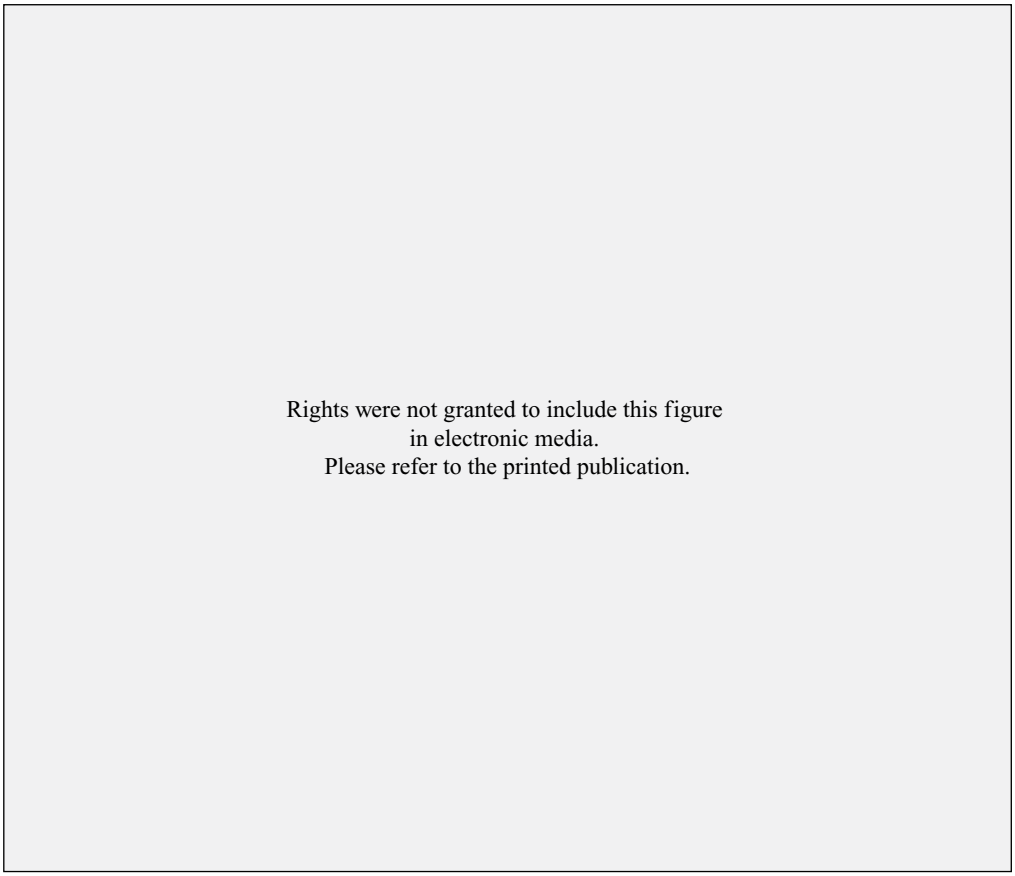

Figure 132-2. Tonotopic maps in the inferior colliculus (central nucleus) of a chinchilla. All maps were derived from single neuron recordings in electrode tracks along the dorsoventral axis of the inferior colliculus as shown. Neuron characteristic frequency was derived from receptive field plots similar to those shown in the cat experiments of Figure 132-1. The *upper graphs* plot neuron characteristic frequency as a function of electrode excursion. The *lower diagrams* represent the tonotopic maps; isofrequency contours are indicated at octave intervals. **A,** Results from a normal adult subject. **B,** In this subject, a basal cochlear lesion was made within days of birth, and the inferior colliculus tonotopic map was derived 4 months later. In the map, the *shaded area* shows the ventral region of the inferior colliculus in which all neurons had a common characteristic frequency. **C,** In this subject, the cochlear lesion was made in the adult animal and was mapped 3 weeks later. *(Adapted from Harrison RV, Ibrahim D, Mount RJ. Plasticity of tonotopic maps in auditory midbrain following partial cochlear damage in the developing chinchilla.* Exp Brain Res. *1998;123:449-460.)*

similar results are also found at the cortical level if the lesions are made in an adult animal. This was initially reported by Robertson and Irvine,[21] who were the first authors to report observations of altered central tonotopic maps resulting from peripheral lesions. Other studies subsequently confirmed these findings in adult animals.[19,20,36]

Figure 132-4 shows results from a chinchilla. Here a normal tonotopic map (Fig. 132-4A) is compared with a map recorded from an adult animal (Fig. 132-4B) with cochlear lesions induced.[19] The anatomic extent of the lesion is shown on the cochleogram, and the corresponding ABR audiogram shows the functional consequences. A typical finding is an overrepresentation of neurons with characteristic frequency of approximately 2.5 to 3.5 kHz (shaded area). In the adult animal, as with the developing subject, neurons in deafferented cortical regions seem to become connected to adjacent noninterrupted ascending input. Similar principles of adult cortical map reorganization are found in somatosensory and visual systems.[2,37,38]

These modifications to cortical frequency maps seem to be the result of neural rewiring, not an experimental artifact. The excitatory receptive fields of neurons tuned to the common frequency are qualitatively similar in shape. They have similar minimum thresholds and bandwidths, independent of where they are located across cortical space. This is an important observation because it argues against the possibility that the common characteristic frequency is an artifact caused by simply truncating all neuronal tuning curves above a certain frequency (corresponding to the lesion boundary along the cochlear sensory epithelium). This possible "pseudoplasticity" (i.e., the appearance of reorganization when there is really none) has been discussed by Kaltenbach and colleagues.[39]

Adult versus Developmental Plasticity of Sensory Systems

The importance of early sensory stimulation in driving the development of the mature brain has been emphasized by many investigators starting with Wiesel and Hubel[23,24] and reinforced by other experiments in various sensory systems.[3,31,40,41] At the level of auditory cortex, there seems to be a pattern of reorganization of tonotopic maps after cochlear lesions induced in the developing neonate similar to that of the adult animal. Intuitively, one might expect considerable differences in the extent of the cortical tonotopic map reorganization in subjects with lesions made in early development compared with lesions made in adulthood. Qualitatively, this seems to be the case,[19] but there have been no careful within-species studies to answer this question specifically. If we explore tonotopic map reorganization in subcortical auditory nuclei, however, there are significant differences in map reorganization after lesion experiments in a developmental model compared with the mature subject. At subcortical levels, we see evidence of age-related plasticity.

Tonotopic Map Reorganization at Subcortical Levels

In cats with cortical map reorganizations similar to those shown in Figure 132-3, Stanton and Harrison[42] injected neural tracers (e.g.,

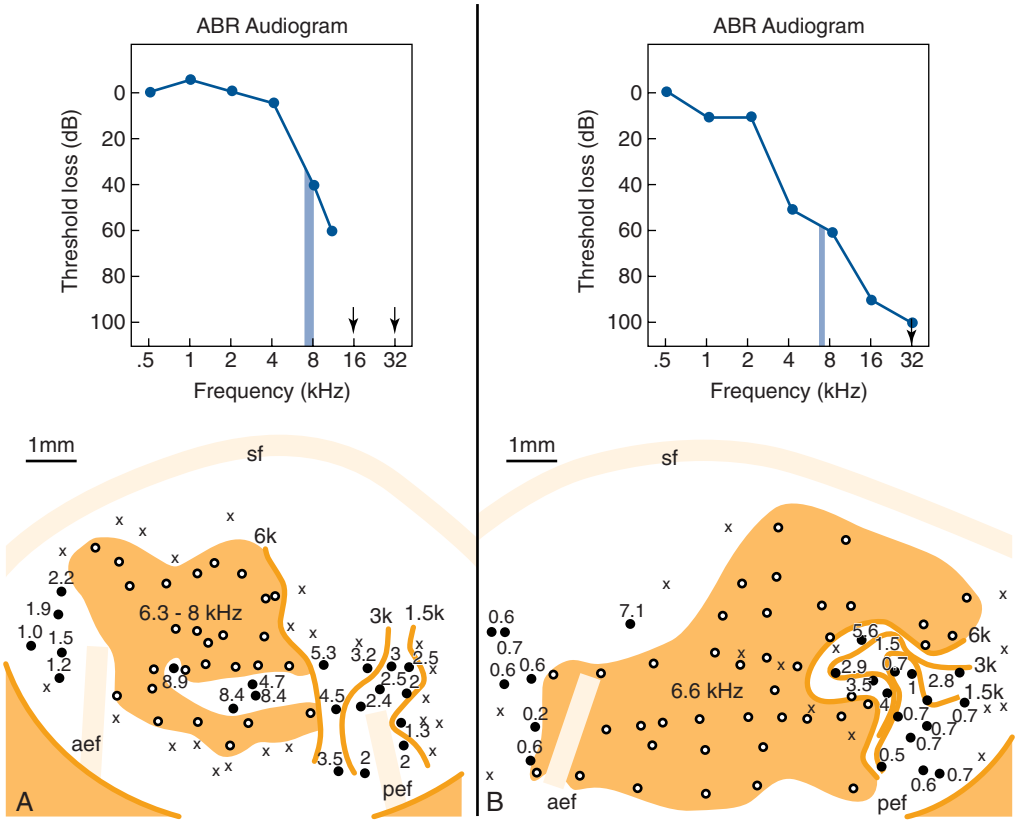

Figure 132-3. Cortical tonotopic maps that developed in two cats with neonatal basal cochlear lesions. The kittens were treated with the ototoxic aminoglycoside amikacin to produce basal lesions to the cochlea. The effects of such lesions are reflected in the auditory brainstem response (ABR)–derived audiograms (*upper panels*). **A,** In this subject, the cochlear lesion was confined to the basal region. **B,** In this subject, hair cell damage was maximal at the cochlear base, but scattered hair cell loss extended up to apical regions. Tonotopic maps are plotted as for Figure 132-1. Isofrequency contours are at octave intervals. *Shading* indicates regions in which all neurons have similar tuning properties. *(Adapted from Harrison RV, Nagasawa A, Smith DW, et al. Reorganization of auditory cortex after neonatal high frequency cochlear hearing loss.* Hear Res. *1991;54:11-19.)*

horseradish peroxidase and fluorogold) into the reorganized, frequency-overrepresented cortical areas, and followed the connections back to the medial geniculate body of the thalamus. They found that the projections were as ordered, (i.e., had the same point-to-point trajectories) as in normal animals. The observed cortical map reorganizations must also be present at the thalamic level. In a developmental plasticity model, cortical frequency map reorganization in large part reflects reorganization occurring at a subcortical level.

More direct evidence for this conclusion comes from studies made at the level of the inferior colliculus. Figure 132-2A shows the normal tonotopic map of the chinchilla inferior colliculus (central nucleus). The orderly progression of the neuron characteristic frequency as the recording electrode is moved through the inferior colliculus is shown in the upper plot. Figure 132-2B shows the result of an experiment in which the inferior colliculus tonotopic organization was determined after a cochlear lesion was made in a neonate.[16,17] The lower plot presents an overview of the results. It shows normal, octave-spaced frequency contours within the inferior colliculus up to the 10-kHz region, then in further, more ventral areas, there is a large region containing identically tuned neurons. The upper plot of the neuron characteristic frequency versus recording electrode position (along the dorsal ventral inferior colliculus axis) clearly shows the grouping of neurons tuned to 10 kHz (arrow in Fig. 132-2B). These results are qualitatively similar to earlier work by Willott[43,44] in inferior colliculus recordings from presbycusic mice.

These studies establish that tonotopic map reorganization occurs at low levels in the auditory pathway after basal cochlear lesions induced in an early postnatal period. Such subcortical reorganization apparently does not occur for similar lesions made in the adult, however. In adults, partial cochlear deafferentation produces no true reorganization at the level of the cochlear nucleus[39,45] or at the midbrain level.[46] Figure 132-2C illustrates the effects of a basal cochlear lesion made in an adult chinchilla, on the tonotopic map in the inferior colliculus. In the adult, there is little evidence of an isofrequency region, which is typical of map reorganization in the developmental model.

The schematic diagram depicted in Figure 132-5 is helpful in summarizing the differences in tonotopic map connectivity in developmental versus adult models. Unless there is future evidence to the contrary, it would seem that the plasticity of subcortical regions (in terms of remodeling tonotopic projections) is possible only during an early developmental period. In adults, such plastic change seems to be confined to the cortex (or perhaps the thalamocortical complex). In this sense, these experimental data exhibit an age-related plasticity in the auditory system. We return to consider in more detail the wiring patterns of Figure 132-5 in the later discussion of basic mechanisms of plasticity.

Tonotopic Map Changes after Long-term Local Excitation of the Cochlea

In the studies outlined so far, in which cochlear lesions (deafferentation) have been induced, the general conclusion is that changes in the pattern of peripheral neural excitation can modify the development or maintenance of central tonotopic projections. What happens if, instead of reducing activity, we locally augment cochlear afferent activity? One such experiment[47] has been reported in which kittens were reared (for many weeks postnatally) in an environment where an 8-kHz acoustic signal was constantly present. To be more accurate, the 8-kHz (± 1 kHz) signal was at a level of 55 to 60 dB. Being suprathreshold, it actually stimulated cochlear neurons across a 7- to 12-kHz range. The 8-kHz tone was frequency modulated (± 1 kHz; at 1 Hz) to

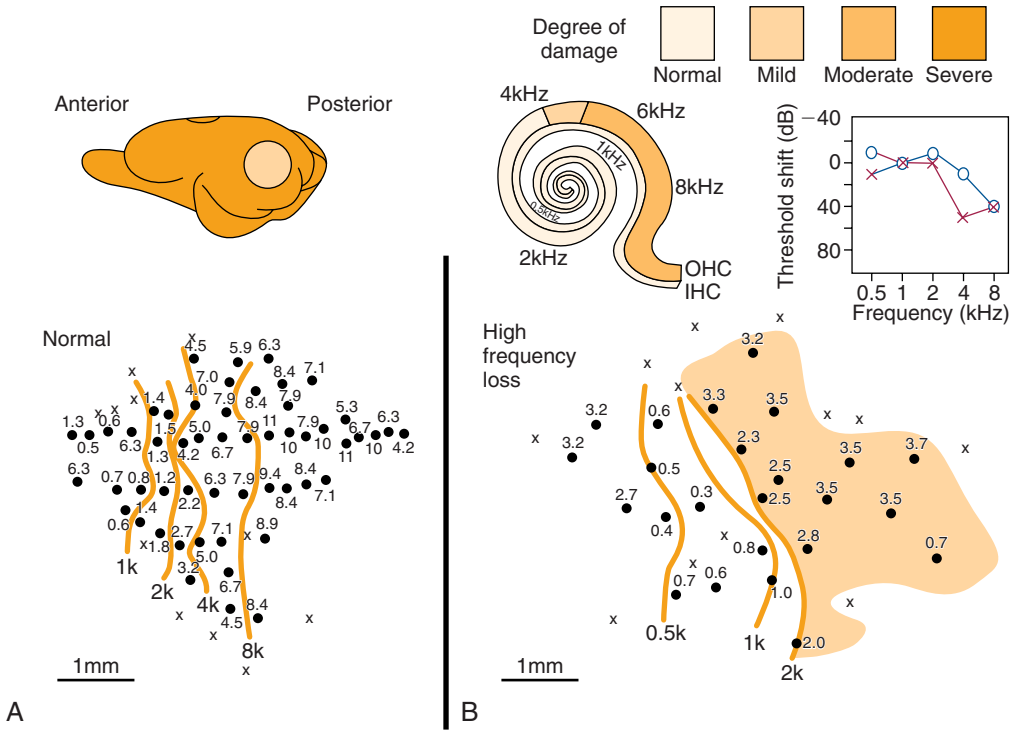

Figure 132-4. Cortical tonotopic maps in a normal adult chinchilla (**A**) and in a subject 4 weeks after making cochlear lesions by amikacin treatment (**B**). Methods for cortical maps were derived with methods similar to those described for Figures 132-1 and 132-3. Isofrequency contours are octave spaced. The peripheral deficit in the treated chinchilla (**B**) is reflected in the cochleogram and in the auditory brainstem response audiogram. The *shaded* area in the abnormal cortical map indicates the regions in which most neurons had very similar tuning properties. IHC, inner hair cell; OHC, outer hair cell. *(Adapted from Kakigi A, Hirakawa H, Mount RJ, et al. Tonotopic mapping in auditory cortex of the adult chinchilla with amikacin-induced cochlear lesions.* Audiology. *2000;39:153-160.)*

circumvent auditory adaptation effects and to avoid cochlear hair cell trauma. Six months after this initial rearing period, cortical tonotopic maps were assessed.

Figure 132-6 summarizes the main result. Compared with normal age-matched control subjects (Fig. 132-6A), the "augmented" kitten (Fig. 132-6B) showed a significant increase in the cortical space devoted to the frequency region extending from 8 to 12 kHz (shaded area in Fig. 132-6B). The ambient sound signal had no obvious behavioral significance to the young kittens and perhaps can be considered as simply causing an increased firing rate of a group of midcochlear neurons compared with the surrounding basal and apical cochlear regions. The lower schematics are hypothetical wiring patterns to help represent the experimental results.

Conditions for Plasticity in the Adult Cortex

In adult animals, there have been numerous studies that have explored the plasticity of sensory cortex after repeated chronic exposure to well-specified stimuli. Many of these studies report that plastic changes are evident only if the sensory stimulus has some behavioral significance to the animal. Long-term changes in the auditory neuron receptive field were induced in tonal stimulation associated with various behavioral conditioning tasks.[48-50] Based on evidence that such plastic changes are potentiated by the presence of acetylcholine, a useful model was proposed by Weinberger and Bakin[51] suggesting that the nucleus basalis, the source of cholinergic projections to the sensory cortex, has an important role in plastic modifications to cortical networks. Many experimental studies in which sensory neuron receptive field changes were facilitated by electrical stimulation of nucleus basalis or by local application of acetylcholine support such a model.[52-54]

Apparently, stimulus-initiated plastic change (e.g., to auditory neuron receptive fields) is often achieved in an adult subject only with a behaviorally relevant paradigm. The developing system may be significantly different. As the 8-kHz rearing experiment outlined previously shows, a "passive" overstimulation paradigm can result in the development of a modified tonotopic map. It could be suggested, however, that the kittens develop some behavior to avoid the polluting acoustic signal, so perhaps it is not entirely passive.

Animal Models of Deafness and Effects of Cochlear Implant Electrical Stimulation

In animal models, a wide range of structural and functional changes have been observed in the auditory system in association with experimental and naturally occurring deafness.[55-62] One view of the observed changes is that they result from a reduction or lack of stimulus-driven activity. A term sometimes applied here is "negative plasticity," which describes a system that is not undergoing the usual plastic changes that accompany physiological activity. It is also difficult to separate negative plasticity effects with some more basic underlying neural pathology associated with the hearing loss. In any case, a clinically important question relates to whether stimulation with a cochlear implant can serve to restore critical features of auditory function, such as synaptic integrity.

Such questions have been addressed directly by the study of cochlear electrical stimulation in animal models of deafness. Auditory nerve endings in deaf white cats exhibit morphologic abnormalities that are (partly) reversible with restored activity with cochlear implantation.[63,64] Investigators have also observed positive effects of electrical stimulation on auditory brainstem nuclei,[58,65] the midbrain,[66-68] and auditory cortex.[57,69,70] There may be considerable residual limitations to auditory neuron performance after functional restoration induced by electrical stimulation.[71] At the cortical level, restorative effects seem to promote normalized, layer-specific activity within the primary auditory cortex in young kittens, but not in older cats.[57] Such findings implicate a critical period or at least an age-related plasticity for the developing auditory cortex.

Basic Mechanisms of Plastic Change

It is impossible in the context of this chapter to provide a comprehensive review of basic mechanisms of plastic change, but the otologist or

Figure 132-5. A schematic to summarize salient aspects of developmental and adult plasticity experiments, with suggestions for possible neural wiring patterns. Each panel represents the ascending auditory pathway from cochlea to cortex. **A,** Early developmental stage when neural projections between levels have considerable divergence. **B,** Normally developed projection system. It is characterized by good point-to-point connections between auditory nuclei. **C** and **D,** Data from subjects after basal cochlear lesions induced neonatally (**C**) and in an adult (**D**).

hearing health care professional might benefit from this overview of some commonly proposed mechanisms for neural plasticity and synaptic strengthening. Neuronal reorganization is the result of numerous mechanisms, some of which we know about in detail, some of which we know about only vaguely, and many of which are still unknown. The behavior of interconnected neurons depends on the establishment of synaptic connections in the first place, perhaps the "pruning" of underused synapses, then the adjustment of the strength or efficacy of individual connections. Finally, there might be some consolidation process to maintain the new organization. In addition, as mentioned in the preceding section, there are additional external neural and hormonal factors that can play a role in facilitating plastic change. In the case discussed previously, it was the modulating influence of an acetylcholine system that facilitated, or perhaps consolidated, plastic change.

Some mechanisms present during an early developmental period may not play such an important role in the mature brain. The initial period of formation of auditory connections from the cochlea to the thalamus and then axonal growth into primary auditory cortex involve chemotropic guidance of axons to target cells and myelination processes that may not exist in the mature brain. In addition, the drastic pruning of interneuronal connections that occurs during early development is impossible in the more mature brain. It is important to keep in mind the distinction between adult and developmental plasticity when thinking about mechanisms of plasticity. In the following sections, we discuss such mechanisms of plastic change, first at the "systems physiology" level, focusing on the examples of tonotopic map reorganization already presented. After that, we review some of the cellular and subcellular mechanisms that might underlie the experimental observations.

Mechanisms of Plasticity at a Systems Physiology Level

Let us first consider the reorganization of tonotopic maps resulting from neonatal cochlear lesions. Figure 132-5 provides a simple schematic to help conceptualize the tonotopic organization in normal and reorganized conditions. Figure 132-5B depicts the normal, point-to-point, cochleotopic projection system from cochlea to cortex in an adult subject. Figure 132-5A depicts an early developmental phase characterized by "divergent" neural projections throughout the system. With a normal pattern of activity from the cochlea, the divergent innervation pattern (see Fig. 132-5A) develops into the normal point-to-point projection system (see Fig. 132-5B).

Many mechanisms are likely involved in this normal developmental process. When growing neurons are attempting to make connections with target cells, there may be a physical space competition such that the neurons that are most proximal win out. Synaptic strengthening, through various mechanisms of long-term potentiation (LTP), may strengthen the most direct connections and promote their survival over connections that are less direct. Sound-driven neural activity likely is more influential in the formation of the adult-like point-to-point connectivity than non–stimulus-driven spontaneous activity. This would definitely be the case if the synaptic strengthening follows hebbian rules.[72] Further details about hebbian processes are given in the next section. In short, a robust strengthening of connection between neurons

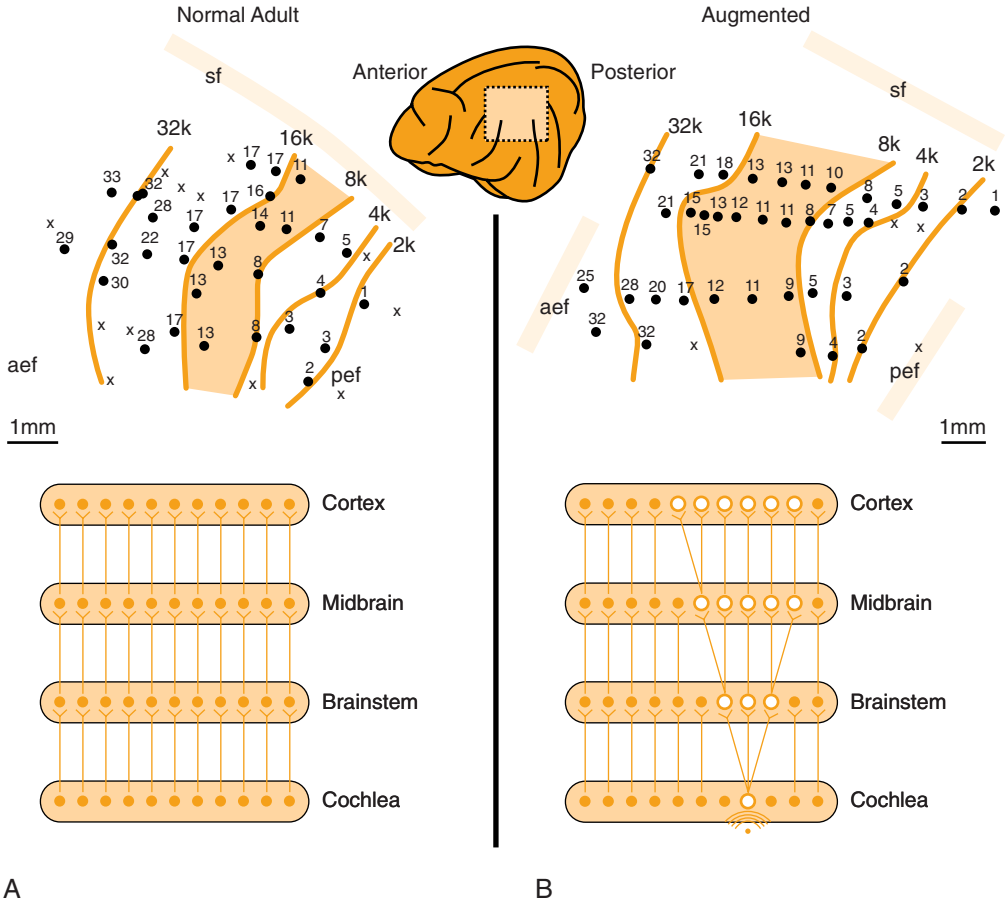

Figure 132-6. Tonotopic maps in the auditory cortex of a cat. Methods for constructing the maps are the same as those noted for Figure 132-1. Isofrequency contours are at octave intervals. **A,** Frequency map is from a normal control subject. **B,** Map is from a cat that spent about 1 month postnatally in an acoustic environment with a constant 8-kHz signal. In both examples, the 8- to 16-kHz octave interval is shaded to emphasize the main difference between the subjects. Hypothetical wiring patterns, representing the results, are shown below the maps. aef, anterior ectosylvian fissure; pef, posterior ectosylvian fissure; sf, sylvian fissure. *(Adapted from Stanton SG, Harrison RV. Neonatal auditory augmentation modifies cochleotopic mapping in primary auditory cortex of the cat.* Aud Neurosci. *1996;2:97-107.)*

is achieved under conditions where patterns of presynaptic and postsynaptic activity (depolarization) are highly correlated. This would particularly be the case when acoustic stimuli drive identical patterns of activity in neighboring cell groups. Conditions for hebbian synaptic strengthening are unlikely to occur when local groups of neurons do not have a common (stimulus-driven) activity, or simply have independent and random patterns of spontaneous firing.

Tonotopic Map Reorganization in the Developing Subject

Figure 132-5C depicts the auditory projections that result from making a basal cochlear lesion during an early developmental period (e.g., in neonatal kittens or chinchilla pups). At the level of the auditory cortex and at the midbrain, experimental data show that deafferented areas contain neurons that seem (based on characteristic frequency tuning) to be connected to a common point along the cochlea, typically the border of the cochlear lesion. It is possible to invoke numerous possible mechanisms that could produce such a wiring diagram. The most economical scheme is to suppose that the divergent neural projections that exist in very early development (as depicted in Fig. 132-5A) are simply not eliminated because in the adjacent, deafferented region, there are no longer neurons competing for target cells.

Perhaps we do not need to consider the supposed divergent innervation pattern in early development, but rather assume that there is always a small degree of divergence associated with tonotopic projections. Then it is possible that a modest "edge-effect" spread, resulting from the lack of neural competition on the deafferented side at each synaptic level in the auditory pathway, would accumulate to become a substantial area of overrepresentation at the cortical level.

The other developmental plasticity experiment that we considered involved rearing kittens such that the 8-kHz region of the cochlea is chronically excited.[47] The resulting reorganization of the cortical tonotopic map is shown in Figure 132-6, together with a hypothetical tonotopic wiring diagram. Here it is easy to suppose that within the driven region of the neural array, LTP, especially if operating under hebbian rules, would significantly strengthen and consolidate active connections compared with connections in less excited adjacent areas. The physical spread of enhanced connectivity, to produce overrepresentation at the cortex, could be explained by having edge-effect spread on both sides of the activated region of the neural array, and incrementing at each auditory nucleus up to the auditory cortex.

Cortical Map Plasticity in Adult Subjects

The schematic in Figure 132-5D represents data from studies of tonotopic map changes after cochlear lesions in a mature animal. Very little evidence of frequency map reorganization has been found at subcortical levels, at least in terms of an overrepresentation of a specific sound frequency (or, more correctly, the overrepresentation of activity from a specific cochlear location). The "incremental with level" model of Figure 132-5C does not apply here. Rewiring to produce overrepresentation would seem to be largely confined to the thalamocortex. We need to consider other possible mechanisms, which one can divide into two categories: (1) alterations to preexisting neural connections made

by increasing or reducing their relative strengths, and (2) new growth processes, such as neurogenesis, axon sprouting, and synaptogenesis.

Within the auditory cortex and thalamus, and in all auditory nuclei, there is some degree of divergent input, there are laterally connecting local interneurons, and often there are longer range interneuronal connections. It has been suggested that much of the activity of these preexisting lateral connections is normally inhibited, but that local deafferentation serves to release that inhibition. In other words, there is an "unmasking" of existing lateral connections. There is evidence that lateral inhibition is reduced in cortical neurons of subjects with cochlear lesions[73] and in the brainstem and midbrain auditory areas after trauma to the cochlea.[14,15,74,75]

Such findings seem to be correlated with observations of reduced γ-aminobutyric acid levels in central auditory areas of deafened animals.[76,77] Perhaps because of their release from inhibition, or unmasking, local lateral connections become more active and are strengthened. Now that our discussion is at the level of individual neuronal connections, it is appropriate to consider some cellular and subcellular mechanisms that are known to contribute to synaptic strengthening. In the following section, we briefly review LTP, hebbian synaptic strengthening, and the *N*-methyl-D-aspartate (NMDA) receptor.

Cellular Level Mechanisms of Plasticity

Any discussion of mechanisms of synaptic plasticity should perhaps start with "post-tetanic potentiation." This was one of the first described neurophysiologic mechanisms related to synaptic strengthening. In an experimental situation in which a presynaptic neuron excites a second neuron, repeated presynaptic stimulation can result in an increased effectiveness of the synapse that is maintained for some time (minutes to hours). The classic theory behind this relatively short-term plasticity is that it is caused by presynaptic calcium ion accumulation that temporarily enhances neurotransmitter release; more recent studies have embellished this story, but the mechanism is primarily presynaptic.

Long-Term Potentiation

The next major step forward occurred a few decades ago with reports that long-term modifications of mammalian synapses (lasting for weeks and months) could be experimentally induced.[1,78] This LTP can result from a repeated activation of the synapse. It was originally observed in experiments in the hippocampus, but LTP is now known to exist almost ubiquitously in the brain. In seeking mechanisms for LTP, attention was drawn first to the postsynaptic receptors, in particular the NMDA receptor. The NMDA receptor is a fast, ionotropic ion channel that is activated by glutamate, the major excitatory transmitter in the brain. Synapses with NMDA receptors can develop LTP, but not when the receptor is blocked. The key aspect of the NMDA receptor is that its ion channel has a voltage-dependent Mg^{2+} block that can alter the cell excitability, partly by controlling Ca^{2+} permeability. Although the NMDA receptor was the first to be implicated in the synaptic strengthening underlying LTP, it is only one of many. The metabotropic glutamate receptor can be involved in LTP processes. Other receptor types are likely involved with synapses that exhibit the corollary of LTP—long-term depression.

Hebb's Postulate

One significant feature of synaptic systems involving NMDA receptors is that they often (but not always) follow hebbian rules. In 1949, Hebb[72] put forward many ideas concerning the conditions that might cause synaptic strengthening. His main postulate is as follows: "When an axon of cell A is near enough to excite a cell B and repeatedly or persistently takes part in firing it, some growth process or metabolic change takes place in one or both cells such that *A*'s efficiency, as one of the cells firing *B*, is increased." This notion has commonly been expressed as: "Cells that fire together, wire together."

In modern studies of LTP, many systems have been shown to follow such hebbian rules. As discussed previously, the conditions commensurate to hebbian-type strengthening of connections in the auditory pathway are optimally produced when there is sound-driven activity. Acoustic stimulation results in groups of auditory neurons in ascending arrays with highly correlated activity. Such conditions could be important for establishing and maintaining tonotopicity in the auditory system. In addition, hebbian-type synaptic strengthening resulting from the correlated, driven activity of bilateral auditory input undoubtedly plays a major role in establishing sound localization mechanisms.

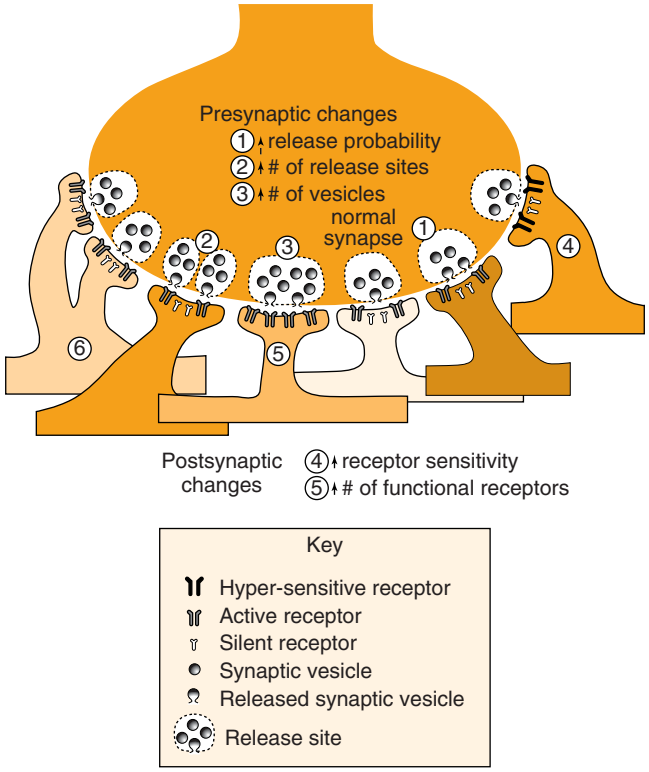

Figure 132-7. Overview of six possible presynaptic or postsynaptic mechanisms for enhancing synaptic efficacy. *1,* More presynaptic vesicles undergo exocytosis at a release site compared with the normal synapse. *2,* An increase in the number of release sites. *3,* Potentiation of a release site because of an increase in number of vesicles available for release. *4,* Increase in the sensitivity of existing postsynaptic receptors. *5,* Increase in the number of receptors. *6,* Synaptogenesis (i.e., new growth of synaptic contacts). *(Adapted from Wang JH, Ko GY, Kelly PT. Cellular and molecular bases of memory: synaptic and neuronal plasticity.* J Clin Neurol Physiol. *1997;14:264-293.)*

Other work exploring mechanisms of synaptic strengthening has implicated changes in presynaptic and postsynaptic areas. The potential complexity of various mechanisms that might contribute to changing the efficacy of a single synapse is emphasized by Figure 132-7.[79] Any combination of up to six presynaptic or postsynaptic mechanisms can modify the performance of a synapse. A typical auditory neuron can have many hundreds of synapses; the possibilities for modification seem almost limitless.

Finally, we come to the processes whereby synapses, modified in various ways, have their plastic changes consolidated. What mechanisms can make LTP permanent? The short answer is that structural components of synapses, including the number and type of presynaptic release sites and the postsynaptic receptors, have to be maintained in cells with substrates that are constantly turning over. Mechanisms of protein synthesis and gene expression play an important role.

Practical Issues Relating to Neural Plasticity in Otology

What does all this new knowledge about neural plasticity mean to the otologist or hearing health care professional? What practical benefits can arise from an understanding of mechanisms of plastic change? In the following sections, we discuss some common practical issues in

otology, now illuminated by our appreciation of neural plasticity; some of the discussion is speculative.

In many areas, this new knowledge has no immediate impact on the practice of health care, other than offering some further explanations of cause (e.g., understanding the genesis of some types of tinnitus). In other areas, a further understanding of the mechanisms of plastic change could potentially change otologic case management. This has been the case in relation to the early detection and intervention in sensorineural hearing loss. The concepts and concerns raised by developmental neural plasticity experiments have heightened our appreciation of age-related plasticity, and this has significantly improved practice.

Hearing Loss in Infants

The take-home message from numerous clinical observations and experimental studies, some described here, is that central auditory system development largely depends on the pattern of neural activity from the periphery. Hearing loss, especially during early development, may negatively affect central development. Perhaps there is a critical period during which cochlear function needs to be particularly intact.

Many of the experimental animal studies of plasticity that clearly show central structural and functional alterations involve drastic manipulations, such as total cochlear ablation or partial deafferentation. We have to extrapolate beyond such radical examples, however, to consider that more subtle types of hearing loss also change normal peripheral stimulation patterns. Mild sensorineural hearing loss, chronic conductive hearing loss (especially in repeated episodes of otitis media), and bilaterally asymmetric hearing loss, which might not be considered to impair "significantly" ongoing hearing function, may nevertheless alter normal central pathway development.

One of the difficulties with testing such notions is that the manifestation of abnormal auditory development might be delayed. Neonatal hearing disorders that might lead to problems in language development become evident only 4 or 5 years later, when such development can be assessed. Perhaps the best practical strategy is to assume the worst and make every possible effort to normalize hearing during early postnatal years. This strategy involves having an early detection of hearing problems through neonatal or infant hearing screening programs and subsequent early intervention with hearing aids, cochlear implants, and auditory habilitation training. We are presently in the midst of implementing these strategies.

Our concerns about early detection of hearing loss and early intervention have been fueled by experimental evidence from animal and human studies. With regard to the latter, some of the best "experiments" have been in deaf children with cochlear implants. Figure 132-8 shows data from our own pediatric cochlear implant program.[22] Each panel shows average postimplantation performance on a standard speech understanding test. All children were prelingually (mainly congenitally) deaf, and the population was homogeneous in terms of degree of residual hearing, school setting, and access to habilitation therapy. The data set has been divided into children implanted at an early age compared with children implanted later. On average, children implanted at a young age eventually outperform others. Similar conclusions are reached from a wide range of other intervention outcome studies in vision, sensorimotor training, and education. Compensation for any neural deficit is best achieved by early intervention.

Central auditory system development is significantly guided by cochlear activity patterns. It follows that a cochlear implant or other hearing prosthesis provided to a young infant would have a dual purpose. Not only does the device aid "hearing," but also the augmented stimulation of the system would have an influence on central development. Many questions arise from this notion. Is a stimulation paradigm designed to provide good auditory input the most optimal for stimulating developmental change? It may be more beneficial to have implant devices that are constantly active, even when not being used for hearing, so that they constantly provide stimulation to the developing auditory brain. Does the pattern of stimulation from a cochlear implant result in the development of an unusual central auditory system? To the latter I would say, almost certainly, yes. If so, what does this mean for changing devices, or even speech coding paradigms, later in life? In the future, as we intervene in even younger infants, we will need to give more attention to the developmental aspects of cochlear implants (and infant hearing aids).

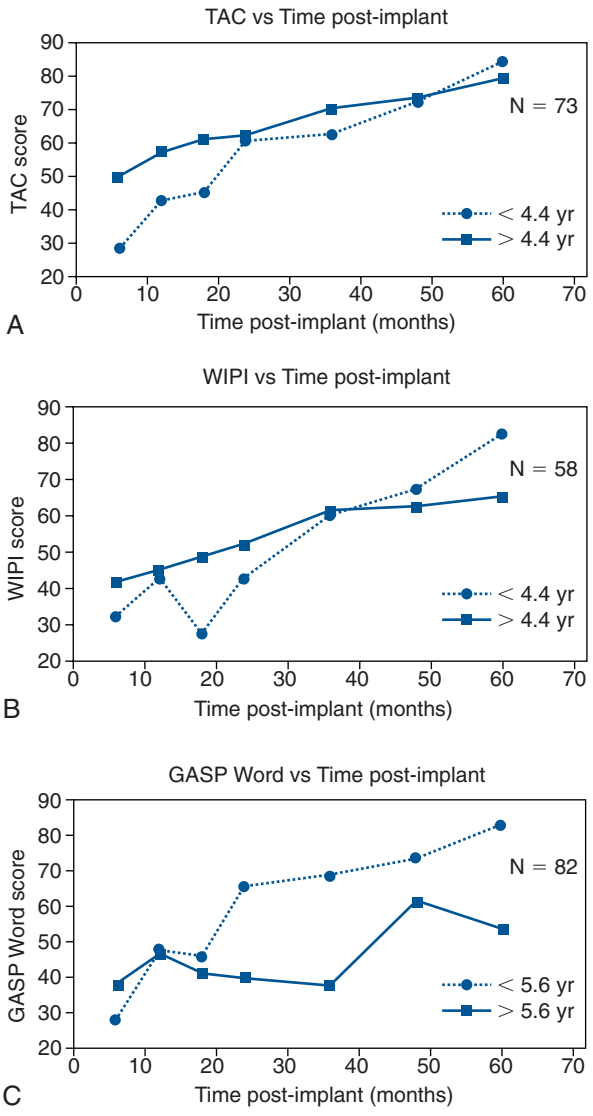

Figure 132-8. The influence of age at implantation on various speech/hearing tests in congenitally or prelingually deaf children using cochlear implants. **A,** Average performance over time after implantation for Test of Auditory Comprehension (TAC) scores. Data are from 73 children divided into groups implanted before and after age 4.4 years (*dotted lines,* <4.4 years; *solid lines,* >4.4 years). **B,** Average performance of children implanted before or after age 4.4 years (*dotted lines,* <4.4 years; *solid lines,* >4.4 years) on the Word Intelligibility by Picture Identification (WIPI) test. Data are based on 58 subjects. **C,** Results using Glendonald Auditory Screening Procedure (GASP). Data from 82 children are divided into groups implanted before or after age 5.6 years (*dotted lines,* <5.6 years; *solid lines,* >5.6 years). *(Adapted from Harrison RV, Panesar J, El-Hakim H, et al. The effects of age of cochlear implantation on speech perception outcomes in prelingually deaf children.* Scand Audiol. *53(30 Suppl):73-78, 2001.)*

Other Hearing Disorders

There is much evidence of radical plastic change in the brains of congenitally deaf or blind subjects, where cortical areas that no longer serve one modality seem to take on some function for the remaining, dominant sense.[80-82] In a signing deaf subject, some processing of visual information is carried out in the auditory cortex.[83] These are examples

of brains that have developed with very unusual alterations to sensory input. From a practical perspective, such knowledge might be useful when considering whether a cochlear implant would be beneficial to a signing, congenitally deaf adult.

In extrapolating to humans from the animal plasticity studies outlined in this text, any type of sensorineural hearing loss, whether from ototoxic poisoning, acoustic trauma, or presbycusis, might result in some organizational change at the cortical level. Does such change have any functional significance? Does it improve auditory processing, or does it contribute further to hearing dysfunction? Presently, we do not have good answers to such questions. There is no evidence that the cortical overrepresentation of certain sound frequencies has any correlate in an improved psychophysical performance. On the negative side, however, it is easy to speculate that such isofrequency areas would contribute to loudness recruitment and perhaps the generation of some types of tinnitus. In an experimental animal (as in Figs. 132-3 and 132-4) with a large region of auditory cortex apparently connected to a narrow region of the cochlea, certain frequencies of acoustic stimulus would "light up" vast areas of the auditory cortex. It is difficult to imagine that this degree of cortical activation would not be reflected in a perceived increase in loudness.

With regard to tinnitus, a few speculative comments are in order. First, certain types of tinnitus could arise from auditory neurons that somehow develop self-perpetuating activity. The brain is full of networks that might allow this, such as local and reciprocal intracortical connections or thalamocortical feedback loops. With our understanding that synaptic efficacy can be considerably increased by LTP and hebbian mechanisms, it is easy to conceive of local circuits being reinforced to the point of reverberation (i.e., having a positive feedback mode). For this and other reasons, the need for extensive and continuous inhibitory control within the brain is obvious. When there are extensive isofrequency areas in the auditory cortex with the potential for massive synchronous activity, it is possible that such inhibitory mechanisms cannot sufficiently suppress positive feedback processes.

An even simpler mechanism for tinnitus production is plausible. Suppose that the synchronous firing of these extensive isofrequency neural populations results in them all being connected together. This is quite feasible; remember Hebb's rule: "Cells that fire together, wire together." Assuming that conscious perception has some basis in cortical neuronal activity, perhaps even low levels of "resting" activity in a vast, linked network of cells could give rise to a chronic sound sensation.

In light of the experimental data on plasticity, one further comment about tinnitus is relevant. There is much discussion about the different types and origins of tinnitus. One distinction often made is between "central" and "peripheral" tinnitus. The studies on central auditory plasticity draw attention to the fact that a cochlear lesion can cause central reorganization. It is plausible that some traumatic event at the cochlear level, causing either less afferent input (after hair cell loss) or more afferent input (injury discharge from dying neurons), could set up connection patterns that result in cortical overrepresentation. Although the central neurons are presumably the immediate cause of the tinnitus sensation, the intimate link to a causal peripheral lesion blurs any notion about the real origin of the tinnitus.

Summary

Many aspects of plastic change in otology have not been adequately covered in this chapter. In particular, the plasticity of the vestibular system, and that of sound localization, have not been addressed. Nevertheless, we have covered considerable ground in relation to auditory system plasticity, and we have reviewed some important basic mechanisms relevant to all sensory systems. We have also initiated some discussion on the clinical relevance of this new knowledge

We tend to think about the brain as a complex, wired system that, under certain circumstances, is capable of being rewired. These reorganizations, as noted in some of the studies described here, are often initiated by alterations to sensory input. As we learn more about the plasticity of synaptic connections and the variety of potential mechanisms that can alter how neurons connect and communicate, it has become clear (at least to this author) that the brain is a constantly reorganizing system. Plasticity is the rule, not the exception. Sometimes it seems that we should be seeking not the evidence and mechanisms of plastic change, but rather the mechanisms that stabilize the brain and prevent plasticity. In a final note on age-related plasticity in the auditory system, perhaps this is what maturity is all about. It is not so much a decline in plasticity, but the gradual application of a stabilizing brake.

CHAPTER ONE HUNDRED AND THIRTY-THREE

Diagnostic Audiology

Paul R. Kileny

Teresa A. Zwolan

Key Points

- The audiologic test battery encompasses a range of behavioral/psychophysical and objective/physiologic tests that provide key insights into otologic disorders.
- Some components of the auditory test battery are nonspecific (e.g., tonal and speech audiometry); others (e.g., electrocochleography) are specific for the diagnosis of specific auditory system pathologies.
- It is necessary to apply certain basic tests, such as pure-tone audiometry, speech audiometry, immittance testing, and otoacoustic emissions, to characterize the basic properties of the auditory system for every new patient with auditory complaints.
- More specific and physiologic tests need to be tailored based on patient complaints, the results of the basic test battery, and clinical suspicion.
- If administered and interpreted correctly, physiologic tests, such as electrocochleography, auditory brainstem response testing, and otoacoustic emission testing, offer substantial specificity and sensitivity. Critics citing low specificity and sensitivity of audiologic tests (i.e., auditory brainstem response in the diagnosis of small acoustic neuroma) do not take into consideration poor technical quality.

Audiologic Test Battery

In his book, *Practical Observations on Aural Surgery and the Nature and Treatment of Diseases of the Ear,*[1] Wilde stated:

> The degree of deafness may be learned, and the hearing distance measured by holding an ordinary watch near the external meatus, and the distance at which the tickings can be accurately counted, and at which the patient is conscious of an interval between these sounds, should be recorded. To effect this properly, the watch should be approached gradually to the ear until it gets to within the hearing point, and again applied directly to the auricle, and gradually removed to some distance.

Wilde[1] continued, "It is absolutely necessary, if we wish to watch the progress of a case not only to conduct these observations with great care, but also to take a written note of the hearing distance the first and each subsequent time we see the patient." Wilde also recommended placing the watch "gently between the teeth of the patient, and the amount of hearing thus obtained likewise noted"—an early attempt at bone conduction testing.

Founded on such clear, practical thinking, the clinical science of audiology has advanced through the availability of instrumentation that accurately quantifies the sensitivity and acuity of human hearing. In his book, *Disease of the Ear,*[2] Dench stated that "it is scarcely necessary to mention the more complicated instruments which from time to time have been devised for determining quantitative audition. Their use has never become universal on account of the complex construction." Dench[2] described and illustrated the electric audiometer developed by Urbantschitsh in 1890—a device that extended technology made available by the invention of the telephone. He further discussed the phenomena of crossover and interaural attenuation, cautioning against errors that may occur when a loud sound is presented to a profoundly deaf ear in the presence of a normal-hearing contralateral ear.

Similar to otologists today, these early otologists used the results of auditory testing in two ways: to quantify hearing loss and to assist in the differential diagnosis of ear disease on the basis of auditory phenomena. Today, our clinical armamentarium consists of highly sophisticated and specific clinical test modalities that provide accurate quantitative information regarding a patient's hearing sensitivity. Other tests capitalize on specific auditory phenomena to provide differential diagnostic site-of-lesion information. The clinical audiology test battery can be classified into two groups on the basis of how the results are obtained: (1) behavioral or psychophysical tests, requiring a specific behavioral response to an auditory stimulus, and (2) objective tests, which are based on a physical or a physiologic measurement associated with an auditory stimulus. An example of a physical measurement is the acoustic immittance typically used to determine middle ear status. An example of a physiologic measurement is the auditory brainstem response (ABR) and other electrophysiologic phenomena.

Typically, diagnosis is based on a combination of information obtained from the patient's history, physical examination, and audiologic test battery results. As a rule, there is a hierarchy of auditory diagnostic tests specifically based on patient symptoms and complaints, and results obtained in one manner can often be verified by the results obtained using a different modality. An air-bone gap shown by pure-tone audiometry can be confirmed by an abnormal tympanogram, the typical otoscopic appearance of a retracted eardrum, and its poor mobility on pneumatic otoscopy to determine the presence of a conductive hearing loss caused by middle ear pathology.

Tests for Hearing Sensitivity or Acuity

Pure-tone audiometry is the most commonly used test for evaluating auditory sensitivity. Auditory pure-tone signals are delivered primarily through air conduction and bone conduction. The American National Standards Institute (ANSI)[2a] defines the threshold of audibility as "the minimum effective sound pressure level of an acoustic signal producing an auditory sensation 'in a specified fraction of the trials.'" Most often, threshold is defined as the lowest signal intensity at which multiple presentations are detected 50% of the time.[3]

When used clinically, audiometric threshold data are most often displayed on a graphic plot called an audiogram (see Figs. 133-2 through 133-4). Various symbols are used to represent data obtained for the right and left ears by use of air-conducted and bone-conducted signals. The current audiogram representation was recommended by the American Speech, Language, and Hearing Association in 1974, and was adopted by ANSI S3.21-1978. Data are presented in hearing level (HL), which is calibrated to referent sound pressures (ANSI S3.6-1969, 1970) that represent the hearing sensitivity of normal young adults when tested under reasonably quiet test conditions. An audiogram represents a patient's ability to hear sounds compared with the hearing sensitivity of a group of normal young adults.

Pure-Tone Air-Conduction Testing

Pure-tone air-conduction thresholds measure the function of the total hearing system, including the external, middle, and inner ear. In typical audiometric testing, pure tones that range in octave spacings from 250 to 8000 Hz are presented to the listener by headphones or insert earphones. Threshold is usually determined by the use of a version of the Hughson-Westlake "ascending method,"[4] in which sounds are initially presented well above threshold, and are then presented in decreasing steps of 10 to 15 dB until the sound is inaudible. The tone is increased in "up 5-dB, down 10-dB steps" until the single HL at which a response is obtained three times is reached.[5]

Because air-conduction thresholds measure the acuity of the entire hearing system, when evaluated alone they provide little information regarding the etiology of hearing loss and specific auditory pathology. When examined in conjunction with thresholds obtained by bone-conduction testing, however, they help determine the type and the severity of the hearing loss. When plotted on an audiogram, pure-tone thresholds also provide information regarding the severity of the hearing loss. Thresholds that fall into the 0- to 25-dB range are considered normal, whereas thresholds greater than 25 dB represent various levels of hearing loss (see Fig. 133-1).

Pure-Tone Bone-Conduction Testing

Pure-tone bone-conduction thresholds provide auditory threshold information when the cochlea is stimulated more or less directly, with stimuli bypassing external and middle ear structures. Differences between thresholds obtained through air and bone conduction are used to determine the type of hearing loss (normal hearing versus conductive loss versus sensorineural hearing loss [SNHL]) and the magnitude of conductive hearing loss if it exists.

The location of the bone-conduction thresholds on the audiogram helps determine the severity of the hearing loss (Figs. 133-1). In bone-conduction testing, a bone oscillator is typically placed on the mastoid process. Although this placement does not guarantee that the responses obtained are from the ear located on the side on which the oscillator was placed, such placement provides an enhanced dynamic range compared with other placements, such as at the frontal bone.[6] Most audiometers currently in use are calibrated for placement of the vibrator on the mastoid.

The relationship between air-conduction and bone-conduction thresholds is used to determine the type of hearing loss. When air-conduction thresholds are elevated relative to normal bone-conduction thresholds—a phenomenon referred to as an *air-bone gap*—the loss is classified as conductive (Fig. 133-2). When air-conduction and bone-conduction thresholds indicate the same amount of hearing loss, the loss is classified as sensorineural (Fig. 133-3). Finally, when air-conduction thresholds are elevated relative to abnormal bone-conduction thresholds, the loss is classified as mixed (Fig. 133-4).

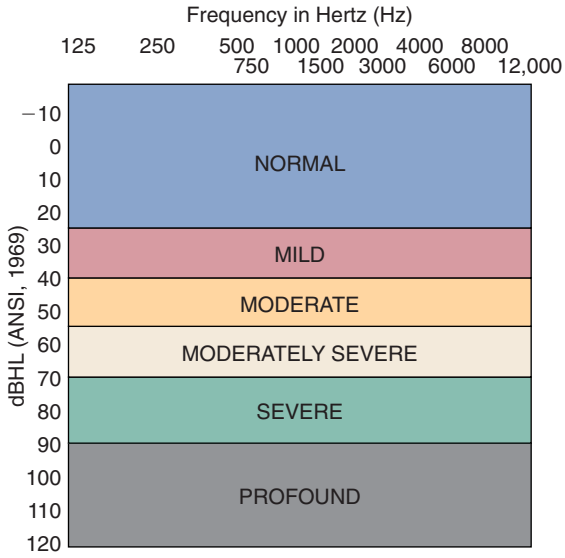

Figure 133-1. Graphic representation of categories of hearing loss.

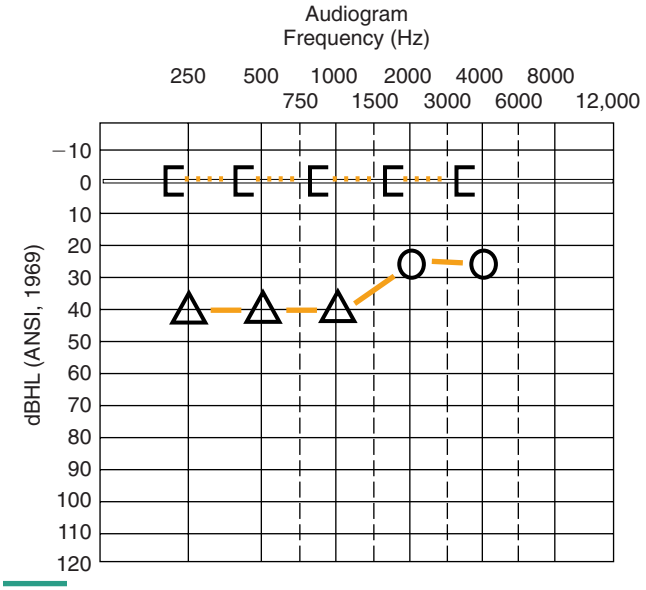

Figure 133-2. Example of an audiogram characterized by an air-bone gap indicating a conductive hearing loss.

Speech Testing

Another essential component of the audiologic test battery is the evaluation of the listener's ability to detect and recognize speech. Three speech tests are commonly included in the audiologic test battery: determination of the speech detection threshold (SDT), determination of the speech reception threshold (SRT), and speech discrimination or recognition. The SDT indicates the intensity level at which a listener can barely discern the presence of a speech signal 50% of the time.[7] With such a task, the listener is not required to recognize the stimulus, but is merely asked to acknowledge its presence. Conversely, the SRT represents the intensity level at which a listener can repeat 50% of the speech material.[7] In contrast to the SDT, the SRT requires the listener to repeat the word that was presented. The SRT is usually 8 to 9 dB higher than the SDT,[8] whereas the SDT usually coincides with the pure-tone average (PTA), an average of the pure-tone thresholds obtained at 500 Hz, 1000 Hz, and 2000 Hz. The

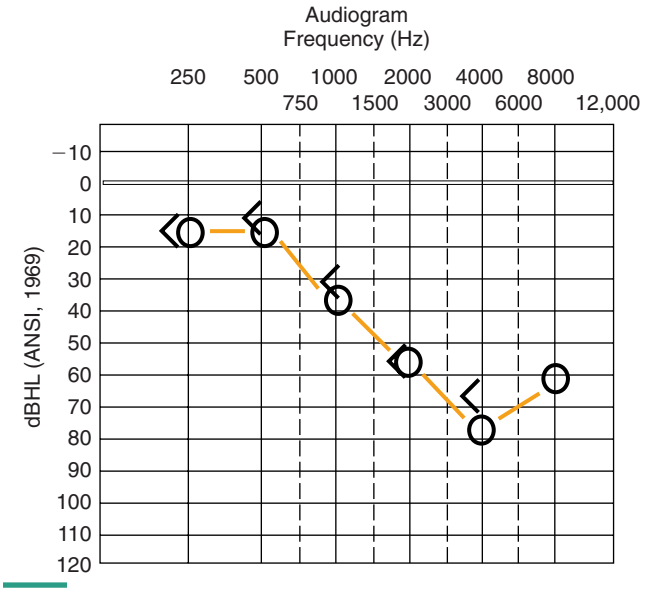

Figure 133-3. Audiogram showing a sloping, high-frequency sensorineural hearing loss (air-conduction and bone-conduction thresholds are identical).

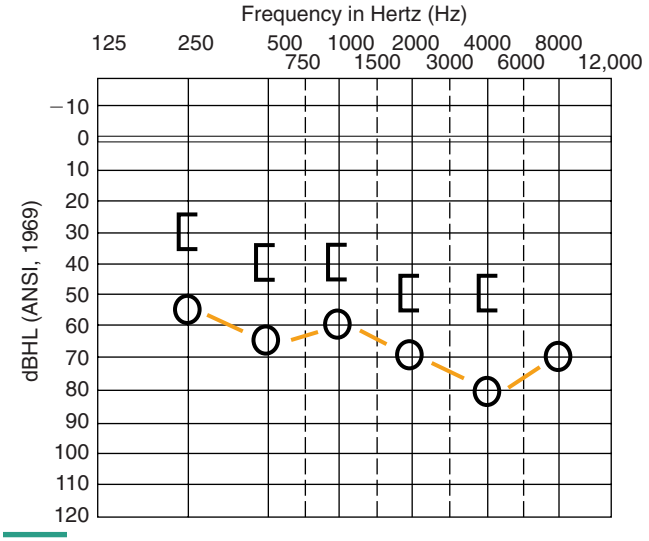

Figure 133-4. Audiogram showing a mixed hearing loss. Air-conduction and bone-conduction thresholds are elevated; however, there is also an air-bone gap.

SDT and SRT can be obtained using either air conduction or bone conduction.

Determination of speech discrimination is a more complex task than determination of either SDT or SRT. Speech discrimination is an important part of the audiologic test battery because it provides information regarding the listener's ability to recognize speech under well-controlled conditions. Speech discrimination test results are used in conjunction with the findings of other tests to help determine the differential diagnosis of hearing loss; provide information about the listener's ability to communicate effectively; aid in decision making regarding candidacy for various surgical procedures; provide useful information about rehabilitative needs, including the effectiveness of hearing aids or cochlear implants; and provide information regarding central auditory function.[7]

Various materials and formats have been used to evaluate speech discrimination. The most commonly used as part of an adult audiometric test battery include monosyllabic words presented in an open-set format, such as the CID W-22 word lists[9] and the Northwestern University Auditory Test No. 6 (NU-6).[10] Although taped materials are optimal when evaluating speech discrimination, materials are often presented through live voice for rapidity and ease of administration. Speech discrimination materials are usually presented 50 dB above the patient's SRT—a level that should be well within their audible range.

Patients with a conductive hearing loss frequently have excellent speech discrimination scores when test stimuli are presented at a sufficiently loud level. Patients with a cochlear sensory hearing loss often have reduced scores on speech discrimination tests, even when the stimuli presented are well within their audible range. Patients with lesions of the eighth cranial nerve or beyond tend to have lower speech discrimination scores than patients with a cochlear lesion site, and may have reduced speech discrimination in the presence of normal auditory pure-tone thresholds. The extreme of this phenomenon may be found in patients with cortical lesions who are unable to understand speech or any type of complex auditory signal.[11]

Masking

If a sufficiently loud signal is presented to the test ear, it may cross the skull where it will be perceived by the nontest ear, a phenomenon referred to as *crossover*. It may be necessary to deliver a masking signal to the ear that is not being tested. When crossover occurs, responses to air-conducted pure tones that have crossed over from the poorer ear shadow the thresholds of the better ear. Such "shadow" responses reflect the threshold levels of the better ear elevated by the amount of interaural attenuation at each test frequency.

Interaural attenuation refers to the reduction in sound when it crosses from one ear to the other. The lower limit for interaural attenuation for bone-conduction testing is essentially 0 dB across frequencies.[12,13] Because of this, masking should be used routinely with bone-conduction testing when threshold levels between ears are asymmetric. Additionally, because the signal primarily travels to the nontest ear through bone conduction, the need for masking arises when air-conduction thresholds for the test ear are poorer than the bone-conduction thresholds for the nontest ear. Masking is useful in such situations because it shifts the sensitivity of the cochlea of the nontest ear to prevent it from hearing the signal that is delivered to the test ear.

The need for masking with air-conducted signals depends on how the signal is delivered. Interaural attenuation ranges from 35 to 50 dB for stimuli delivered via headphones and 60 to 65 dB for earphones,[14] depending on the frequency of the test signal, with a tendency for greater interaural attenuation at the higher frequencies.[12] Insert earphones have less contact with the lateral temporal bone than standard headphones, so less sound energy is delivered contralaterally. Greater levels of effective masking to the nontest ear are possible, with less crossover occurring to the test ear, when insert earphones are used.

Masking should be used with air-conduction testing when the air-conduction threshold of the test ear and the air-conduction or bone-conduction threshold of the nontest ear differ by the interaural attenuation factor for the frequency being tested. When determining the SRT, masking should be used whenever the SRT of the test ear and the SRT, air-conduction PTA, or bone-conduction PTA of the nontest ear differ by 45 dB or more. With speech discrimination testing, masking should be used whenever the presentation level used to deliver stimuli to the test ear is 45 dB or more above the SRT, air-conduction PTA, or bone-conduction PTA of the nontest ear.[12]

The critical bandwidth concept dictates that the extent of threshold shift produced by a masking signal is affected by its frequency and intensity.[12] The term *effective masking* refers to the intensity level of the test signal that is barely masked by presentation of a masking noise to the ipsilateral ear. When selecting a masking signal, the goal is to select a signal that provides the largest shift in threshold with the least intense noise. Because the effective masking level depends on the structure of the test signal, various types of noises are used for clinical masking. Narrow band noises centered around a specific frequency identical to that of the pure-tone test signal are most often used with pure-tone testing, whereas speech noise of a more complex nature is most often used when masking for speech tests.

Occasionally, test situations arise in which masking is necessary, but is impossible, such as with cases of bilateral conductive or mixed hearing loss. This phenomenon—referred to as a *masking dilemma*—may occur when bone-conduction thresholds for both ears are normal, and the air-conduction thresholds equal or exceed interaural attenuation. In such cases, unmasked air-conduction thresholds likely reflect the responses of the nontest ear, whereas masked air-conduction and speech thresholds may seem worse than they actually are because of overmasking. Overmasking occurs when the masking noise presented to the nontest ear "crosses over" and affects the responses obtained for the test ear.

Tests to Evaluate Middle Ear Function

The term *acoustic immittance* is used to refer to either acoustic admittance (the ease with which energy flows through a system) or acoustic impedance (total opposition to the flow of sound energy). Acoustic immittance measures are used clinically as screening and diagnostic tools for the identification and classification of peripheral (particularly middle ear) and central auditory disorders, and may be used as a tool to estimate auditory sensitivity objectively.[15] The acoustic immittance measures used most often clinically include tympanometry and stapedial reflex measures.

Tympanometry measures the acoustic immittance in the ear canal as a function of variations in air pressure in the ear canal. Testing includes placement of a probe into the ear canal to form an airtight seal. Air pressure within the canal is varied in positive and negative directions (relative to ambient pressure) while a probe tone is delivered to the ear. The amount of acoustic energy that is reflected from the eardrum is measured, providing information about the transmission characteristics of the middle ear. The magnitude of the reflected acoustic energy changes as a function of middle ear and eardrum status: the less compliant the system, the greater the intensity of the reflected tone. In a normal ear, acoustic admittance is maximal near ambient pressure and decreases as the pressure in the ear canal is either decreased or increased relative to the ambient pressure.

Specifically, tympanometry provides an estimation of intratympanic pressure, eustachian tube function, tympanic membrane integrity and mobility, and continuity of the ossicular chain. Acoustic admittance is optimal when the same air pressure is present on both sides of the tympanic membrane. The peak of the tympanogram reflects the resting pressure in the middle ear. Because the eustachian tube serves to ventilate the middle ear space, the tympanogram peak also provides information regarding eustachian tube function; a negative tympanogram pressure peak almost invariably indicates that the eustachian tube is not adequately ventilating the middle ear space because of eustachian tube obstruction caused by inflammation, infection, a mass lesion, or neuromuscular dysfunction.

A commonly used procedure is employed in classification schemes for tympanogram shapes. It was first described by Liden[16] and later modified by Jerger,[17] Jerger and colleagues,[18] and Liden and colleagues.[19] This classification of tympanogram shapes is described in Figure 133-5.

Type A tympanograms indicate normal middle ear pressure as indicated by a tympanogram peak at decaPascal. There are two subcategories of type A tympanograms: type A_D and type A_S. Type A_D shapes indicate an unusually high pressure peak and may indicate tympanic membrane or ossicular chain hypermobility caused by an atrophic tympanic membrane scar or an ossicular chain discontinuity. Type A_S shapes indicate a pressure peak at 0, although the peak is reduced in amplitude. This reduction may be caused by the presence of ossicular chain fixation, which may be caused by otosclerotic stapes footplate fixation. A type B tympanogram is flat, indicating no point of maximum compliance. Type B tympanograms may be seen in cases of otitis media with effusion, space-occupying lesions of the tympanic cavity, and tympanic membrane perforations. A type C tympanogram indicates negative middle ear pressure as reflected by a negative pressure peak and may indicate eustachian tube dysfunction. A type C tympanogram also may be present in the early stages of otitis media without effusion. A type D pattern, which has a notch in the pressure peak, is often seen with scarred eardrums or with normal, hypermobile eardrums.

Acoustic immittance tools also provide information regarding the volume of air medial to the probe. This information, when used in conjunction with that derived from the evaluation of a tympanogram's shape, can provide useful diagnostic data. Generally, ear canal volumes normally range from 0.5 to 1 mL in children and 0.6 to 2 mL in

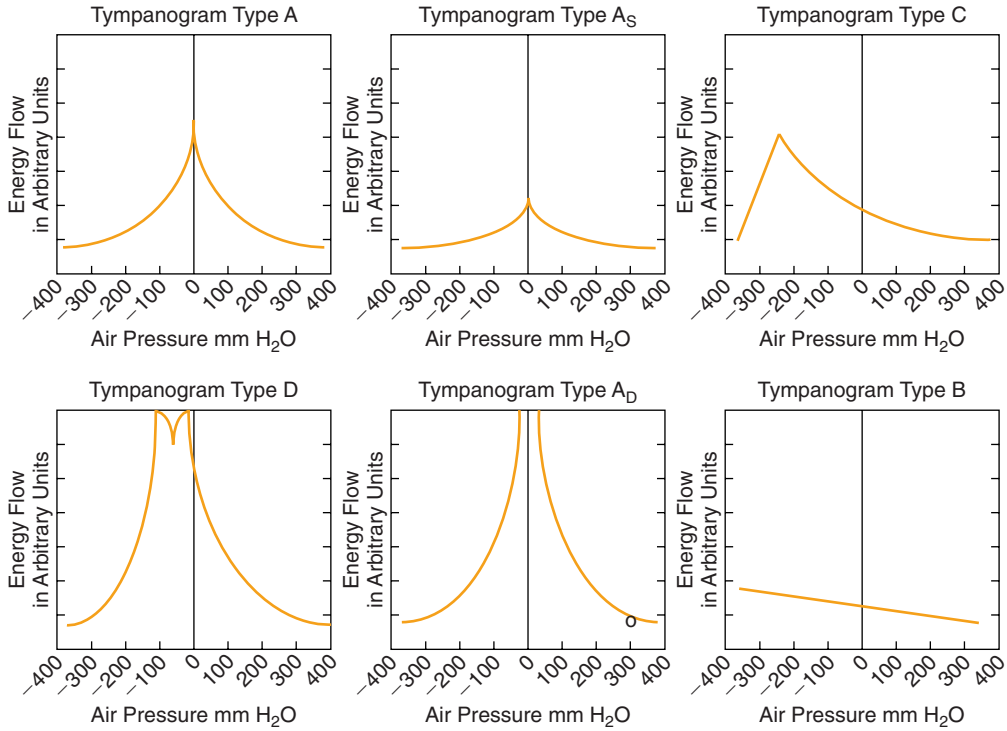

Figure 133-5. Classification of tympanograms: type A, type A_S, type C, type D, type A_D, and type B.

adults.[20] Volume measurements greater than 2 mL in children and greater than 2.5 mL in adults usually indicate a tympanic membrane perforation or a patent pressure equalization tube[21,22] because the volume measurement includes the ear canal and the tympanic cavity.

Stapedial reflex measures are also part of the middle ear test battery, and provide important and useful diagnostic information. The two most commonly used stapedial reflex measures include the acoustic reflex threshold and acoustic reflex decay. Both of these tests measure changes in tympanic membrane compliance caused by contraction of the stapedius muscle and are particularly useful for differentiation of cochlear and retrocochlear lesion sites. The acoustic reflex threshold test determines the softest level of sound that elicits stapedial muscle contraction. This normally occurs bilaterally after either ipsilateral or contralateral stimulation when a pure tone or noise is presented to a normal-hearing ear at levels of 70 to 100 dB HL.[23] The neural network of the acoustic reflex is located in the lower brainstem. The contralateral acoustic reflex arc includes the acoustic nerve and ventral cochlear nucleus, the medial superior olive, the contralateral motor nucleus of cranial nerve VII, and the contralateral stapedius muscle.[23]

Any type of middle ear disorder prevents the tympanic membrane from showing a change in compliance when the stapedius muscle is contracted. Ipsilateral and bilateral reflexes are absent bilaterally when the patient has a conductive hearing loss in the test ear. In cochlear pathologic conditions, the acoustic reflex often occurs when the impaired ear is stimulated at a level of 60 dB or less, indicating the presence of loudness recruitment. As the cochlear loss increases to greater than 60 dB HL, however, the chance of observing an acoustic reflex threshold decreases.[23] In most cases of retrocochlear pathology, the acoustic reflexes are absent when the involved ear is stimulated. If acoustic reflexes are present, an ear with a retrocochlear disease frequently is unable to sustain contraction of the stapedius muscle as measured with the acoustic reflex decay test. Finally, the absence of contralateral reflexes, with ipsilateral reflexes intact, may be seen in patients with brainstem disease as a result of the presence of a lesion in the area of the crossed brainstem pathways.[23]

The stapedius reflex also provides valuable clinical information regarding the level of a facial nerve lesion in patients with facial nerve paralysis. If the lesion is proximal, an absent stapedius reflex may be expected. If the lesion is distal to the stapedius branch, an intact reflex may be expected. Stapedius reflex measurement should be included routinely in the evaluation of patients with facial paralysis.

Acoustic reflex decay measures the ability of the stapedius muscle to maintain sustained contraction. During this test, a signal is presented 10 dB above the acoustic reflex threshold for 10 seconds. A response is considered abnormal if the response amplitude decreases to one half or less of its original amplitude within 5 seconds. Because reflex decay is common in many normal ears at higher test frequencies, frequencies of 500 Hz and 1000 Hz are most often used in acoustic reflex decay tests. Abnormal reflex decay may indicate retrocochlear disease. Patients with a cochlear or conductive hearing loss show negative acoustic reflex decay when an acoustic reflex threshold is present in the test ear.

Objective Tests for Differential Diagnostic Applications

Otoacoustic Emissions

Until more recently the term *objective test,* when referring to the auditory system, denoted exclusively the measurement of neuroelectric events associated with auditory stimulation, beginning with Davis' discovery of the cortical auditory evoked potential in 1939.[24] The discovery of the ABR by Jewett and Williston[25] marked the beginning of a revolution in the clinical application of auditory electrodiagnostic tests. The ABR changed the way hearing was tested in newborns and infants, and provides physicians and audiologists with a reliable and informative neurodiagnostic tool and a reliable technique to monitor auditory function during surgery. With the discovery of the evoked otoacoustic emissions,[26] it became possible to analyze and investigate auditory function from hair cells to the auditory cortex. Otoacoustic emissions are not electric events, however. Rather, they are audiofrequency signals that can be recorded with a sensitive microphone by use of sophisticated signal processing, and they are thought to reflect the motility of the cochlea's outer hair cells.

The active motility of outer hair cells is thought to serve as an amplifier of the displacement of the cochlear partition, resulting in various forms of otoacoustic emissions as by-products that are detectable at low intensities.[27] These acoustic by-products of outer hair cell motility are often referred to as *cochlear echoes*. Acoustic emissions may be divided into spontaneous emissions, which occur without acoustic stimulation of the ear, and evoked otoacoustic emissions, which represent a response to an acoustic stimulus delivered to the ear.[28] The evoked otoacoustic emissions may be subdivided further into transient evoked otoacoustic emissions, elicited by a transient, brief stimulus such as a click or a brief tone burst; stimulus-frequency otoacoustic emissions, elicited by a pure tone; and distortion-product otoacoustic emissions, generated by pure tones separated by a specific frequency difference. With some exceptions, evoked otoacoustic emissions may be obtained from essentially all ears with normal hearing, and may be reduced or absent in ears with a hearing loss greater than 35 to 40 dB.

Compared with evoked potential measurements, an advantage of evoked otoacoustic emission measurements is the simple and brief patient preparation and examination. The test requires a probe containing a miniature loudspeaker and a microphone to be sealed into the ear canal. The stimulus eliciting the evoked otoacoustic emission is delivered by the loudspeaker, and the microphone samples the output or the emission for approximately 20 ms after stimulus stimulation. The output from the microphone is filtered, amplified, and averaged to enhance the signal-to-noise ratio. The transient evoked otoacoustic emissions consist of a delayed echo of the stimulus.[26] Transient evoked emissions span a frequency range from 0.4 to 6 kHz. The latency is typically 5 to 20 ms in humans, and the amplitude of transient evoked otoacoustic emissions tends to decrease as frequency increases.[28-30]

Distortion-product otoacoustic emissions are elicited by two stimulus tones delivered at a 55- to 85-dB sound pressure level, separated in frequency. The most prominent distortion-product otoacoustic emission occurs at the cubic difference frequency described by the expression $2f_1$-f_2, in which f_1 represents the lower frequency stimulus, and f_2 represents the higher frequency primary tone. The resultant emission typically has an amplitude that is 60 dB lower than the levels of the primary tones. It is advantageous for the two primary tones to be 10 to 15 dB apart.[28] It has been shown that there is little intrasubject variability in otoacoustic emission measurements, and that such measurements are stable over several years for any one ear.[26,28,31,32] Otoacoustic emissions also provide functional information about well-defined, frequency-specific regions of the cochlea, assisting the tracking of change in inner ear pathology characterized by outer hair cell dysfunction, such as noise-induced hearing loss or ototoxicity. Figure 133-6 illustrates transient-evoked and distortion-product otoacoustic emissions obtained from the same normal-hearing individual.

Otoacoustic emissions may be useful differential diagnostic tools for acoustic neuroma, including treatment planning. The presence of robust otoacoustic emissions indicates full cochlear outer hair cell and efferent fiber integrity, and this may serve as supplemental information supporting a planned hearing preservation surgical approach. Additionally, as shown later in this chapter, otoacoustic emissions represent an integral diagnostic measure for the diagnosis of auditory neuropathy or dyssynchrony.

The following case illustrates the differential diagnostic use of transient evoked otoacoustic emissions and ABRs. A 53-year-old man in good health noticed high-pitched tinnitus in his left ear. Pure-tone audiometry revealed normal hearing bilaterally through 2000 Hz, with bilateral notches at 4000 Hz at 20 dB in the right ear and 25 dB in the left ear. Speech recognition scores were excellent (100% for the right ear and 92% for the left ear). Because of the presence of unilateral tinnitus, however, ABR testing was carried out (Fig. 133-7). All of the component peaks of the ABR were present with left ear and right ear stimulation. Although the I to III interpeak latency was 2.28 ms for

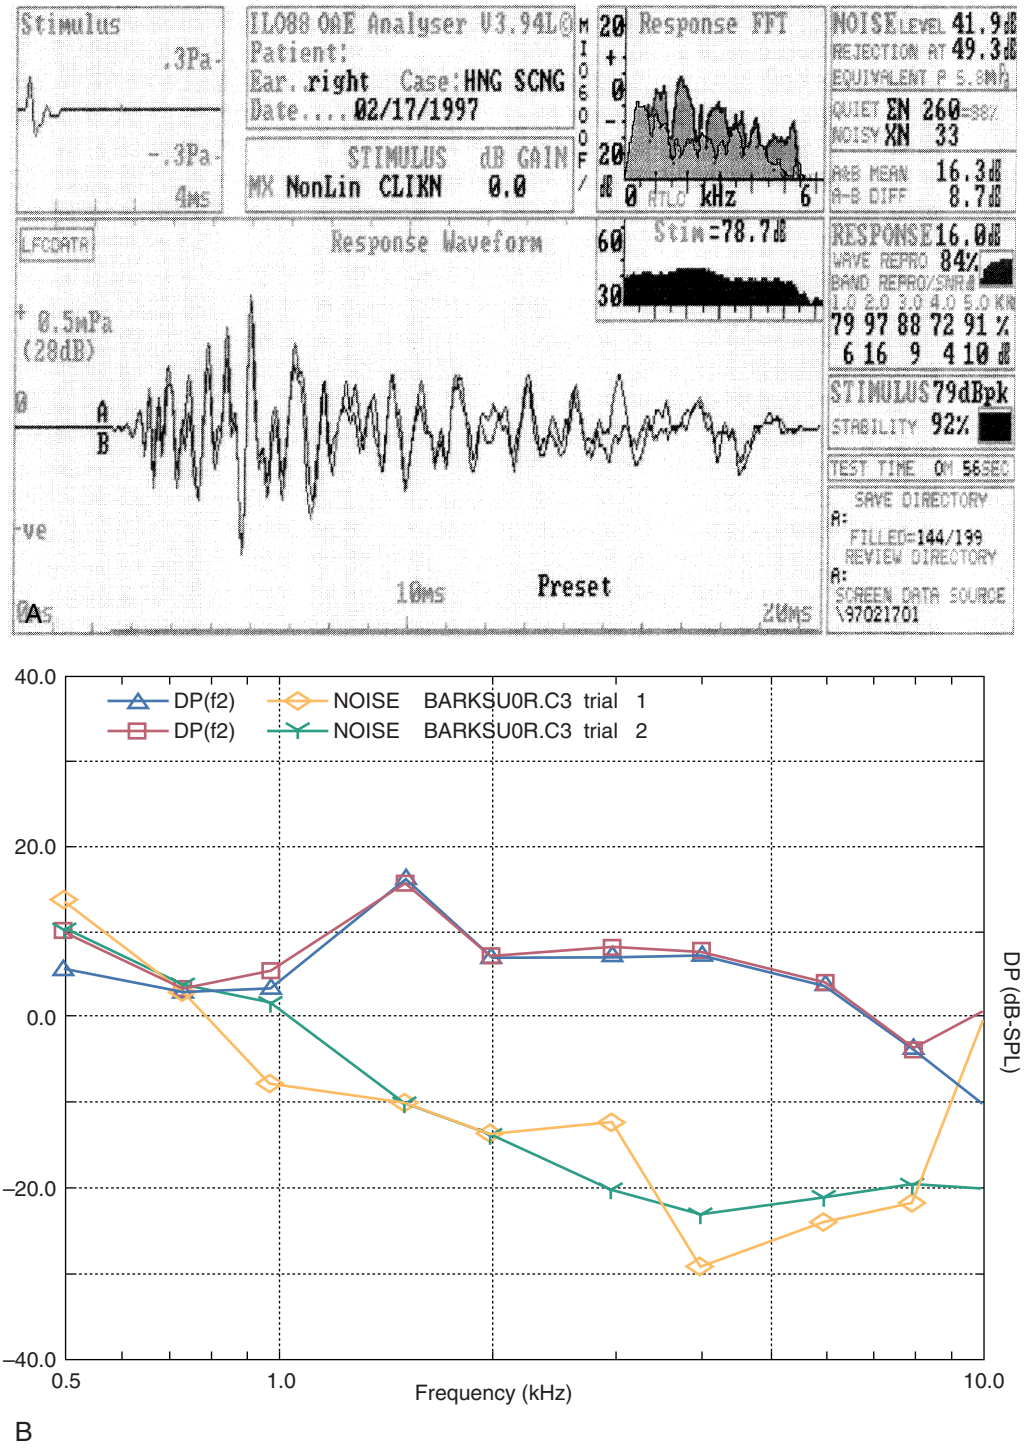

Figure 133-6. Transient evoked otoacoustic emissions **(A)** and distortion-product otoacoustic emissions **(B)** from the same normal-hearing ear.

the right ear (within normal limits), it was outside the normal limits in the left ear (2.58 ms). Magnetic resonance imaging (MRI) identified a 7-mm enhancing mass in the porus acusticus region of the left internal auditory canal.

Otoacoustic emission testing was also done to determine if there was any significant cochlear involvement (see Fig. 133-7B). This consisted of reproducible emissions at 1000 Hz and 2000 Hz (72% and 92% reproducibility), with no discernible emissions at the higher frequencies. Despite the minimal high-frequency hearing loss, this result indicated some early, subclinical cochlear involvement. Although still speculative, our observation is that impaired otoacoustic emissions in patients diagnosed with an acoustic neuroma indicate a poor prognosis for postoperative hearing preservation.

Electrocochleography

The term *electrocochleography* refers to the measurement of neuroelectric events generated by cochlear structures and the auditory nerve in response to acoustic stimulation. Depending on the mode of stimulus delivery, the electrocochleographic response may consist of the cochlear microphonic, the summating potential (SP), and the whole-nerve action potential (AP) generated by the auditory nerve. A primary clinical application of electrocochleography is in the differential diagnosis

of hydropic conditions of the cochlea that may be associated with Meniere's disease or other diseases. It is believed that the presence of hydrops affects the elasticity of the basilar membrane and contributes to the increased amplitude of the SP relative to that of the AP. A relatively large SP/AP ratio is considered diagnostic of endolymphatic hydrops.[33] The SP/AP amplitude ratio is used instead of the absolute amplitude of the SP to avoid contamination of this measurement by interpatient variability. Patients with endolymphatic hydrops are thought to exhibit relatively larger SP/AP ratios. In one study, SP/AP ratios measured for subjects with normal hearing for their age were found to range from 0.04 to 0.59.[34] Gibson and associates[35] reported transtympanic SP/AP percentage ratios ranging from 10% to 63%. Coats and colleagues[36] found that 44% of ears considered to have Meniere's disease were below the 95% upper limit values for normal ears.

Measurement of these events requires an electrode placed as close as possible to their source. The components of the electrocochleographic response are most prominent when recorded directly with an electrode placed on the round window. Because this requires surgical exposure of the middle ear, however, it is not widely accepted for routine outpatient clinical applications. An alternative method is the use of a transtympanically placed needle electrode referenced to an electrode external to the ear (forehead or tragus).

Other, less invasive recording techniques are available as well, including the use of electrodes (e.g., the Coats leaf electrode, a gold foil–wrapped foam plug, or a tympanic membrane surface electrode) placed extratympanically in the external ear canal. The tympanic membrane surface electrode is gaining in popularity because of ease of placement and the clarity and amplitude of the responses it provides.

One type of tympanic membrane surface electrode consists of a hydrogel tip encasing a silver wire threaded through a soft polyethylene tube. This electrode is positioned gently over the lateral surface of the eardrum under microscopic visualization with a small nasal or Lempert speculum to avoid dislodging the electrode, as would be the case if a standard ear speculum were used. Although the amplitude of the response obtained with the tympanic membrane surface electrode is attenuated compared with a transtympanic needle recording, its ease of placement and noninvasive nature make up for this disadvantage. Figure 133-8 illustrates an electrocochleographic response recorded with a hydrogel tympanic membrane surface electrode. This response was elicited by an alternating click presented at an 85-dB normal hearing level (nHL) and clearly consists of a well-defined SP and AP.

Gibson[37] evaluated the use of electrocochleography in the diagnosis of Meniere's disease, and suggested that measurement of the absolute amplitude of the SP from responses to 1-kHz tone-burst stimuli was optimal. He considered an SP with an amplitude exceeding 3 mV abnormal. Margolis and coworkers[38] used tympanic membrane surface electrodes and provided detailed statistical information on the click-evoked SP/AP ratio, the latency difference of the AP when elicited by condensation versus rarefaction clicks, and the absolute amplitude of the SP from responses to 1- and 2-kHz tone-burst stimuli. This was a normative study involving 53 subjects. The authors found mean SP/AP ratios to depend on stimulus level, ranging from 0.22 at 78-dB nHL to 0.29 at 68-dB nHL. Ratios in the 95th percentile ranged from 0.40 to 0.49. The authors also determined normative ranges for absolute SP amplitude from responses to tone bursts. By use of a criterion of 0.35 or less for a normal SP/AP ratio and 0.5 or larger for a definitely abnormal test, Pou and associates[39] found that 57% of patients with clinically diagnosed endolymphatic hydrops were correctly identified.

The following case illustrates the utility of electrocochleography in the management of a patient with Meniere's disease. A 51-year-old woman has been followed in our department for the past 7 years. She initially presented in our clinic with a complaint of episodic vertigo, fluctuating hearing loss, aural fullness, tinnitus, and subjective hearing distortion in her right ear. Her right-sided fluctuating hearing loss has been well documented with low-frequency thresholds varying from 20 to 60 dB and values in between. She also presents with a stable high-frequency hearing loss in her right ear. The audiogram in her left ear has shown stable hearing with slightly elevated low-frequency thresholds, normal hearing in the middle frequencies, and a mild high-frequency hearing loss (Fig. 133-9).

The patient was treated conservatively with a low-salt diet and diuretics with which she was compliant; however, her hearing thresholds continued to fluctuate, and she continued to present with episodic vertigo and the frequent sensation of impending attacks. After 7 years of these symptoms, it was decided to treat her with right-sided labyrinthectomy because her hearing loss remained consistently in the moderate range with poor speech discrimination (52%). Before undertaking the operative procedure, however, it was important to confirm right-sided hydrops by electrocochleography and to rule out hydrops in her left ear to avoid ablative surgery in a case of potentially bilateral Meniere's disease.

Electrocochleography was done using a combination of surface electrode and a tympanic membrane surface electrode introduced under microscopic observation. The tympanic membrane surface electrode consists of a Silastic tube–enclosed silver wire with its uninsulated tip surrounded by hydrogel. For optimal recording, the hydrogel was briefly dipped into conductive electrode cream and inserted into the external ear canal using a small nasal speculum and the otomicroscope. It is important for the hydrogel end of the electrode to make contact with the tympanic membrane. The electrode is secured in the canal using the compressible foam tip of the insert transducer used to deliver the auditory stimuli to elicit the response.

Figure 133-10. Electrocochleography results from a patient with right-sided Meniere's disease. The summating potential-to-action potential (SP/AP) ratio was elevated to 0.50 on the right, involved side and was normal with a value of 0.22 on the left, uninvolved side.

Figure 133-10 shows the results of the electrocochleography evaluation. A two-channel recording protocol is illustrated: the upper trace is the electrocochleography recording using the tympanic membrane electrode, the lower trace is a contralaterally recorded auditory brainstem response (ABR). In this fashion, it is possible to record and evaluate the ABR simultaneously. With right (symptomatic) ear stimulation, a prominent SP was noted, and when calculating the amplitude ratio of the SP to AP (reference to a prestimulus baseline), the ratio for the right ear was elevated with a value of 0.5 and the ratio for the left, asymptomatic ear was normal with a value of 0.22. These results confirmed the presence of hydrops in the patient's right symptomatic ear and ruled out hydrops in her left ear. She subsequently underwent a right-sided labyrinthectomy with no complications. At the same time, she received a bone-anchored hearing aid on the right side to compen-

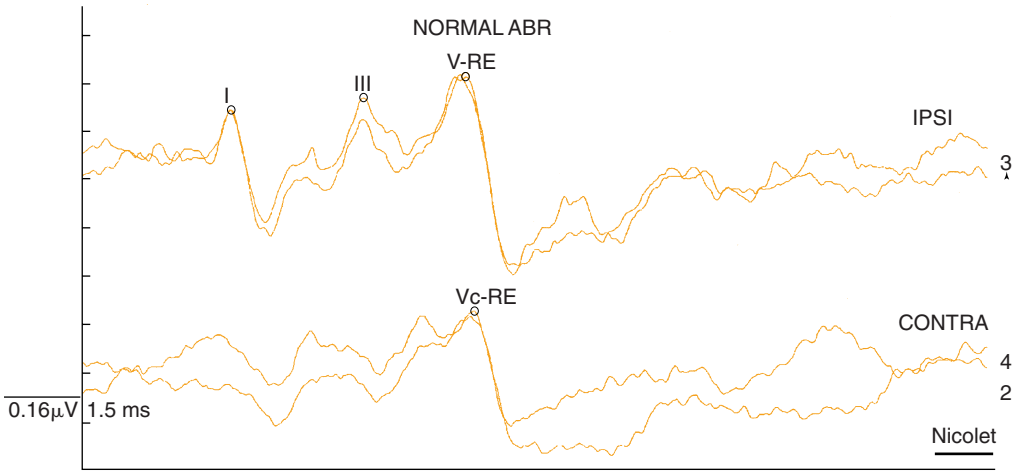

Figure 133-11. Typical two-channel auditory brainstem response recording obtained from a normal-hearing patient using 75-dB nHL clicks.

sate for the complete loss of hearing on the right resulting from labyrinthectomy. This patient has been followed in our otology clinic for several months since her surgery, and she is completely free of her previous vestibular symptoms.

Auditory Brainstem Response

The ABR is a surface-recorded averaged response representing the activity of the distal portion of the auditory pathway. It is used to determine auditory sensitivity objectively, to diagnose neuropathology along the auditory pathway, and to serve as a reliable intraoperative monitoring tool during surgical procedures that place auditory structures at risk. A normal ABR contains five to seven peaks occurring within a time frame of less than 10 ms. For neurodiagnostic purposes, the first five positive polarity peaks (waves I through V) are typically considered. Audiometric evaluation must always precede the ABR test to ascertain that the level of stimuli used to elicit the ABR is within the patient's auditory dynamic range. Clicks and brief frequency-specific tonal stimuli may be used to elicit the ABR. Clicks are brief rectangular pulses (typically 100 ms in duration) delivered to an acoustic transducer at constant or alternating polarity. Tone-pips are brief sinusoidal stimuli (one to two cycles) with short rise and fall times. Both types of stimuli have the ability to generate the synchronized activation of auditory nerve fibers necessary to elicit an evoked potential. Typically, 1000 to 3000 sweeps triggered to coincide with the onset of the stimulus should be averaged to obtain a robust, well-defined ABR. Replication of each condition is advisable to confirm the presence and configuration of the response.

The ABR may be recorded with standard or disposable surface electrodes placed high on the forehead below the hairline or at the vertex (noninverting electrode); on the medial surface of the ipsilateral earlobe; or on the medial surface of the contralateral earlobe (ipsilateral and contralateral inverting electrodes) and on the center of the forehead (ground electrode). These electrodes may be used for a typical two-channel montage with the ipsilaterally referenced channel emphasizing wave I (synonymous to the N1 of the electrocochleogram), and the contralaterally referenced channel emphasizing the separation between waves IV and V.

In addition to signal averaging, the configuration of the response is improved and shaped further through the use of bandpass filtering. Typically, a high-pass filter setting of 100 Hz and a low-pass filter setting between 1000 Hz and 3000 Hz are used. The use of a high-pass filter setting significantly greater than 100 Hz is not advised to avoid the reduction of the amplitude of wave V. A robust wave V is desirable for hearing sensitivity testing applications and neuro-otologic applications.

Investigations by Moller and Jannetta[40] suggest that the neural generators of peaks I through V originate from the cochlear nerve through the nucleus of the lateral lemniscus in the midbrain. Waves I and II of the ABR reflect the activation of the distal and proximal segments of the cochlear nerve. The two APs generated by the cochlear nerve may be attributed to the change from Schwann's cell endoneurium peripherally to the neuroglial cover of the proximal segment of the nerve. This shift occurs near the porus acusticus, and contributes to a change in neural conduction properties. Waves III and IV reflect the activation of the cochlear nucleus complex and the superior olivary complex.

Moller and Jannetta's study[40] also indicates that wave V is associated primarily with the activation of the lateral lemniscus and not the inferior colliculus as was previously considered. Ponton and colleagues[41] have shed further light on the generator sources and maturation of the ABR. They concur with Moller and Jannetta[40] regarding the generator sources for waves I and II. Their studies indicate that wave III originates from axons coursing from the cochlear nuclei in the ventral acoustic stria. The studies further indicate that waves IV and V also are associated with the activation of parallel subpopulations of ascending axons originating from the cochlear nuclei continuing on to higher brainstem levels. The III to IV interpeak interval indicates axonal conduction within the pathway from the cochlear nuclei to the contralateral lateral lemniscus and inferior colliculus.

Figure 133-11 illustrates a typical two-channel ABR elicited from a normal-hearing patient by 75-dB nHL clicks. The ipsilaterally referenced channel strongly emphasizes wave I, whereas the contralaterally referenced channel emphasizes the separation between waves IV and V.

The ABR reflects the activation of the auditory pathway from the cochlear nerve through the first two or three synapses of the afferent auditory pathway. ABR thresholds correlate well with behavioral auditory thresholds (see Chapters 134 and 190), and changes in the configuration or latency structure may provide information regarding the presence of neuropathology in the cerebellopontine angle or brainstem. Because the brainstem is relatively impervious to sedatives, anesthetics, and central nervous system depressants, it is an ideal tool to determine auditory sensitivity objectively, to diagnose neuropathology along the auditory pathway, and to serve as a reliable intraoperative monitoring tool during surgical procedures that place auditory structures at risk.

Neurodiagnosis with the Auditory Brainstem Response

The typical effect of mass lesions in the vicinity of the auditory pathway or, more specifically, in the cerebellopontine angle is associated with abnormal ABR configuration as a result of pressure-related displacement or attenuation of neural components of the auditory pathway. ABR abnormalities associated with such pathologies may range from a complete absence of ABR coexisting with reasonable hearing thresholds to absent ABR components or simply to delayed peak latencies. The presence of hearing loss, which is common in patients who undergo

workup for retrocochlear disease, should be carefully considered when interpreting the ABR. If audiologic information is ignored, an absent ABR may be interpreted as an extreme abnormality associated with a mass lesion of the auditory pathway, when it actually may result from the use of inadequate auditory stimulus levels given the magnitude of the patient's hearing loss. The authors propose a hierarchy of ABR interpretation meant to take into consideration auditory sensitivity and neuropathologic aspects.[42,43] This diagnostic analysis consists of the following three steps:

1. The first step is determination of the presence or absence of an ABR when an appropriate stimulus is used. A complete absence of ABR elicited by 85-dB nHL clicks in a patient with severe to profound hearing loss may not indicate retrocochlear pathology. Every effort needs to be made to elicit a response at levels that would be expected based on the patient's auditory thresholds.

2. Given the presence of a replicated response, the presence or absence of all major component peaks needs to be established. This is done considering that wave V is the most robust of the ABR components and persists with significant degrees of hearing loss; waves I and III are less robust. Wave I is difficult to resolve with hearing loss exceeding 40 to 45 dB at higher frequencies, with wave III persisting beyond that. Failure to identify wave I does not correlate with neuropathology along the auditory pathway. An absent wave V in the presence of a replicated wave I or III is a definitive diagnostic indicator of retrocochlear involvement, however.

3. Given that the presence of a response has been established, and ABR component peaks I, III, and V are clearly present and replicable, diagnostic decisions are based on the measurement of interpeak latencies I to III, interpeak latencies III to V, or the absolute latency of wave V and its interaural latency difference. This is especially helpful when interpeak latencies cannot be measured because of the absence of wave I. Interpeak latencies such as I to III or I to V are considered the most sensitive measures of retrocochlear involvement. Audiometric configuration needs to be taken into consideration, however, because it may affect the I to V interpeak latency.[44] Notched high-frequency hearing loss may be associated with increased I to V interpeak latencies in the absence of mass lesions of the cerebellopontine angle. This is most likely a reflection of the greater role assumed by high-frequency generators in producing wave I relative to those responsible for generating wave V. The I to III interpeak latency is affected to a lesser degree by cochlear hearing impairment. The most sensitive interpeak latency measure seems to be the increase in the I to III interpeak latency of the affected side.[45,46] Measurement of waves I and III is the gold standard for neurologic diagnostic applications. At our facility, we have used the following interpeak latency and interaural absolute latency diagnostic criteria for click stimuli since 1985: I to III, 2.3 ms or higher; III to V, 2.1 ms or higher; I to V, 4.4 ms or higher; and interaural latency difference to V, 0.4 ms or higher.

We also routinely use 1000-Hz tone-pips to elicit ABRs in an attempt to disregard the effects of elevated auditory thresholds in the 2000- to 4000-Hz frequency range on absolute and interpeak latencies of the click-evoked ABR.[47] By use of a Blackman Gating function[11] with a rise or fall time of 2 ms and no plateau, we established that it is possible to elicit ABRs from patients with normal hearing across the frequency range and from patients with high-frequency hearing loss. We compared wave V latency for 1000-Hz tone-pips between two groups of patients with cochlear SNHL; one group consisted of subjects with normal hearing, and one group consisted of subjects with hearing loss at 2000 to 4000 Hz or greater. These two groups had identical, normal thresholds at 1000 Hz. There were no significant differences in wave V latencies for 1000-Hz tone-pips between the two groups. Conversely, there was a statistically significant difference in absolute latency of wave V to click stimuli, with patients with high-frequency hearing loss greater than 1000 Hz presenting with prolonged absolute wave V latencies despite the absence of retrocochlear involvement.

Next, wave V latency values for 1000-Hz tone-pips were compared for two audiometrically identical groups. The first group consisted of subjects with cochlear hearing loss, and the second group consisted of subjects with confirmed acoustic neuromas, but pure-tone audiograms identical to those of subjects with cochlear losses. The results of the study indicated that patients with confirmed acoustic neuromas had significantly delayed wave V latency values compared with the control group with identical pure-tone profiles. Subjects with cochlear hearing losses had a mean wave V latency for 1000-Hz tone-pips of 6.7 ms, whereas subjects with confirmed acoustic neuromas had a mean wave V latency of 7.6 ms for the same stimuli, representing a statistically significant difference.[47] We also found small differences in wave V latency for ABRs elicited by 1000-Hz tone-pips, especially when stimulus levels were 85- or 95-dB nHL. At the same time, the wave V latencies obtained for four patients with confirmed acoustic neuromas significantly exceeded the latencies of patients with identical hearing losses.[48] Because latency differences with increased hearing thresholds diminished when higher level stimuli were used (≥85-dB nHL), we now recommend that 1000-Hz tone-pips be delivered at 85- to 95-dB nHL (see Fig. 133-7) regardless of pure-tone hearing sensitivity.

The following case illustrates the diagnostic application of ABR testing and the supplemental information derived from otoacoustic emission testing in patients in whom an acoustic neuroma was eventually diagnosed. The intraoperative monitoring use of the ABR is also illustrated by this case study.

A 56-year-old man presented with a complaint of a slight right-sided subjective hearing loss. He had a positive history of noise exposure, but was otherwise healthy, and had no other previous otologic problems. The pure-tone audiogram obtained (Fig. 133-12) shows normal hearing in low and middle frequencies in the left ear with a 35-dB notch at 4000 Hz with a slight improvement of threshold in higher frequencies. In the right ear, he had normal hearing in the low and middle frequencies (although 10 to 15 dB elevated compared with the left ear) and a 4000-Hz notch with a threshold of 50 dB (compared with 35 dB in the left ear). Speech discrimination was excellent in the left ear (100%) and still very good in the right ear (96%). Tympanograms were normal (type A) bilaterally, and ipsilateral and contralateral acoustic reflex thresholds were between 85 dB and 90 dB bilaterally with negative reflex decay in the left ear and the right ear.

Distortion product otoacoustic emission testing was also carried out with left ear and right ear stimulation. In the left ear, robust emissions (>6 dB above noise floor) were obtained at six test frequencies ranging from 700 to 4000 Hz. With right ear stimulation, robust emissions were obtained at the same frequencies as in the left. Otoacoustic emission testing ruled out outer hair cell involvement bilaterally within low and middle frequencies. Emissions were absent bilaterally in the high frequencies compatible with the noise-induced hearing loss–associated notch.

ABR studies were also done because of the patient's complaint and slightly asymmetric hearing loss (Fig. 133-13). Robust responses were obtained bilaterally with peaks I through V easily identified and well replicated. Steps 1 and 2 in our diagnostic protocol were negative. Next, peak and interpeak latencies were evaluated. With left ear stimulation using clicks, the I to III (2.16 ms) and I to V (4.02 ms) interpeak latencies were normal. The absolute latency of wave V with 1000-Hz tone-burst stimulation was also normal with a value of 7.8 ms. With right ear stimulation, the I to III (2.70 ms) and the I to V interpeak latency (4.50 ms) were outside normal limits, suggesting the presence of retrocochlear involvement. The absolute latency of wave V with 1000-Hz tone-burst stimulation was also abnormally prolonged to 7.80 ms (as opposed to 7.08 ms with left ear stimulation).

These results indicate a high likelihood for the presence of retrocochlear involvement, and subsequent MRI studies identified an 8-mm right-sided acoustic neuroma. Because of the good hearing, the presence of robust otoacoustic emissions, the excellent speech discrimination score (96%), and the small size of the tumor, a middle cranial fossa approach with planned hearing preservation procedure

was undertaken. During the surgical procedure, continuous facial muscle electromyography and ABR monitoring were carried out. Figure 133-14 shows a sequence of ABRs obtained during the middle cranial fossa surgical resection of this mass. As can be seen in this figure, the ABR remained robust with minor changes in overall latency. The bottom two superimposed traces represent the baseline ABR obtained before tumor resection but after the opening of the dura. The second superimposed wave form is the final measurement obtained after the successful resection of this mass. These two responses are almost completely identical, attesting to an excellent prognosis for postoperative hearing preservation. Serial audiograms obtained postoperatively over 1 year indicate minimal changes in right-sided audiometric thresholds. At the most recent evaluation, speech discrimination scores in the right ear were measured to be 100%.

Neurodiagnostic Studies in Patients with Auditory Neuropathy or Dyssynchrony

Auditory neuropathy or dyssynchrony is a condition that may be referred to in simpler terms as *neural hearing loss*. This condition is diagnosed predominantly in infancy and early childhood, and has received particular attention in recent years. Although there are many variants of this condition, and different degrees of severity, the condition is typically characterized by significant hearing loss that is evident behaviorally and, if some form of audiometry can be obtained, audiometrically.

Although most cases of newly diagnosed nonconductive hearing loss are due to a cochlear etiology (i.e., either a diminished or absent outer hair cell population or a complete absence of hair cells), this condition is by all indications not specifically related to cochlear function. Experimental studies[49] have shown, however, that this condition can be modeled by temporarily disabling inner hair cell function. Similar diagnostic test results may be obtained in patients with substantial hyperbilirubinemia and respiratory distress syndrome. In this population, this condition may be reversible in some cases during the first year of life.

The ideal management of these patients is subject to disagreement among audiologists and otolaryngologists. Some clinicians strongly oppose even the attempt of acoustic amplification; others consider this a condition similar to other types of sensorineural hearing loss, and believe that at least an initial trial with amplification is warranted. There is, however, reasonable agreement in the field that if all else fails many of these patients may be considered cochlear implant candidates, and there is now evidence that many of these patients do well with a cochlear implant.

The diagnostic battery in these patients includes ABR testing with constant polarity stimuli (rarefaction *and* condensation) to attempt to identify the presence of a cochlear microphonic in the absence of an ABR, and otoacoustic emissions. The "typical" picture is of a child or infant with all behavioral indications of significant hearing loss; a completely absent ABR—a completely absent wave V at even high intensities the presence of appropriate phase cochlear microphonics (i.e., the polarity should mirror the polarity of the stimulus); and relatively intact otoacoustic emissions.

The presence of a cochlear microphonic and of the otoacoustic emissions serves as an indication for the presence of relatively intact outer hair cell function. The absent wave V at even high stimulus intensities coincides with the behavioral and audiometrically demonstrated hearing loss. If an electrically evoked ABR is carried out in these patients preoperatively using transtympanic stimulation,[50] wave V appears. Some workers have used this information to conclude that because electrical stimulation is more effective to recruit neural synchrony, and a wave V is identifiable with electrical stimulation, the underlying problem is one of poor neural synchrony, which results in an absent acoustic ABR and the aforementioned behavioral manifestations.

First, let us dispel a myth: "Only patients with auditory neuropathy have a cochlear microphonic." Figure 133-15 illustrates ABRs from a normal-hearing subject using rarefaction and condensation clicks. As can be seen in this figure, following the click is electromagnetic stimulus artifact; opposite-polarity cochlear microphonics can be seen in the early portion of these tracings preceding robust wave Vs obtained with rarefaction and condensation click stimulation. The bottom traces illustrate an attempt to obtain ABRs using rarefaction and condensation clicks from a patient with auditory neuropathy.

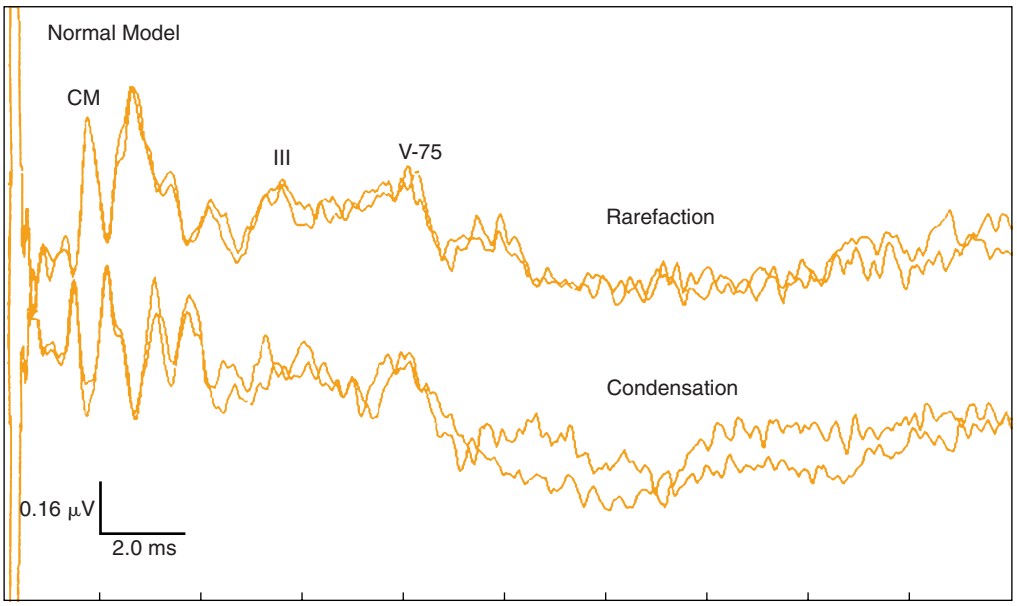

Figure 133-15. Auditory brainstem responses including robust cochlear microphonics obtained from a normal-hearing infant using condensation and rarefaction clicks.

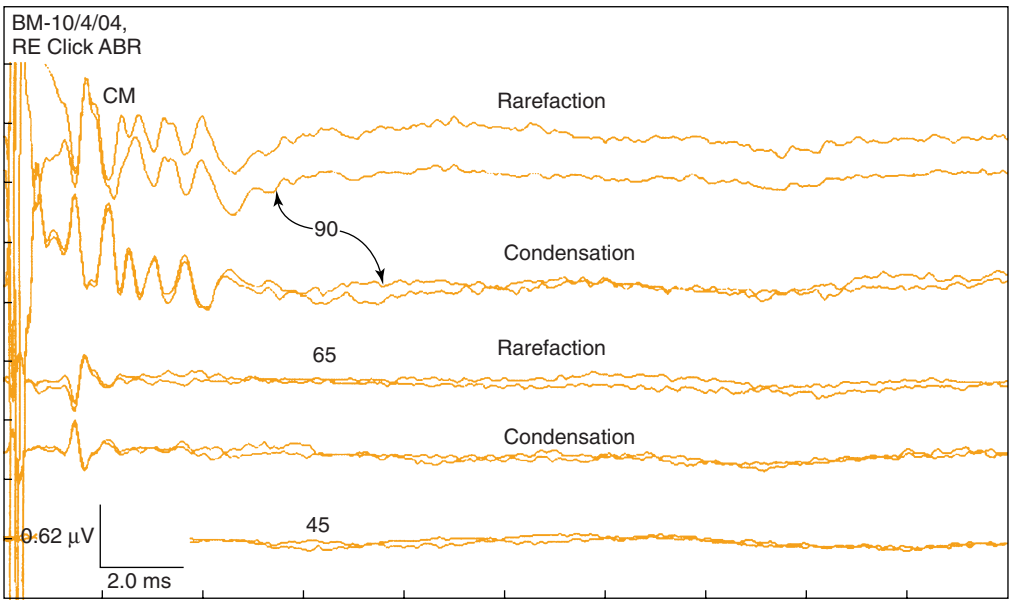

Figure 133-16. Cochlear microphonics without auditory brainstem response components obtained using condensation and rarefaction clicks from a patient diagnosed with auditory neuropathy or dyssynchrony.

Opposite-polarity microphonics can be identified particularly in the upper set of traces obtained at 90 dB; however, no synchronous electrophysiologic activity, such as wave V, can be seen in the continuation of this time window.

If one so desires, one can look at cochlear microphonics in patients with normal hearing, but in those cases the cochlear microphonic is followed by waves I, II, III and V of the ABR, which are not present in patients with auditory neuropathy. Most of the time, however, we do not attempt to obtain cochlear microphonics, in particular if wave V is noted at any intensity. Most clinicians do not comment on the presence or absence of cochlear microphonics in patients with normal hearing as indicated by the ABR or in patients with a hearing loss characterized by a threshold elevation where wave V is present at threshold and separate threshold levels.

The following case illustrates the use of otoacoustic emissions and ABRs and cochlear microphonics in the diagnosis of auditory neuropathy. This patient was diagnosed with severe to profound sensorineural hearing loss at 10 months of age. A neurodiagnostic evaluation indicated completely absent ABRs—no wave V was identified at the limits of the equipment (95 dB); however, as illustrated in Figure 133-16, cochlear microphonics were present when using rarefaction and condensation clicks. Otoacoustic emissions were present at most frequencies tested. When combining the presence of behavioral hearing loss, lack of adequate speech and language development,

absence of wave V at even high intensities, presence of cochlear microphonics, and otoacoustic emission, the conclusion was that this patient presented with a hearing loss secondary to some type of auditory neuropathy.

The patient was considered to be a cochlear implant candidate. Transtympanic promontory, electrically evoked ABR testing was carried out to determine if the auditory neural pathway could be synchronously activated with electrical stimulation. This testing resulted in the presence of a wave V with electrical stimulation, and indicated the strong likelihood that this patient would respond positively to a cochlear implant. Cochlear implant candidacy and issues related to auditory neuropathy and cochlear implants are discussed in Chapters 134 and 158 through 160.

Evaluation of Functional Hearing Loss

Functional hearing loss, or pseudohypoacusis, is more common in adults than in children. Motivating factors in children seen with pseudohypoacusis often involve attention-seeking behavior or the avoidance of some unwanted activity, whereas direct or indirect financial gain is often a motivating factor in adults. The diagnosis of patients suspected to have pseudohypoacusis involves two components: the diagnosis of the pseudohypoacusis and the determination of the patient's true hearing sensitivity. Many patients ultimately diagnosed with pseudohypoacusis also may have an underlying true hearing loss. When taking the patient's history, it is important to note the presence of inconsistencies, complaints, and exaggerated listening effort. The patient's voice and speech quality provide important information. A patient claiming bilateral significant hearing loss with normal voice level and articulation should be suspected of functional behavior.

A simple and straightforward audiometric indicator of pseudohypoacusis is disagreement between the 500-, 1000-, and 2000-Hz PTA threshold and SRT. Typically, these two measures should agree within 5 dB. Elevated PTA thresholds with a lower SRT should be a reason to suspect pseudohypoacusis.

All patients with a unilateral hearing loss should undergo a pure-tone Stenger test.[51] This test is based on the principle that when two acoustic stimuli identical in every regard but intensity are introduced simultaneously into the left and right ears, the patient would perceive only the louder of the two stimuli. When used for the determination of pseudohypoacusis, it is common to present a tone to the better ear at about 10 dB above its threshold simultaneously with an identical tone into the poorer ear at approximately 10 dB below its voluntary threshold. If the patient's threshold in the poorer ear is correct, the patient would naturally respond to the tone presented at 10 dB above threshold in the admitted better ear. If the patient exaggerates hearing loss in the poorer ear, however, he or she would perceive the louder tone presented to the poorer ear, would be unaware of the suprathreshold tone presented to the better ear, and would not respond to these stimuli. Essentially, the patient's lack of response in this situation is an admission of having perceived the tone in the so-called poorer ear (positive Stenger).

One can bracket thresholds in the poorer ear by maintaining the suprathreshold stimulus in the better ear at a fixed intensity, while increasing the intensity of the stimulus in the allegedly poorer ear in 5-dB steps. The patient's actual threshold in the poorer ear would coincide with the level at which he or she ceases to respond despite the fact that the suprathreshold stimulus is consistently present in the better ear. This technique is referred to as minimum contralateral interference levels.

The Stenger test also can be administered using spondee words as stimuli presented simultaneously to the left and right ears. As in the case of the pure-tone Stenger, this test is appropriate if the interaural SRT difference the patient is admitting to is at least 20 dB. It is important that a sloping or rising audiometric configuration be ruled out before extended effort is invested in resolving functional hearing loss in a patient. Some patients may have a true SRT of 10-dB HL along with a steeply sloping high-frequency SNHL with normal thresholds in the low-frequency range.

Sources of Error in Audiologic Testing

Audiologic errors may originate from two main sources: faulty clinical judgment or decision and technical errors.

Errors in Clinical Judgment

Inappropriate diagnostic test selection and failing to refer a patient for further audiologic or other diagnostic tests are the most common errors related to clinical judgment. Failure to follow up on a discrepancy between the three-frequency PTA threshold (500 Hz, 1000 Hz, and 2000 Hz) and SRT may lead to failure to diagnose functional hearing loss. Failure to continue the audiologic testing with a Stenger test in a case of apparent unilateral hearing loss, especially when the patient's history is contributory, also may result in missing the diagnosis of functional hearing loss. Stenger testing is strongly recommended for every patient with a unilateral or asymmetric hearing loss. Another error related to clinical judgment is the failure to recommend and carry out appropriate follow-up in a patient with preexisting bilateral SNHL who has an asymmetric unilateral progression of hearing loss. This failure may lead to a misdiagnosis or delayed diagnosis of retrocochlear involvement, among other problems. The following case is illustrative of this type of error.

A 61-year-old man with a 7-year history of bilateral, high-frequency SNHL came to our clinic for a second opinion. The patient had reported a further progression of his hearing loss, predominantly in the left ear, approximately 6 months before coming to the clinic. He was seen elsewhere and was reassured that he was experiencing an expected change in hearing related to his preexisting hearing loss. Figure 133-17 illustrates this patient's two most recent audiograms (not taken at our clinic), which were obtained approximately 1 year apart. Over the course of 1 year, there was a progression of hearing loss in the right ear at 4000 Hz and 8000 Hz of 20-dB HL and 25-dB HL. In the left ear, hearing thresholds were elevated across the frequency range, more so for the high frequencies, where up to a 55-dB threshold shift was observed at 8000 Hz. Speech discrimination scores remained very good at 96% and 92%, for the right and the left ears.

ABR testing carried out during his first visit to the clinic (Fig. 133-18) consisted of normal configuration and normal peak and interpeak latencies for the right ear and a poorly resolved response in the left ear with reduced amplitude and abnormal increased interpeak latencies. MRI showed a small cerebellopontine angle mass on the left side, with most of the mass within the porus acusticus. This was subsequently diagnosed as a vestibular schwannoma and resected through a translabyrinthine approach. In this case, inattention to the more pronounced progression of hearing loss in the patient's left ear, coupled with the maintenance of normal speech discrimination scores in the affected ear, may have contributed to the lack of concern and the failure to consider further clinical tests. It is clear, however, that hearing loss in the patient's left ear progressed more substantially than that in the right ear, and warranted further clinical investigation.

Technical Errors

Lack of attention to interaural attenuation and insufficient or excessive masking are the most common sources of technical error. This is most pronounced in patients with mixed, bilateral hearing loss who give rise to the so-called masking dilemma. The main problem in these patients is that when attempting to mask the nontest ear, overcoming the conductive component may involve masker levels exceeding interaural attenuation. This causes the masker to cross over to the test ear, resulting in artificial elevation of its threshold. Conversely, inadequate masking in unilateral moderate to severe SNHL may create a false air-bone gap, and the impression of a surgically correctable conductive hearing loss. This would occur because in the presence of inadequate masking, bone-conduction thresholds in the test ear with a true, severe SNHL would continue reflecting the shadow curve of the contralateral ear, exhibiting a false air-bone gap between the true air-conduction thresholds and the false bone-conduction thresholds. Because of the more substantial interaural attenuation associated with air-conducted signals, it is easier to obtain accurate, masked

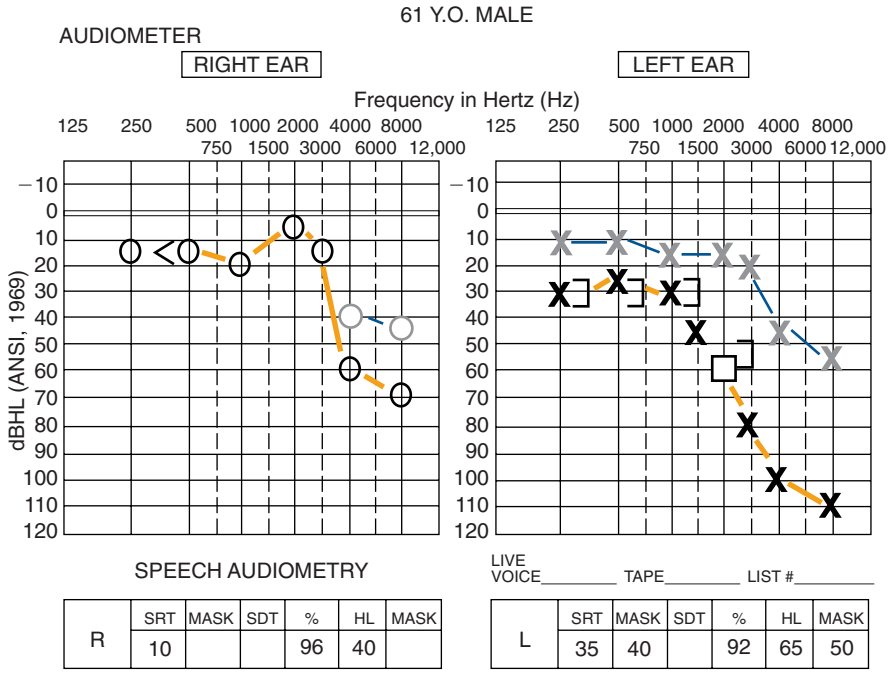

Figure 133-17. Audiograms showing asymmetric threshold shift (left more than right) occurring over a 1-year period in a patient subsequently diagnosed with a left-sided acoustic neuroma.

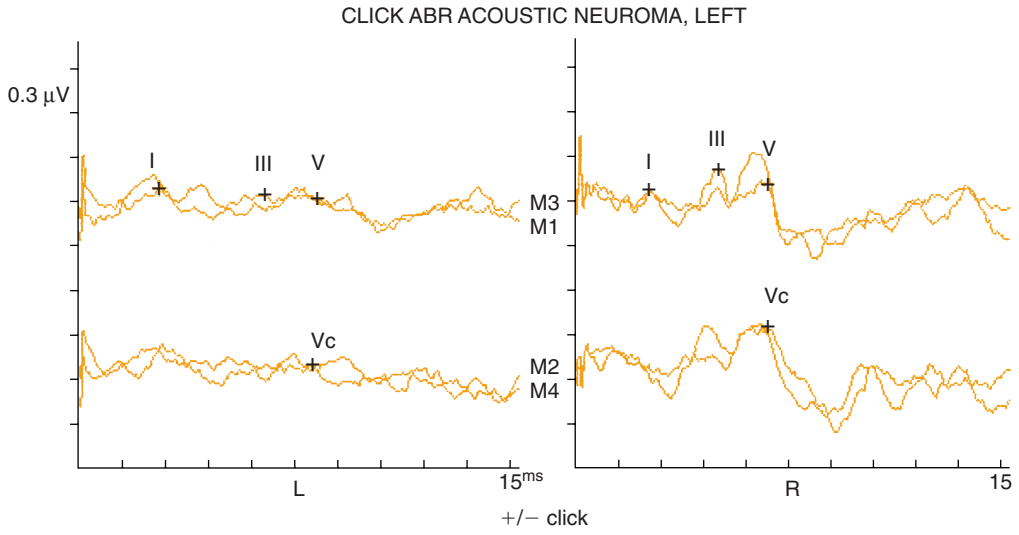

Figure 133-18. Auditory brainstem responses (ABRs) from a patient with left-sided acoustic neuroma. The left ABR is characterized by reduced amplitude and abnormal inner peak intervals.

air-conduction thresholds. Sufficient masking of the nontest ear can resolve such a problem.

CHAPTER ONE HUNDRED AND THIRTY-FOUR

Electrophysiologic Assessment of Hearing

Carolyn J. Brown

Tiffany A. Johnson

Key Points

- Otoacoustic emissions are sounds generated in the cochlea and recorded in the ear canal that reflect activity of the outer hair cells.
- Otoacoustic emissions can be recorded in quiet, but more commonly are evoked in response to acoustic stimulation. Clicks or tone bursts can be used to elicit transient evoked otoacoustic emissions (TEOAEs). Continuous sinusoidal stimuli are used to evoke distortion product otoacoustic emissions (DPOAEs).
- Otoacoustic emissions can be used to assess the status of cochlear outer hair cells. Specifically, the presence of otoacoustic emissions (either TEOAEs or DPOAEs) is consistent with normal outer hair cell function, and indicates that the individual being tested is likely to have no worse than a mild to moderate sensorineural hearing loss.
- Otoacoustic emissions have also proven to be useful in diagnosing dyssynchrony within the auditory periphery.
- Electrocochleography is a measure of the synchronous response of the auditory nerve to the presence of an acoustic stimulus. It is optimally recorded using an electrode placed on the tympanic membrane or the promontory of the middle ear. Clinical applications include assisting in the differential diagnosis of Meniere's disease and as a method of assessing the response of the auditory nerve during otoneurologic surgery.
- Auditory brainstem responses (ABRs) are far-field recordings of the synchronized response of neurons within the synaptic relay stations of the auditory brainstem, and can be used to detect impaired neural conduction from various potential neurotologic pathologies.
- The primary application for the ABR in medical settings today is as a tool that can be used to estimate auditory sensitivity in very young or otherwise difficult-to-test populations.
- The auditory steady-state response (ASSR) is an evoked potential that reflects a far-field recording of electroencephalographic activity evoked using continuous sinusoidal stimuli that are either amplitude or frequency modulated.
- The ASSR has emerged as an alternative to tone burst evoked ABR for estimating auditory sensitivity.
- Although less frequently recorded in routine clinical practice, numerous cortical or precortical auditory evoked potentials can be used to assess higher level auditory function. These responses generally require less neural synchrony than the ABR, and as a result have the advantage of being able to be recorded using longer duration, more frequency-specific tonal stimuli or speech.
- Each of the acoustically evoked auditory potentials described in this chapter can also be elicited in response to electrical stimulation provided by a cochlear implant.
- Electrically evoked auditory potentials can be used to assist with the process of fitting the speech processor of the cochlear implant, to help differentiate between cochlear implant failures and lack of neural response in patients who are showing limited or no benefit, and to monitor changes over time in the neural response to electrical stimulation.
- When applied in a strategic manner, the techniques of electrophysiologic recording from the auditory pathology described here provide complementary and highly specific guidance in the clinical assessment of auditory, vestibular, and skull base disorders.

This chapter describes the range of electrophysiologic techniques that can be used to assess hearing sensitivity, and to assist in the differential diagnosis of the site of a lesion within the auditory system for individuals with impaired hearing. These measures include otoacoustic emissions (OAEs), electrocochleography (ECoG), auditory brainstem response (ABR), auditory steady-state responses (ASSRs), middle and long latency evoked potentials, and a similar range of electrically evoked auditory potentials. This chapter provides the reader with an overview of these measures: how they are recorded, their strengths, their weaknesses, and potential clinical applications. Chapter 133 expands this focus to provide case studies and a series of examples of how these evoked potentials can be used to inform clinical decision making.

Otoacoustic Emissions

In 1978, Kemp[1] showed that the healthy inner ear emitted very low intensity sounds that could be measured using a sensitive microphone

sealed into the ear canal. These responses not only occurred spontaneously, but also could be evoked. Kemp theorized that these low-level acoustic signals originated from the outer hair cells (OHCs) of the cochlea and were a by-product of the nonlinear processing of the healthy inner ear. In the years that followed, support for Kemp's theories grew. In the early 1980s, Brownell[2] showed that OHCs were capable of changing shape (contracting and elongating) when stimulated, and in the 1990s, Mammo and Ashmore[3] showed that electrical stimulation of isolated OHCs could move or modify the motion of the basilar membrane.

The general thinking today is that the normal cochlea functions much like a highly tuned, exquisitely sensitive amplifier, and it is the inherently nonlinear nature of such a system that results in the generation of OAEs. Consistent with this theory are observations that ears with damaged OHCs generally exhibit reduced sensitivity, broader tuning, and absent OAEs.[4-7] This link between the presence or absence of OAEs and the function of the OHCs has made OAEs a powerful tool for researchers and for clinicians.

There are two general classes of OAEs: spontaneous and evoked. Spontaneous OAEs are low-level acoustic signals that can be recorded in the ear canal without any external stimulation. Spontaneous OAEs are recorded only in 50% to 70% of ears with normal hearing sensitivity.[8,9] They are recorded more frequently in women than men,[10,11] and in some cases are intense enough to be detected without amplification or sophisticated recording equipment.[12,13] The presence of spontaneous OAEs is not strongly correlated with the presence of tinnitus, and the amplitude and the frequency of the spontaneous OAE can vary significantly across time.[14,15] All these factors limit the clinical applicability of spontaneous OAEs. Although their presence may indicate that at least a portion of the OHC system is intact, their absence is not clinically significant.

There are several different types of evoked OAEs, but the two that are most widely used in clinical settings are transient evoked otoacoustic emissions (TEOAEs) and distortion product otoacoustic emissions (DPOAEs). TEOAEs are low-level acoustic signals that are recorded after presentation of a brief acoustic stimulus, typically a fairly high-level click (e.g., 80 dB peSPL). The click itself has a broad frequency spectrum, and elicits oscillatory responses from OHCs located across a wide section of the cochlear partition. These local vibrations are transmitted back through the middle ear and create low-level, typically inaudible, sound pressure waves in the ear canal. TEOAEs are recordings of sound pressure waves recorded using a microphone in the ear canal. TEOAEs are typically recorded within approximately 20 ms after onset of the stimulus. High-frequency components in the response, which originate from locations near the base of the cochlea, require a shorter travel time, and consequently are recorded earlier than the low-frequency components, which reflect response from OHCs located closer to the apex of the cochlea.

TEOAEs are usually analyzed in the frequency domain. Despite the fact that the stimulus used to elicit the TEOAE is broadband, the response itself provides frequency-specific information about the status of the cochlea between approximately 1000 Hz and 4000 Hz. Typical criteria used to establish the presence or absence of a response within a specific frequency band are signal-to-noise ratios of greater than 6 dB coupled with reproducibility measures of more than 90%. The presence of TEOAEs in ears with normal middle ear function suggests normal OHC function and is considered to be indicative of normal audiometric sensitivity. Conversely, the absence of TEOAEs within a specific frequency band is typically interpreted as evidence of audiometric thresholds worse than 25 to 30 dB HL.[7]

Figure 134-1 shows audiograms and TEOAEs recorded from three different listeners. Figure 134-1A shows results obtained from an individual with normal hearing; B and C show results from individuals with sensorineural hearing loss (SNHL). The TEOAEs recorded from the listener with normal hearing are robust for frequencies ranging from 1000 to 4000 Hz. The subject whose data are shown in Figure 134-1B has a relatively flat, moderate SNHL and no measurable TEOAE. Figure 134-1C shows results obtained from an individual with normal hearing for frequencies less than 2000 Hz and a moderate SNHL for audiometric frequencies between 3000 Hz and 8000 Hz. This subject has measurable TEOAEs only for frequencies less than 2500 Hz. No response was obtained for frequencies between 3000 Hz and 8000 Hz. The presence of TEOAEs suggests normal OHC function, and typically indicates that the listener has good audiometric sensitivity, at least for frequencies ranging from 1000 to 4000 Hz.

It is also possible to evoke OAEs using frequency-specific stimuli. DPOAEs are recorded in response to the presentation of two continuous sinusoidal signals (F1 and F2) that are introduced simultaneously into the ear canal. Because the normal cochlea is highly nonlinear, the response that is recorded in the ear canal shows evidence of distortion. The recording made using a sensitive microphone sealed into the ear canal not only includes energy at the two primary frequencies, F1 and F2, but also includes energy at numerous other frequencies that are mathematically related to the primaries. These are called *distortion products*. The distortion product most frequently used to assess auditory function is 2F1-F2. The presence of significant amounts of energy at the 2F1-F2 frequency is considered a sign that the OHCs in the region of the primaries are functioning normally, and is a finding typically observed in individuals with normal audiometric sensitivity. SNHL is often associated with loss or damage to OHCs. When the OHCs are no longer functional, the movement of the basilar membrane becomes more linear, and the energy at the distortion product frequency decreases.

Studies have shown that the most robust DPOAEs are recorded when the frequency ratio of F2 to F1 is approximately 1.2.[16,17] Additionally, for clinical applications, the levels of the two tones typically are set at 65 dB SPL and 55 dB SPL (L1 and L2) because these levels most accurately identify the ear as either normal hearing or hearing impaired.[18] By systematically varying the frequency of the two primary tones, DPOAEs can be recorded across a wide frequency range from 1000 Hz through approximately 8000 Hz. The amount of energy at the 2F1-F2 frequency that is recorded in the ear canal is compared with estimates of the noise floor of the recording system. DPOAE amplitude-to-noise ratios of approximately 6 dB typically are required before a response is considered present. To interpret the response, the amplitude of the DPOAE is compared with normative values.[6]

Figure 134-2 shows the relationship between DPOAEs and audiometric thresholds for two subjects. Figure 134-2A shows DPOAE results for a listener with normal hearing. DPOAE amplitudes ranging from −5 to 15 dB SPL were obtained for each of the test frequencies. These amplitudes were compared with the normative ranges, which are indicated by the shading on the figure. Responses above the top boundary of the shaded area are consistent with normal DPOAEs and indicate normal hearing. Responses below the lower boundary are consistent with abnormal DPOAEs and indicate hearing loss. Responses falling within the shaded region are equivocal because amplitudes in this range can be produced by ears with normal and impaired hearing. The DPOAE results shown in Figure 134-2A are above the upper boundary of the shaded region, indicating normal DPOAEs and normal hearing. The DPOAE results shown in Figure 134-2B are for a listener with normal hearing through 3000 Hz and a high-frequency hearing loss from 4000 to 8000 Hz. Consistent with these audiometric findings, DPOAEs recorded for frequencies less than 4000 Hz are normal; however, DPOAEs from 4000 to 8000 Hz fall below the lower boundary of the shaded region, indicating abnormal DPOAEs and hearing loss. Consistent with the results shown in Figure 134-2, the absence of DPOAEs in a patient with normal middle ear function suggests audiometric thresholds greater than 30 to 35 dB HL.[6]

Clinical Applications

DPOAEs and TEOAEs have become a routine part of the audiologic assessment battery in many clinics nationwide. Both of these OAEs assess the same underlying cochlear phenomenon. A finding that a patient has robust evoked OAEs, regardless of the type, is a strong indicator that the patient has normal or near-normal OHC function. This finding is typically correlated with normal hearing sensitivity. Neither DPOAEs nor TEOAEs are reliably recorded in ears with conductive pathology, nor are they recorded from individuals with more than a mild to moderate degree of SNHL. There is some indication that TEOAEs may be more sensitive to very mild amounts of hearing loss than DPOAEs, particularly at 1000 Hz. Conversely, DPOAEs may

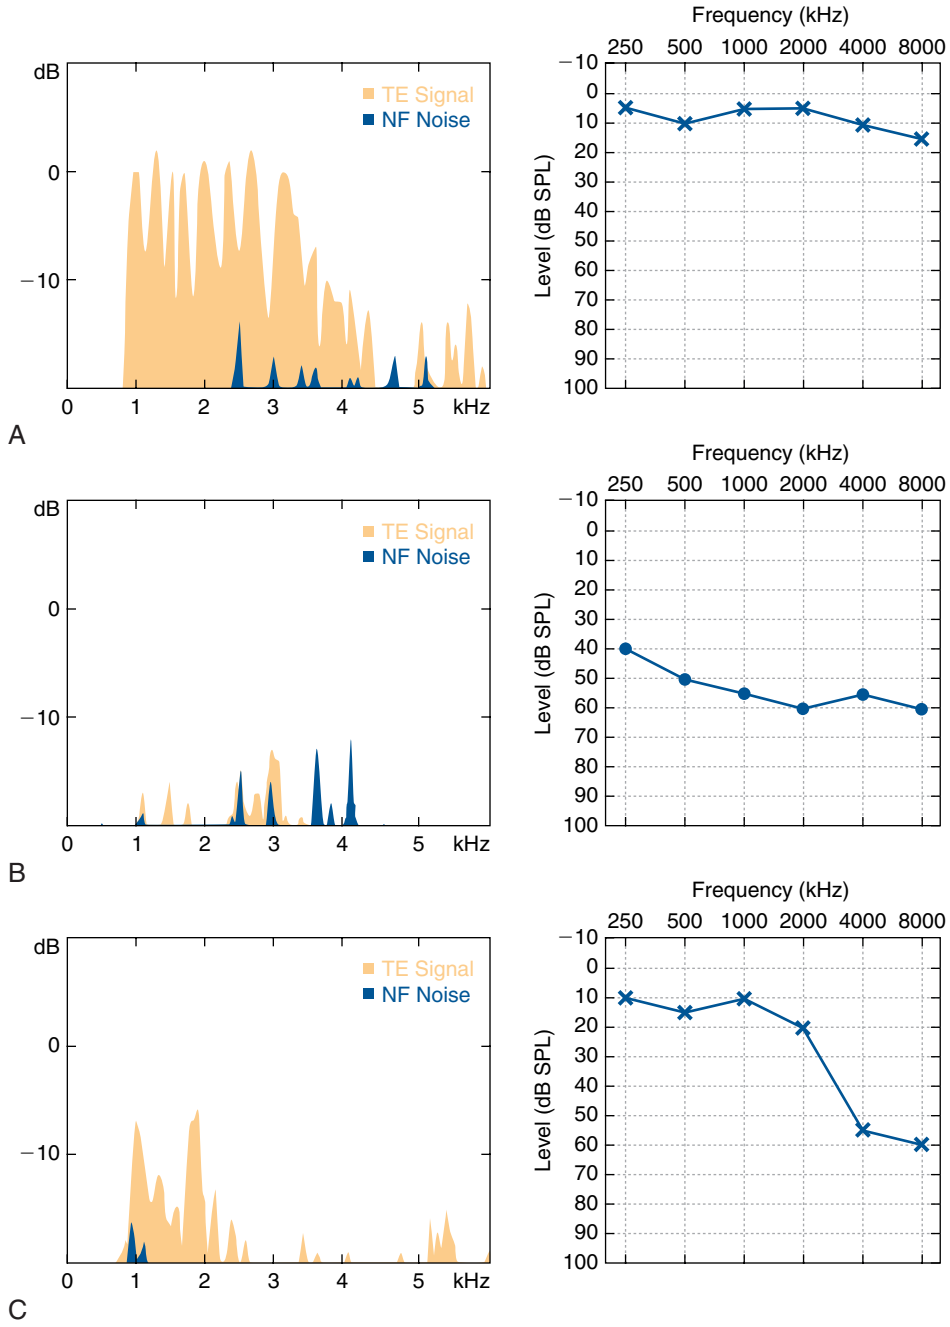

Figure 134-1. **A-C,** Transient evoked otoacoustic emissions (TEOAEs) and pure-tone audiograms are shown for three subjects. The results shown in **A** were obtained from an individual with normal hearing. Results shown in **B** and **C** were obtained from individuals with sensorineural hearing loss. The spectral components of the TEOAE are shown in *yellow* (TE Signal). The noise floor of the measurement system is shown in *blue* (NF Noise).

be slightly more sensitive to mild degrees of hearing loss for frequencies between 4000 Hz and 6000 Hz.[7,19]

The strength of evoked OAEs as a clinical tool is for screening (see Chapter 133). These responses can be recorded from neonates. They are not affected by sleep or sedation, and do not require application of recording electrodes or active participation by the child. Absence of evoked OAEs does not indicate that a child is deaf, however, and the presence of an evoked OAE does not tell anything about the integrity of the auditory nerve or central auditory system. Evoked OAEs have been recorded in profoundly hearing-impaired individuals whose hearing loss is the result of neural involvement.

The presence or absence of evoked OAEs (either TEOAEs or DPOAEs) also frequently plays a role in differential diagnosis of the cause of hearing loss—particularly for pediatric patients. Evoked OAEs can be used to assess cochlear function in patients who present with sudden-onset idiopathic hearing loss. A finding of significant evoked OAEs in an ear with audiometric thresholds worse than approximately 40 dB HL suggests that the hearing loss may have a primarily neural origin, that it may be the result of damage to structures in the cochlea other than the OHCs (e.g., the inner hair cells), or that it may serve as a red flag that should cause the clinician to question the validity of the behavioral thresholds.

The amplitude of an evoked OAE is not strongly correlated with audiometric sensitivity.[6] Evoked OAEs cannot be used to determine the degree of hearing loss an individual patient has at a given frequency. Evoked OAE amplitudes are known to be stable and repeatable across

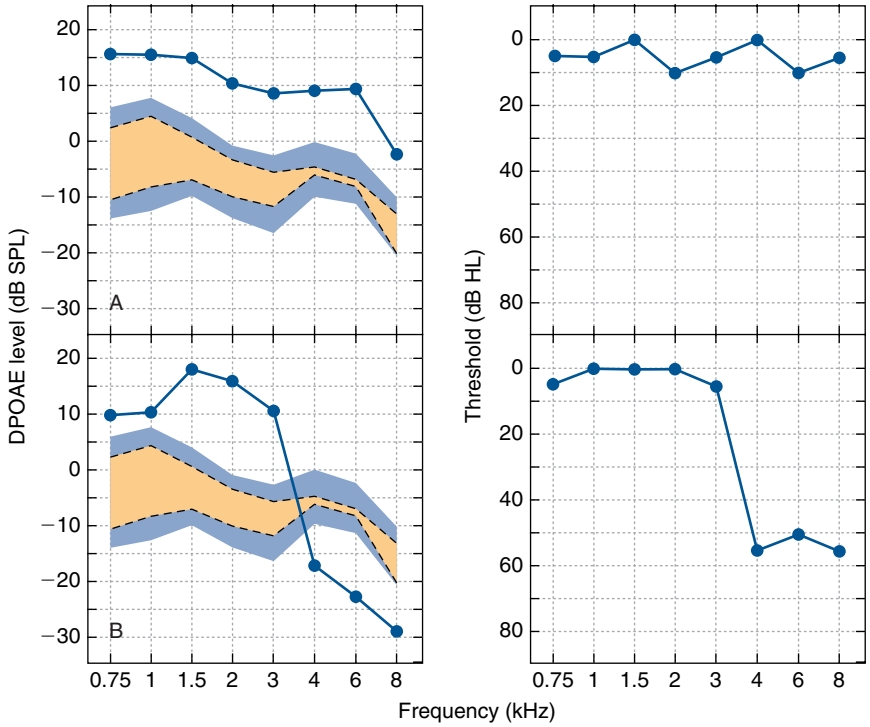

Figure 134-2. **A** and **B,** Distortion product otoacoustic emission (DPOAE) responses and audiometric thresholds obtained from an individual with normal hearing **(A)** and an individual with high-frequency hearing loss **(B)**. *(Shaded area on the graph represents normative data from Gorga MP, Neely ST, Ohlrich B, et al. From laboratory to clinic: a large scale study of distortion product otoacoustic emissions in ears with normal hearing and ears with hearing loss.* Ear Hear. *1997;18:440-455.)*

time, however, with estimates of test-retest variability ranging from ±3 to 5 dB.[20] Clinically, a change in evoked OAE amplitude of more than 4 to 5 dB may signal a change in hearing sensitivity relative to a previously established baseline. Consequently, many clinicians use evoked OAEs to help monitor hearing during or immediately after ototoxic drug exposure. For patients who are very sick at the time of testing, the objective nature of the evoked OAE test itself may prove to be more reliable than behavioral thresholds, and changes in the evoked OAEs may precede changes in cochlear sensitivity.

Finally, *auditory neuropathy* and *auditory dyssynchrony* are terms that are used to describe a condition in which a patient presents with measurable evoked OAEs or cochlear microphonics or both, but with a grossly abnormal or absent ABR. The implication is that for these individuals, the hearing loss is not cochlear in origin, but is the result of some type of nonspecific damage or dysfunction of the auditory nerve. Individuals diagnosed with auditory neuropathy may or may not have other peripheral neuropathies. Audiometric thresholds can vary widely from normal to profound, but many individuals with this disorder have poor speech discrimination and receive limited benefit from amplification.[21-23]

Although many children diagnosed with auditory neuropathy have been shown to benefit from cochlear implantation, others have not shown any benefit.[24,25] Imaging studies have shown that some of these children do not have a viable cochlear nerve despite having residual OHCs, a measurable cochlear microphonic, and robust OAEs.[26] The observation of measurable evoked OAEs in a child who is being considered for cochlear implantation should suggest the medical team working with that child proceed with caution. Care must be taken to rule out the possibility that technical problems were the cause for the absent ABR, and every effort should be made to obtain behavioral thresholds before surgery. Such caution is warranted because there are numerous reports in the literature of individuals with absent ABRs and measurable evoked OAEs who are able to attain reasonable levels of word recognition without the use of a cochlear implant.

Electrocochleography

When a brief acoustic stimulus is introduced to the ear canal of an individual with normal hearing, a large section of the cochlear partition is displaced. Movement of the basilar membrane results in shearing of the stereocilia at the apical surface of the auditory hair cells, a change in the intracellular potential, and release of neurotransmitter into the synaptic cleft. This chain of events can lead to generation of an action potential by the primary afferent neurons that synapse with that hair cell.

It is possible to use electrophysiologic recording techniques to measure this chain of events. This recording is often referred to as ECoG. ECoG is a combination of three distinct evoked potentials: the cochlear microphonic (CM), the summating potential (SP), and the whole nerve or compound action potential (AP). All three potentials are recorded within a 3- to 4-ms time window after presentation of the stimulus and have been described in detail in the literature.

The CM is an intracellular evoked potential that consists of a series of deflections that follow the stimulus and reflect the instantaneous displacement of the basilar membrane.[27] The SP is characterized by a DC shift in the baseline that occurs during stimulation. It is thought to be a measure of the net depolarization of the hair cells within the organ of Corti.[28,29] Neither the CM nor the SP has a measurable response latency—a fact that often makes separation of these neural potentials from the stimulus artifact problematic. Presence of a CM or SP or both can be interpreted as being consistent with the presence of viable cochlear hair cells.

The AP is a recording of the synchronous response of numerous auditory nerve fibers. Although the CM and the SP are measured most easily using long-duration stimuli, the AP is an onset response that is typically recorded using brief stimuli such as clicks or short-duration tone bursts. In humans, the first negative peak of the AP (N1) is the most prominent feature and typically occurs with a latency of 1 to 2 ms. The N1 peak of ECoG reflects postsynaptic neural activity generated by the primary afferent auditory nerve fibers.

ECoG can be recorded noninvasively from numerous different recording electrode positions. The largest amplitude responses are obtained when a transtympanic electrode positioned on or near the promontory of the middle ear is used for recording. As the recording electrode is moved away from the cochlea, the amplitude of the response decreases.[30,31] It is still possible, however, to record ECoG from an ear canal or mastoid electrode if use of a transtympanic or tympanic membrane electrode is not feasible.

For most clinical applications, the CM is minimized through the use of alternating polarity stimulation. The magnitude of ECoG is computed by calculating the amplitude of SP and comparing that with the amplitude of the primary negative peak (N1) of the AP. Because the position of the recording electrode within the ear can have a strong effect on all three components of ECoG, investigators and clinicians often quantify the magnitude of the response that is elicited by computing the SP : AP amplitude ratio.

Clinical Applications

It is possible to use ECoG to assess auditory sensitivity. If a transtympanic or tympanic membrane recording electrode is used, ECoG thresholds can be recorded at stimulation levels that are near or only slightly above behavioral detection thresholds, and several authors have reported finding good correlations between ECoG and behavioral hearing thresholds.[32-34] Many patients do not tolerate placement of a tympanic or transtympanic recording electrode, however, and no study has shown that threshold estimates obtained using ECoG are superior to estimates obtained using the more easily recorded ABR. As a result, in recent years interest in this application for ECoG has waned. Today, the two primary clinical applications of ECoG are as a means of evaluating patients suspected to have Meniere's disease and as a method of assessing the response of the auditory nerve during otoneurologic surgery.

Meniere's disease is a progressive, debilitating disorder characterized by episodic and recurrent vertigo, fluctuating SNHL, a sensation of aural fullness, and tinnitus. The underlying cause of this disorder is thought to be increased endolymphatic pressure within the scala media. There is no way to confirm the presence of endolymphatic hydrops in vivo, and although the disorder was originally described in the medical literature more than a century ago,[35] diagnosing Meniere's disease remains a challenge.

Several studies have shown that ECoG recordings from individuals diagnosed with classic Meniere's disease exhibit enlarged SPs compared with recordings from individuals with normal hearing or SNHL resulting from an etiology other than Meniere's disease.[33] This observation led to the use of the SP : AP ratio in the diagnostic process at many otolaryngology clinics across the United States. In a meta-analysis of the literature published before 2000, Ferraro[36] showed that mean SP/AP ratios in normal ears range from approximately 0.16 to 0.31. SP : AP ratios larger than approximately 0.4 or 0.5 were considered abnormally large consistent with a possible diagnosis of Meniere's disease. The sensitivity and specificity of this electrophysiologic procedure is relatively low, causing many clinicians to question its role in the diagnostic process.[37] What does seem clear is that although the observation of an enlarged SP : AP ratio may support a diagnosis of Meniere's disease, the finding of a normal SP : AP ratio is of limited diagnostic significance.

It is also possible to record ECoG and ABR simultaneously. This is done by using an electrode montage that includes a reference electrode placed on the tympanic membrane or on the promontory of the middle ear. The use of a recording electrode located in such close proximity to the cochlea results in an ABR with a significantly enhanced wave I. This approach allows the response of the peripheral neural response to be measured more quickly and accurately than when the standard ABR recording montage is used; it is a recording technique that is often employed for intraoperative monitoring purposes.

Auditory Brainstem Response

The ABR is a far-field recording of the synchronized response of numerous neurons in the auditory pathways within the brainstem. The ABR was first described by Sohmer and Feinmesser in 1967.[38] Shortly thereafter, Jewett and others[39,40] published a series of studies that contained more detailed descriptions of the ABR. Since that time, research has focused on how best to record and interpret this evoked potential, and today the ABR has become a routine part of standard clinical practice.

The ABR is recorded using differential amplification with an active electrode positioned at the vertex or high forehead, and reference electrodes positioned at the mastoids or on the earlobes. The stimulus used most frequently to evoke the ABR is a 100-μs rectangular pulse or "click." Clicks are ideal because they have a broad frequency response and result in the synchronous or near synchronous firing of numerous auditory nerve fibers. For applications where frequency specificity is important, it is also possible to record an ABR in response to short bursts of a sinusoidal acoustic stimulus (i.e., a tone burst).

In normal-hearing adults, the ABR consists of a series of vertex positive peaks or waves that are traditionally labeled with roman numerals I to V. Wave I of the click-evoked ABR occurs with a latency of approximately 1.5 ms in normal-hearing adults. Each of the subsequent peaks follows at approximately 1-ms intervals such that wave V is recorded 5 to 6 ms after onset of the stimulus. The individual peaks of the ABR reflect the response from neurons located at progressively more central locations within the auditory pathways. Wave I is a measure of the collective response of numerous auditory nerve fibers. Wave V reflects neural activity generated primarily from neurons located within the lateral lemniscal tracks that run between the superior olivary complex and the inferior colliculi.[41]

The effect of intensity on the ABR is illustrated in Figure 134-3. As intensity is decreases, the amplitude of the individual peaks of the ABR decreases, and the latency increases. Near behavioral detection thresholds, the only component of the ABR that can still be resolved is wave V. Figure 134-3 also illustrates the effect of stimulus type on the ABR. The left panel of the figure shows responses recorded using clicks. The right panel shows responses recorded using 500-Hz tone bursts. When low frequencies are used, the response morphology changes. The early peaks of the ABR often become more difficult to identify, peak latencies increase, and response thresholds are slightly elevated relative to behavioral detection thresholds. These trends reflect the fact that, compared with responses recorded using click stimuli, low-frequency tone bursts result in a recording that is dominated by neural activity originating near the apex of the cochlear partition where cross-fiber synchrony is reduced.

A major advantage that the ABR has over other auditory evoked potentials is that it is not strongly affected by attention, sleep, or sedation. This is because the ABR reflects neural activity generated at the level of the brainstem. As a result, the ABR can also be recorded reliably in neonates, making it an ideal tool for pediatric applications.

At birth, the ABR consists primarily of three peaks corresponding to waves I, III, and V of the adult ABR. In very young infants, the amplitude of wave I may be equal to or sometimes even larger than the amplitude of wave V, and the absolute latency of all three waves (I, III, and V) and the I-III and I-V interpeak intervals are prolonged relative to adult norms.[42-44] As a child matures, absolute and interpeak latencies shorten, waves II and IV become more pronounced, and the relative amplitude of wave V increases until the ABR attains its normal adult form by approximately 2 years of age.[42,45,46] These maturational changes in the ABR are significant enough to require the use of age-matched normative data for children younger than 2 years. Although it is possible to record the ABR in premature infants 27 to 30 weeks of gestation, there is evidence of threshold elevation in these very young infants.[44,47] This elevation is most likely a product of an immature auditory system and the suboptimal test environment that is typical of most neonatal intensive care units.

Clinical Applications

There are two primary applications for the ABR. The first is as a tool for estimating audiometric thresholds. The second is as a method of assessing the integrity of the neurologic pathways associated with audition at the level of the brainstem.

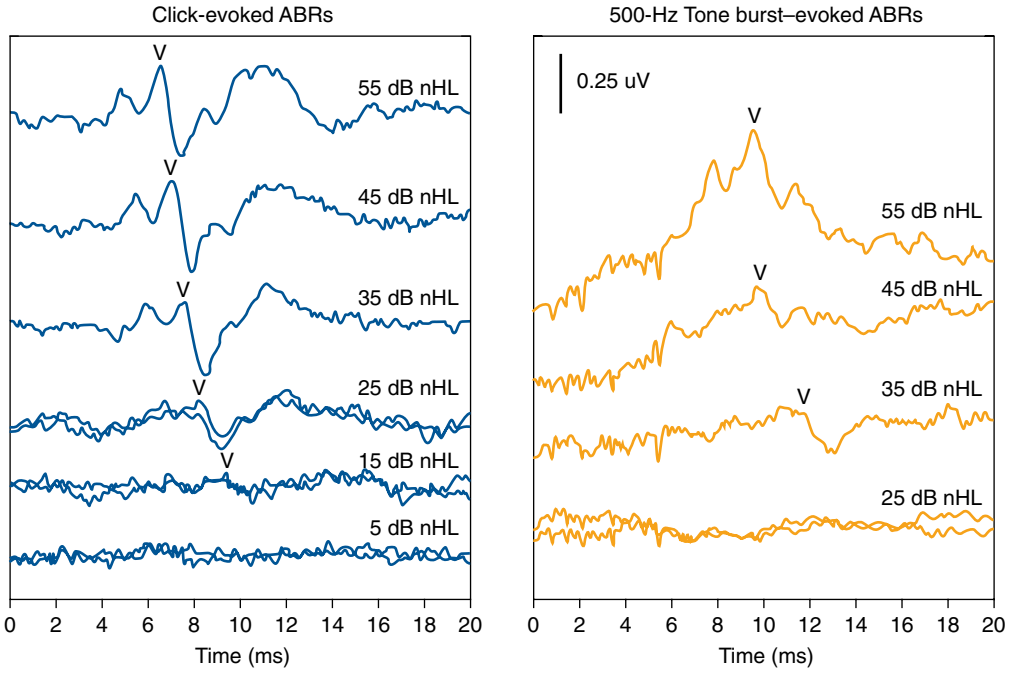

Figure 134-3. A series of auditory brainstem responses (ABRs) recorded from an individual with normal hearing are shown. The *panel on the left* shows responses recorded using click stimuli. The *panel on the right* shows responses recorded using 500-Hz tone burst stimuli.

Assessing Hearing Sensitivity

The stimulus used most frequently to evoke an ABR is a click. Clicks are advantageous because they result in maximum cross-fiber neural synchrony and optimal response morphology. Click-evoked ABRs can be recorded near behavioral detection threshold, and considerable effort has gone into assessing the extent to which the click-evoked ABR can be used to predict audiometric thresholds and type of hearing loss (conductive vs. sensorineural). The major limitation of the click-evoked ABR as a tool for estimating hearing sensitivity is that it is not frequency-specific. To obtain more frequency-specific threshold estimates, most clinicians use tone bursts in place of or in addition to clicks for purposes of threshold estimation.

Estimating Audiometric Thresholds Based on Click-Evoked Auditory Brainstem Response Thresholds

Although it is possible to record an ABR in response to a click stimulus at levels that are very close to the behavioral detection threshold (0 dB nHL), the question of interest is how well ABR thresholds predict audiometric thresholds. This relationship has received a great deal of attention in the scientific literature over the past 2 decades. Some studies have shown click-evoked ABR thresholds to compare best with the average of the 2000-Hz and 4000-Hz audiometric thresholds.[48-50] Other investigators report finding optimal correlations between ABR thresholds and the mean of the 1000- to 4000-Hz audiometric thresholds.[40,51,52] Additionally, the slope of the ABR latency versus intensity function has been shown to help predict the shape of the audiogram. Subjects with steeply sloping high-frequency hearing losses tend to have steeper ABR latency-intensity functions compared with subjects with flat audiometric contours.[49] What is clear from the literature is that there is no correlation between click-evoked ABR thresholds and audiometric thresholds for frequencies less than 1000 Hz, and it is impossible to use the ABR to distinguish between severe and profound SNHL.[53,54]

The click-evoked ABR can be helpful in determining the site of a lesion within the auditory system. A well-formed click-evoked ABR can rule out auditory neuropathy as a cause of hearing loss. Additionally, the click-evoked ABR can be used to distinguish ears in which the hearing loss has a conductive component from ears in which the hearing loss is purely sensorineural. Click-evoked ABRs recorded from patients with conductive hearing loss typically show normal interpeak latencies, but prolonged absolute latencies compared with age-based norms.[55,56] Differences between ABR thresholds obtained using bone-conduction stimuli and similar measures obtained using air-conduction stimuli are also frequently observed in ears with conductive pathology. Although there are challenges associated with recording ABRs in response to a stimulus presented via bone conduction (e.g., excess stimulus artifact and low maximum output levels), it is possible to use the ABR to distinguish between a loss that is purely sensorineural and one that is conductive or possibly mixed. It is also possible to use the ABR to obtain a rough estimate of the magnitude of the conductive component in the test ear, and such information can be extremely important in clinical practice.

Estimating Audiometric Thresholds Based on Auditory Brainstem Responses Evoked Using More Frequency-Specific Stimuli

Much research published during the past 2 decades has focused on identifying ways in which the ABR might be used to obtain more frequency-specific estimates of audiometric threshold. Two general approaches have been described. The first approach is to record the ABR using brief tone bursts rather than clicks. This is the approach used most widely today. Depending on their duration and the way in which they are gated on and off, tone bursts can be considerably more frequency-specific than clicks, and most commercially available evoked potential units have the capability of producing a range of different types of tone burst stimuli. A second approach is to use ipsilateral masking presented simultaneously with a click or tone burst to record the ABR. Ipsilateral masking is used to minimize the contribution to the ABR from neurons located outside a restricted frequency range. Numerous studies have shown that the use of either method results in improved audiometric threshold predictions compared with threshold estimates obtained using clicks.[49,57-60]

Few commercial evoked potential units have been capable of providing a click or tone burst and an ipsilateral acoustic masker. More recent evidence from a within-subject study of individuals with steeply sloping SNHL failed to reveal significant differences in the accuracy of these two approaches to audiometric threshold prediction (i.e., tone bursts presented in quiet vs. clicks presented in an ipsilateral notch noise masker).[61]

Today, tone burst–evoked ABRs have become a routine part of the clinical evoked potential assessment battery. In 2000, Stapells[62]

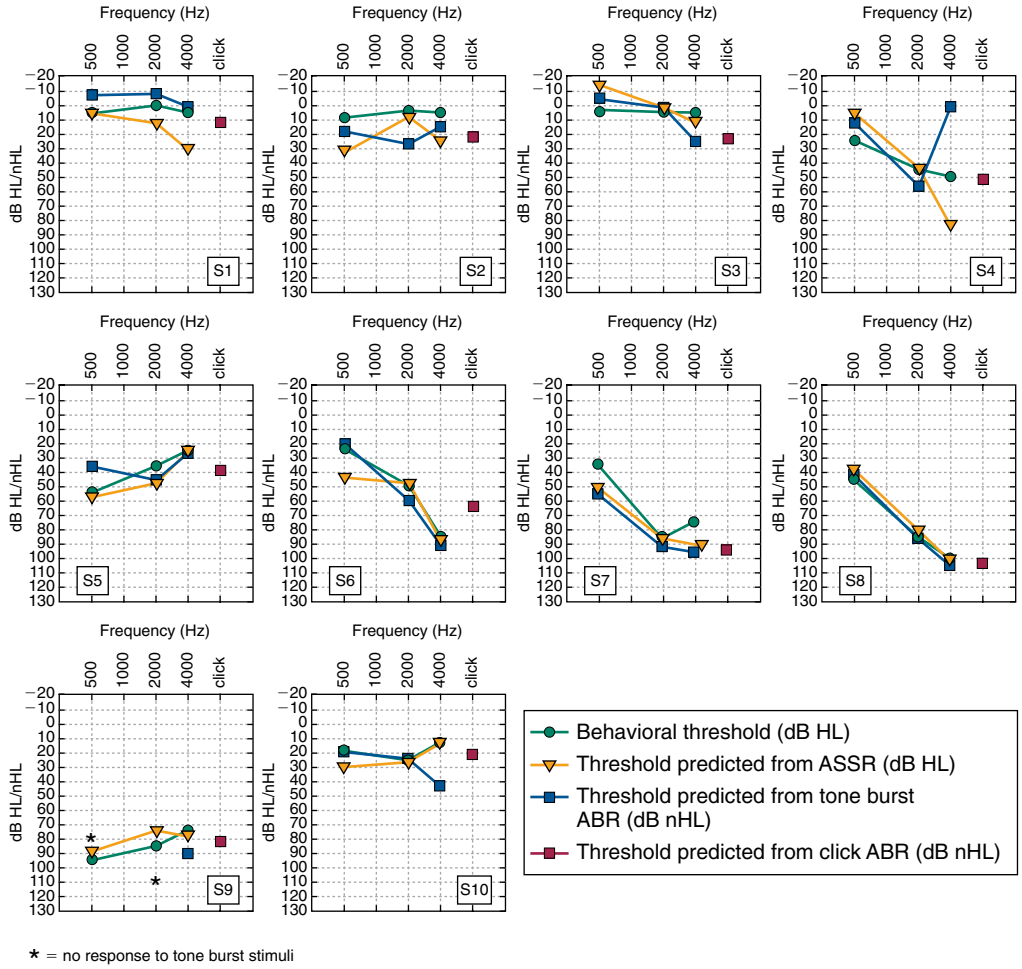

Figure 134-4. Within-subject comparison of behavioral audiometric thresholds and thresholds predicted based on auditory steady-state response (ASSR) and auditory brainstem response (ABR) recordings.

published a meta-analysis of the published ABR literature. This analysis showed that when appropriate filter settings (30 to 3000 Hz) are used, tone burst–evoked ABR thresholds can be recorded within 10 to 15 dB of behavioral audiometric threshold. The size of the correction factor was frequency-dependent—largest for a 500-Hz tone burst and smallest for 2000- to 4000-Hz stimuli. The accuracy of these threshold predictions varied according to the tone burst frequency and the age of the subject, but were approximately 5 dB for 2000- to 4000-Hz tone bursts and 10 dB for 500-Hz stimuli.

From a practical standpoint, several challenges are associated with recording frequency-specific ABRs. The morphology of the ABR elicited using tone burst stimuli is often not as good as it is when a click stimulus is used (see Fig. 134-3). Additionally, when frequency-specific stimuli are used, the latency of wave V of the ABR depends on the stimulus frequency,[49] making identification of the response in the time domain more challenging. Finally, in contrast to the click, calibration standards for tone burst stimuli have not been widely agreed on.

Despite these challenges, tone burst–evoked ABRs are used routinely to estimate residual hearing capacity for individuals who are either too young or are otherwise unable to be tested using behaviorally based audiometric procedures. Figure 134-4 provides an illustration of how ABR thresholds, evoked using tone bursts and clicks, compare with audiometric thresholds. Data are shown for a group of 10 subjects from our clinic with a range of hearing losses and audiometric configurations. Although the agreement between the audiometric thresholds and the ABR thresholds is not perfect, it is typical of what can be expected in clinical practice and is accurate enough to inform decision making relative to amplification and habilitation options for pediatric patients.

Otoneurologic Applications

Historically, the ABR has also been used to assist with the detection of lesions affecting the auditory pathways within the brainstem.[63] Such lesions include space-occupying growths such as vestibular schwannomas and dysfunction resulting from other neurologic conditions, such as multiple sclerosis, stroke, or trauma. In the 1980s, radiographic imaging techniques were not as accurate or widely available as they are today, and the ABR was an important tool in the diagnostic process. Today, reliance on ABR as a diagnostic tool has declined largely owing to the availability and widespread use of computed tomography and magnetic resonance imaging (MRI). Improved imaging has led to a decrease in the typical size of the tumor at the time of diagnosis. A systematic review of the literature has shown a decline in sensitivity of the ABR as a diagnostic tool in recent years. There are still patients and circumstances where radiographic imaging is contraindicated, however. In such cases, the ABR can still prove useful. Additionally, many surgeons have come to rely on intraoperative measures of auditory function during skull base surgery. For both of these applications, the stimulus used to evoke the ABR is a high-level click.

Differential Diagnosis

The ABR is altered in several ways by the presence of pathology affecting the neural pathways within the auditory centers of the brainstem. The ABR may be absent in an individual with good hearing sensitivity, or the ABR that is recorded may consist only of early waves. Such gross

morphologic changes have been interpreted as evidence of potential abnormality and are thought to reflect partial conduction block or significant loss of cross-fiber synchrony along the neural pathways between the cochlea and the inferior colliculus. Space-occupying lesions that impinge on the auditory nerve can also slow neural conduction and result in abnormally long wave V latencies and prolonged interpeak intervals. For normal-hearing individuals, high-level clicks generate an ABR with a wave V latency of approximately 5.5 ms and a I-V interpeak latency of approximately 4 ms. When the absolute latency of wave V is longer than approximately 6.4 ms, or when the interval between wave I and wave V is longer than 4.4 ms, the presence of retrocochlear pathology cannot be ruled out. Finally, vestibular schwannomas typically manifest as unilateral lesions. Interaural differences of greater than 0.3 ms in either the absolute latency of wave V or the length of the I-V interval are also indicative of potential retrocochlear pathology. For a comprehensive review of the criteria used to diagnose an acoustic neuroma, the interested reader is referred to Hall.[64]

Several investigators have attempted to quantify the sensitivity and relative specificity of the ABR as a tool for identifying ears with vestibular schwannomas.[65-69] The results of these studies vary, but depending on the specific criteria used, sensitivity rates of 85% to 100% are common, and there is evidence of reduced sensitivity in ears with smaller tumors. Such sensitivity comes at a cost, however, and false-positive rates for the ABR as a test of the presence of retrocochlear pathology have been reported to be as high as 30%.

In 1997, Don and colleagues[70] described a technique for recording the ABR that they referred to as "stacked ABR." This technique requires recording the ABR in response to a click that is presented simultaneously with a series of six different maskers. One masking condition uses a wide band noise. In the other five masking conditions, the noise is high-pass filtered at cutoff frequencies ranging from 500 to 8000 Hz. Derived band techniques are used to estimate the contribution to the ABR from five different frequency regions along the basilar membrane. The derived band ABR waveforms are temporally aligned (or "stacked") before being summed. The result is a waveform that more accurately represents contributions from neurons across the length of the whole basilar membrane.

In 2005, Don and colleagues[71] reported sensitivity and specificity rates for the stacked ABR relative to the standard ABR in a group of 54 patients with small acoustic tumors and 78 normal-hearing adult controls. Results indicated that the stacked ABR procedures outperformed traditional ABR procedures in this patient population. This approach to neurologic assessment may represent an improvement over traditional electrophysiologic assessment procedures, and may have merit in populations where MRI is not feasible or otherwise contraindicated.

Intraoperative Monitoring

Another application where ABR is used in clinical practice is as a tool to monitor the status of the auditory nerve during skull base surgery. The goal of intraoperative monitoring is to provide the surgeon with feedback about the status of the auditory nerve; this is done by continuously monitoring the latency of wave V or the I-V interpeak interval during the surgical procedure. Prolongation of either index can result from surgical trauma. In some cases, these changes can be reversible. The major drawback to using the ABR for this purpose is that it is a small-amplitude potential that cannot be clearly identified in the ongoing electroencephalography activity. Averaging is required to define peak latencies clearly.

Even in ideal situations, where the ABR is robust and noise levels are manageable, it is impossible to provide the surgeon with instantaneous feedback relative to auditory nerve function. Larger amplitude responses can be recorded if a recording electrode montage is used that includes an electrode placed directly on the exposed auditory nerve during surgery. Although this modification to the recording paradigm can allow for near-instantaneous feedback during the surgical procedure, positioning the recording electrode so that it does not interfere with the surgical field can be challenging.

Although there have been studies that suggest the presence of a viable ABR at the conclusion of a surgical procedure targeting the skull base is correlated with outcome on postoperative hearing tests,[72,73] surgeons do not agree on the importance or efficacy of intraoperative monitoring, and definitive studies addressing the relative efficacy of this procedure are lacking. One thing that seems to be true, however, is that adequate intraoperative monitoring requires that the individual doing the monitoring be technically competent, familiar with surgical procedures, and, perhaps most importantly, able to communicate effectively with the surgical and anesthesia teams. Even with effective monitoring, successful preservation of hearing is sometimes impossible. In our experience, the greatest contribution of intraoperative monitoring is to alert the surgeon when there is a need to slow down or, if possible, to change his or her approach to the tumor.

Additional Applications

In recent years, two new and potentially important applications for ABRs have emerged. One is a procedure called CHAMP, which was initially described by Don and colleagues[74,75] and grew out of their work on the stacked ABR paradigm. In the process of validating the stacked ABR software, these authors tested a numerous patients with Meniere's disease and found that the stacked ABR measures obtained from individuals with this specific disorder differed from those recorded from other individuals with normal hearing or other forms of SNHL. Don and colleagues[74] described results obtained from 23 individuals with confirmed and active Meniere's disease and compared their results with data obtained from a set of 38 normal-hearing controls. Masking levels intense enough to mask wave V of the ABR in normal-hearing listeners were insufficient to mask wave V in the ABR evoked from patients with Meniere's disease. Also, very little change in wave V latency was observed in these patients between the response obtained using a click alone versus one obtained using high-pass, ipsilateral masking.

The hypothesis that is used to explain the lack of change in latency of wave V of the ABR that was observed in the masked condition is that endolymphatic hydrops results in a significant and measurable change in cochlear mechanics. The report describes sensitivity and specificity rates that approach 100%, and although more data are needed, these preliminary results suggest that this test may represent an important addition to the diagnostic protocol used for patients with suspected Meniere's disease.

Finally, Banai and Wible and their colleagues[76,77] described measures of the ABR evoked in response to the presentation of a brief, synthetic speech stimulus (/da/). The response that is recorded has been shown to contain an onset response (the ABR) and a series of steady-state components that are elicited in response to the vowel. This speech-evoked ABR has been shown to be abnormal for a subset of school-age children who have been identified as having learning difficulties. These investigators have theorized that for this subset of children, rapid temporal variations in the speech signal have not been well coded at the level of the brainstem and lead to processing problems. The authors suggest that such recordings might be used to help identify children with learning problems affecting the auditory modalities that may be responsive to treatment. Additional studies are needed to assess the potential impact such a response might have on clinical practice.

Auditory Steady-State Response

The ASSR is an evoked potential that was first described in the mid-1980s.[78,79] It is a far-field recording of electroencephalography activity evoked using continuous sinusoidal stimuli that are either amplitude or frequency modulated. The brain wave activity recorded from surface electrodes on the scalp contains periodic amplitude or frequency variations that follow the slow modulations in the stimulus waveform. The recordings are analyzed in the frequency rather than the time domain. Statistically based software has been developed that allows the presence or absence of a response to be determined automatically.

As a clinical tool, the ASSR has several potential advantages over the ABR. Specifically, the stimuli used to elicit ASSRs are more frequency-specific, the maximum output of the ASSR system is higher than that typically achieved when transient stimuli are used, and no "peak picking" is required. The primary disadvantage of the ASSR is that this is a very small-amplitude response—considerably smaller than the ABR. As a result, obtaining quality ASSR recordings requires par-

ticularly quiet subjects and good control of physiologic and nonphysiologic noise sources.

Clinical Applications

The primary application for the ASSR is as a tool for estimating audiometric thresholds. When originally described, modulation frequencies of approximately 40 Hz were common, and reasonable correlations between ASSR thresholds and audiometric thresholds were reported.[78-80] Initial optimism about this response as a tool for predicting audiometric thresholds in difficult-to-test populations waned when it was noted that these responses were adversely affected by sleep and sedation.[81,82] Subsequent research has shown, however, that if modulation rates between 75 Hz and 100 Hz are used, the ASSR can be successfully recorded even from sleeping children.[82,83] Numerous studies comparing ASSR thresholds with audiometric thresholds followed. These studies typically reported finding good correlations between ASSR thresholds and audiometric thresholds.[84] Commercial instrumentation for recording the response was soon available, and in many otolaryngology clinics, ASSR measures assumed a prominent role—either in place of or in addition to ABR—as a means of estimating audiometric thresholds in pediatric populations. Additionally, it was soon apparent that the ASSR could be recorded from individuals with no measurable ABR.[54,85] As a result, this response has gained popularity as a tool for evaluation of children being considered for cochlear implantation.

Today, clinicians struggle with finding the best way to incorporate the ASSR into their routine evoked potential battery. Although it seems possible to estimate audiometric thresholds using the ASSR with a fair degree of accuracy, less is known about the effects of factors such as auditory neuropathy, age, the impact of recording electrode position, and stimulation. Concerns have been raised about the possibility that the ASSR can be adversely affected by stimulus artifact, particularly when stimuli are presented either at a high level or via a bone-conduction transducer, and within-subject comparisons between the ASSR and tone burst–evoked ABR are limited. Such comparisons are shown in Figure 134-3; results from 10 subjects with a range of audiometric thresholds and configurations are shown. This figure illustrates the generally good correspondence between ASSR-based and ABR-based threshold estimates and audiometric thresholds. These preliminary data revealed a generally good correspondence between ASSR-based and ABR-based threshold estimates, and this conclusion was later substantiated by Johnson and Brown,[61] who tested individuals with steeply sloping audiometric configurations, and found the two evoked potentials to predict audiometric thresholds with approximately similar degrees of accuracy. Future research is likely to define more fully how ASSR can best be incorporated into clinical practice.

Middle and Long Latency Evoked Potentials

Two auditory evoked potentials that are recorded less frequently in clinical practice are the middle latency response and the long latency P1-N1-P2 response complex. These two evoked potentials are named based on the time window in which they are recorded, and can be used to assess neural processing of acoustic stimuli at the level of the auditory midbrain or cortex or both. The middle latency response is characterized by a series of peaks, typically labeled Na, Pa, Nb, and Pb, which are consistently recorded within a time window that extends from about 10 to about 70 ms. Cortically generated evoked potentials such as the P1-N1-P2 response complex (Fig. 134-5) are recorded between about 80 ms and 300 ms after presentation of the stimulus. Generally, both responses are larger in amplitude than the ABR and have been used to estimate auditory sensitivity.

One advantage that the middle latency response and more cortically generated auditory evoked potentials have over their more peripherally generated counterparts is that they are not as dependent on neural synchrony, and consequently can be measured using a wider range of stimuli than are typically used to record the ABR. Clinical applications for these longer latency potentials include (but are not limited to) assessing low-frequency sensitivity and evaluation of higher level auditory processing. There are, however, numerous practical limitations that have limited enthusiasm for these responses in clinical settings. Most problematic is the fact that both responses are adversely affected by sleep, sedation, and anesthesia, and both have a long developmental trajectory.[86,87] Today, acoustically evoked middle and long latency auditory evoked potentials are recorded infrequently in all but a few otolaryngology clinics in the United States, and typically only in cases where the integrity of the higher order auditory pathways is in question.

Electrically Evoked Auditory Potentials

Cochlear implantation has become the treatment of choice for profound, bilateral SNHL. Since cochlear implants were introduced in the early 1980s, researchers and clinicians alike have been interested in finding ways to record electrically auditory evoked potentials. Initially, the goal was to find an electrically evoked auditory potential that might correlate with the status of the surviving auditory nerve. It was thought that if such a potential could be identified, this would help predict postimplant performance. As the age of implantation decreased, and as more individuals with multiple physical and developmental delays began receiving cochlear implants, the focus shifted toward finding ways in which electrically evoked auditory potentials could be used to facilitate the process of fitting or programming the speech processor of the cochlear implant to the individual.

Early studies focused on the electrically evoked auditory middle latency response (EMLR), primarily because this evoked potential had peak latencies long enough that they could be recorded without significant contamination by electrical artifact. It quickly became clear, however, that the populations for whom such measures were potentially most important were very young children and infants. As a result, the focus quickly shifted to the electrically evoked auditory brainstem response (EABR). In 1990, the first studies were published describing a method for recording electrically evoked compound action potentials (ECAPs).[88] The ECAP is a gross potential that reflects the synchronous firing of numerous electrically stimulated auditory nerve fibers. The ECAP provided a relatively direct measure of the response of the auditory nerve to electrical stimulation and was not adversely affected by muscle artifact—making it an ideal evoked potential for pediatric applications. Although initially it was possible to record this neural response only from a small group of cochlear implant users with percutaneous connections to the intracochlear electrodes, the major manufacturers of cochlear implants soon developed hardware and software that has made recording the ECAP routine.

Today, the ECAP has largely replaced the EABR and EMLR as a tool for assessing neural response to electrical stimulation in cochlear implant recipients. The ECAP has limitations, however. Specifically, it is a very peripheral measure of the response of the auditory nervous system to a simple electrical stimulus. It cannot easily be recorded using speech stimuli, and it cannot be used to assess the impact of higher level processing within the auditory system. As a result, more recently there has been a resurgence of interest in cortically generated evoked potentials such as the P1-N1-P2 complex. The following sections provide a description of each of these responses and discuss current clinical applications for electrically evoked auditory potentials.

Electrically Evoked Compound Action Potential

The ECAP is a recording of the synchronized firing of numerous electrically stimulated auditory nerve fibers. To record this response, a cochlear implant system is required that has two-way telemetry capabilities and software that allows the electrical stimulus artifact to be minimized. Cochlear Corporation first introduced such technology in 1995. Cochlear Corporation refers to the evoked potential measurement system used to record the ECAP as "neural response telemetry." Shortly thereafter, Advanced Bionics and Med El corporations followed suit introducing new cochlear implants that were similarly equipped.

The primary component of the ECAP is a single negative peak typically labeled N1. This electrically evoked response is in many ways analogous to acoustically evoked ECoG, however, because there is no traveling wave and no time required for transmission between the auditory hair cells and the primary afferent auditory nerve fibers; the N1 of the ECAP has a shorter latency than N1 of the ECoG (see Fig. 134-5). Typical response latencies for the ECAP range from 0.3 to 0.5 ms. The

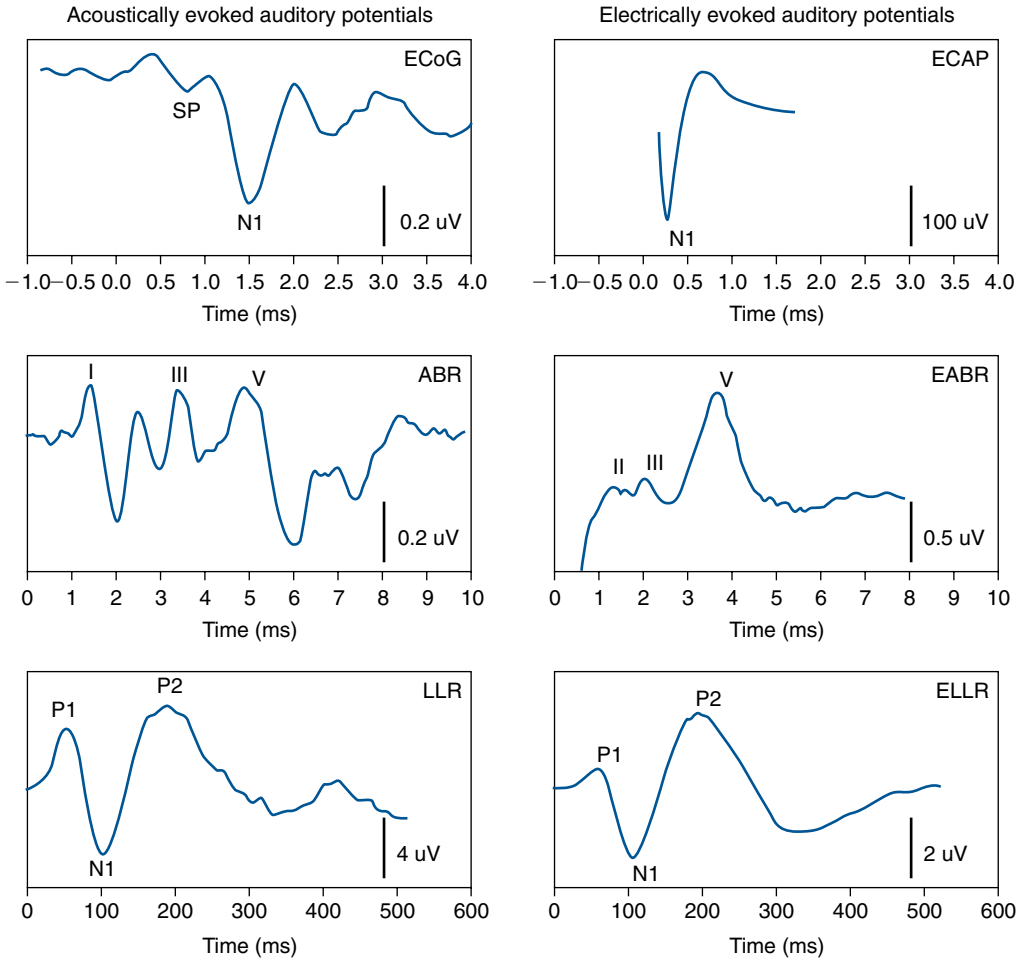

Figure 134-5. Auditory evoked potentials recorded in response to acoustic stimulation from individuals with normal hearing and in response to electrical stimulation from individuals who use a cochlear implant. ABR, auditory brainstem response; EABR, electrically evoked auditory brainstem response; ECAP, electrically evoked compound action potential; ECoG, electrocochleography; ELLR, electrically evoked long latency response; LLR, long latency response.

amplitude of the ECAP is also larger than the amplitude of the N1 peak of the ECoG. This is a direct reflection of the fact that the recording electrode is located within the cochlea, and the fact that auditory neurons respond more synchronously when electrical as opposed to acoustic stimulation is used. Typical ECAP amplitudes range from 100 to 500 μV, and responses measuring 2 to 3 mV have been reported.

The ECAP has several important advantages over other electrically evoked auditory potentials. Specifically, it can be recorded more easily and faster than the EABR. Surface recording electrodes are unnecessary. Perhaps most importantly, because it is recorded from an intracochlear electrode, the ECAP is large in amplitude, and does not require the subject to sleep or even stay still during recording sessions. These factors meant that in contrast to other evoked potentials, the ECAP could be recorded not only at the time of surgery, but also during any of the postoperative visits. During the past decade, the scientific literature has included many studies in which the ECAP was used either to help expand our understanding about the way electrical stimuli are coded at the level of the auditory nerve or to define ways in which this evoked potential could be used to facilitate the process of programming the speech processor of the cochlear implant.

Electrically Evoked Auditory Brainstem Response

The first descriptions of the EABR were published in the mid-1980s.[89-91] The EABR shares many features with its acoustic counterpart the ABR, and similar to the ECAP, the EABR has significantly shorter peak latencies than the ABR. Wave I of the EABR is difficult to record from surface electrodes, however, because it is often contaminated by electrical artifact (see Fig. 134-5). Additionally, the latency of wave V of the EABR changes very little with stimulation level, presumably reflecting the fact that there is no time delay introduced by the traveling wave in the cochlea when electrical as opposed to acoustic stimulation is used. As a result, clinicians must rely on amplitude-intensity as opposed to latency-intensity functions to characterize how an individual ear responds to electrical stimulation.[92,93]

The EABR can be recorded, even from congenitally deaf children, using standard electrode montage and recording parameters intraoperatively and postoperatively.[93-95] Although typically the cochlear implant itself is used to provide the stimulus, an isolated current source coupled to the ear via a transtympanic, extracochlear stimulating electrode that is placed on or near the round window niche can also be used to evoke this response.[96,97] Some cochlear implant teams have argued preoperative or perioperative EABRs can be used to help select the best ear to implant, or to determine whether or not the ear to be implanted is "stimulable."[96,97] Efficacy data are limited, however, and today many of the major cochlear implant programs have chosen to abandon preoperative or perioperative measurement of the EABR in routine cases.[98]

Electrically Evoked Middle and Long Latency Responses

It is also possible to use electrical stimulation to elicit middle and long latency auditory evoked potentials. Evoked middle latency responses (EMLRs) and evoked long latency responses (ELLRs) share most of the latency and morphologic characteristics of their acoustic counterparts. The EMLR is characterized by a series of slow vertex positive peaks occurring within a time window of 10 to 50 ms after stimulation. Electrically ELLRs consist of a series of potentials occurring within a

time window of approximately 50 to 300 ms (see Fig. 134-5). The EMLR reflects electrically evoked neural activity at the level of the auditory midbrain. ELLRs reflect neural activity generated at cortical or precortical regions of the auditory system.

Although less widely studied than the EABR or the ECAP, these more centrally generated, electrically evoked potentials have some distinct advantages over either the EABR or the ECAP. Specifically, EMLRs and ELLRs are less susceptible to contamination by electrical stimulus artifact, and in contrast to their peripherally generated counterparts (the ECAP and EABR), both can be evoked using speech or more speechlike stimuli.

Clinical Applications

Today, children 12 months old and children with multiple physical or developmental challenges are considered candidates for cochlear implantation. Programming the speech processor of the cochlear implant for patients in either of these categories can be challenging. Consequently, one of the more important clinical applications for electrically evoked auditory evoked potentials has been (and continues to be) as a tool that can inform the programming process. Several studies have reported correlations between ECAP thresholds and the levels used to program the speech processor of the cochlear implant.[94,99-103] Depending on the stimulation rates used to program the speech processor of the cochlear implant, ECAP thresholds indicate stimulation levels where the programming stimulus is audible but not uncomfortable for most users. For many subjects, the contour of the ECAP threshold versus stimulating electrode curve roughly parallels the contour in the MAP. There is considerable cross-subject variability evident in each of these studies, however, and a range of different methods have been proposed for improving the accuracy of the ECAP-based MAP predictions.[99,101,102]

ECAP-based MAPs are not perfect, but the evidence suggests that it is possible for most users to attain acceptable levels of speech perception with these programs. They also can serve as a first-order approximation of the MAP that will be fit when the child is able to participate more easily in the fitting process.[102,104]

Perhaps equally important applications for electrically evoked auditory potentials in clinical practice are as tools to help diagnose potential device failures. There are instances where it is helpful to know if there is a neural response to electrical stimulation. Such measures can provide helpful information about how the auditory system is responding over time, and can be used to determine if changes in stimulus characteristics, such as pulse width, level, and rate, are appropriately coded at the auditory periphery. Although they represent the minority of patients who receive cochlear implants, there are times when children (or adults) fail to respond to electrical stimulation, fail to progress as expected with the implant, or show some evidence of a decline in performance over time. If the patient is unable to report accurately changes in perception that may accompany these changes in device function, objective measures such as the ECAP can be particularly helpful.

Today, the EABR is recorded routinely in only a few cochlear implant centers. It has largely been replaced by the ECAP. In many ways, the information provided by these two potentials is redundant. There are situations, however, where the EABR can be particularly useful. Excess stimulus artifact can make it particularly difficult to record an ECAP from patients with congenital cochlear malformations or patients who have very high stimulation thresholds. In such circumstances, the EABR, owing to its longer response latency and the fact that there is more spatial separation between the stimulating and recording electrodes, can often be successfully recorded. Good correspondence between the ECAP and EABR thresholds has been reported.[99,105]

Many studies in the literature have described protocols for measuring the EMLR in clinical populations; however, this response, similar to its acoustic counterpart, is difficult to record reliably in very young children, can be adversely affected by sleep and sedation, has a long developmental trajectory, and has variable response morphology. All of these factors have served to limit the potential clinical applications of this specific evoked potential.

More recently, interest in electrically evoked cortical potentials has resurged. This renewed interest in cortically generated, electrically evoked auditory potentials is due primarily to work by Sharma and coworkers,[106,107] Ponton and colleagues,[86,87] and others who have shown that it is not only possible to record electrically ELLRs in pediatric cochlear implant users, but also that the latency of these responses is affected by factors known to correlate with performance, such as the length of profound deafness before implantation. Specifically, cogenitally deaf children who were implanted after about 7 years of age were shown to have cortical P1 response latencies that were significantly prolonged relative to similar measures made in children who were born deaf but implanted before approximately 2 years of age. Additionally, evidence has shown that the latency of the electrically evoked P1 response can change during the first few weeks or months after hookup, presumably reflecting the plasticity of the auditory system in very young children,[107] and some clinical researchers have advocated the use of electrically evoked cortical potentials to help assess adequacy of the fit of the cochlear implant or hearing aid or to document sensitivity to changes in an ongoing electrical stimulus.[108,109]

Obtaining electrically evoked cortical potentials from pediatric cochlear implant users is not easy. Although the children are not required to participate in the testing procedure, recording these responses requires application of multiple surface recording electrodes and a child who can sit quietly without sleeping for extended periods. The studies described here are generally based on data collected in laboratory, rather than clinical settings. The results are important, however, because they suggest that electrically evoked cortical responses could potentially play an important role in clinical practice. Future research is needed to determine whether or not the information about auditory processing that these electrically evoked auditory potentials can provide outweighs the challenges inherent in recording these responses in clinical settings.

Conclusion

In this chapter, we have reviewed many of the objective measures that are used in clinical practice today to evaluate auditory function in individuals who are either too young or otherwise unable to be tested using behavioral means. Recording these potentials takes training, specialized equipment, and attention to detail. None of these procedures is foolproof, and, perhaps more importantly, none replaces good behavioral assessment techniques. The careful application of these techniques can have a positive impact on the clinical practice of otology, however, and can teach us a great deal about the normal and the impaired auditory system.

CHAPTER ONE HUNDRED AND THIRTY-FIVE

Neuroradiology of the Temporal Bone and Skull Base

Frank M. Warren, III

Clough Shelton

Richard H. Wiggins, III

Key Points

- CT evaluation of the temporal bone with and without contrast enhancement shows bony erosion and adjacent soft tissue inflammation or abscess or both in cases of malignant external otitis.
- Cholesteatoma has distinct imaging characteristics on MRI. The lesion is isointense to hypointense on T1-weighted imaging, is intermediate on T2-weighted imaging, and does not enhance with the addition of contrast medium. Most importantly, the lesion does not restrict on diffusion-weighted imaging.
- MRI and CT are used in the evaluation of glomus tumors. CT is best to determine the degree of involvement of the jugular bulb, and discriminates between a glomus tympanicum or glomus jugulare. MRI defines the extent of disease that is in the neck, the extent of disease that is intracranial, and the amount of carotid involvement.
- High-resolution T2-weighted MRI is the study of choice for screening for acoustic neuromas.
- The diagnosis of superior semicircular canal dehiscence is made using high-resolution CT (HRCT). The dehiscent segment must be greater than 2 mm, with the area of absent bone visualized in three consecutive coronal images. Alternatively, the scan can be reformatted in the plane of the superior canal, and the dehiscent area can be measured directly.
- HRCT imaging is the best modality for evaluation of pediatric patients with sensorineural hearing loss. HRCT detects cochleovestibular abnormalities, internal auditory canal abnormalities, and enlarged vestibular aqueduct.
- The diagnosis of petrous apex lesions is based on their CT and MRI characteristics.
- Lesions of the cerebellopontine angle are discriminated based on their MRI characteristics.
- High-resolution T2-weighted MRI is the study of choice for preoperative evaluation for cochlear implantation. This allows for clear definition of cochlear morphology and evaluation of the seventh and eighth cranial nerve complexes.

Diagnostic imaging is indispensable in the evaluation of otologic patients. Magnetic resonance imaging (MRI), computed tomography (CT), angiography, and nuclear medicine studies aid otolaryngologists in the diagnosis of various conditions and are often crucial in surgical planning. This chapter reviews the utility of MRI and CT for visualizing the structures and identifying pathology in the temporal bone and skull base. The chapter focuses on different anatomic subdivisions of the region: the temporal bone, the cerebellopontine angle (CPA) and internal auditory canal (IAC), and the skull base.

Over the decade leading up to the year 2008, diagnostic imaging of the skull base, temporal bone, CPA, and associated vascular and neurologic structures has improved significantly. As magnet strength has increased to 3 Tesla, the limitations of MRI have diminished, improving the signal-to-noise ratio and leading to resolution of smaller structures. Research continues with scanners of higher strength, up to 7 Tesla, which have not been used clinically. In addition, the use of radiofrequency coils has led to further improvement in resolution by increasing the effective magnetic field strength. These improvements have led to much more detailed images in the temporal bone, as is reflected in the use of high-resolution T2-weighted imaging for the evaluation of cochlear nerve aplasia. MRI is most helpful for visualizing soft tissue structures and the vasculature of the skull base using MR arteriography and MR venography.

CT continues to improve as well; the resolution has increased, while the amount of radiation exposure the patient receives has decreased with the advent of multidetector scanners. The maximum resolution of current CT technology is 0.3 mm, providing unprecedented detail of the temporal bone. CT is best used for visualization of the bony anatomy, especially the cochlea, semicircular canals, vestibule, and vestibular aqueduct. CT is also useful for defining middle ear and mastoid pathology.

Temporal Bone

Temporal bone imaging requires identification and distinction of bony and soft tissue structures, necessitating the use of CT and MRI. Dividing this area into anatomic subsites of the external auditory canal (EAC), the middle ear, the inner ear, the petrous apex, and the intratemporal facial nerve facilitates the discussion of structures in the area.

External Auditory Canal

Congenital lesions rarely affect the EAC. The most common lesions are atresia of the EAC and first branchial cleft fistulas and cysts. Atresia and stenosis of the EAC is best evaluated with high-resolution CT (HRCT) of the temporal bones. The contribution of soft tissue and bony components of the stenosis or atresia is easily defined (Fig. 135-1). The presence of an EAC cholesteatoma behind the atresia plate can be determined. The middle ear may be hypoplastic, and typically the malleus and incus are fused into one ossicular mass that is connected to the stapes. The stapes may be malformed as well, and there may be an associated oval window atresia (Fig. 135-2).[1-3] The position of the facial canal can be quite anomalous; the nerve tends to be dehiscent in the tympanic segment and can be overlying the oval window. The mastoid segment tends to run in a more anterior and lateral position, and the nerve can exit into the glenoid fossa or lateral to the styloid process. All of these anomalies are important in the assessment of the surgeon's ability to perform an atresia repair.[4]

Imaging of severe infections affecting the EAC is generally used to assess for malignant or necrotizing otitis externa. This process typically involves the soft tissues and bone of the EAC, and extends into adjacent soft tissues. Findings on CT typically show soft tissue swelling in the EAC and auricle, with associated bony erosion and an osteomyelitic appearance of the inferior EAC. Contrast-enhanced CT shows enhancement of the soft tissues of the EAC and surrounding cellulitis and abscess (Fig. 135-3). The infection can spread in any direction, and can extend inferiorly to the parotid, masticator, and parapharyngeal spaces; posteriorly into the mastoid air cells; medially into the middle ear and petrous apex; and anteriorly into the temporomandibular joint. Rim-enhancing fluid collections can also be seen in these areas because associated abscesses can develop.

MRI of these lesions shows similar soft tissue thickening. Contrast-enhanced T1-weighted imaging shows diffuse enhancement of the auricle and EAC, with adjacent enhancement in cases with cellulitis, and rim-enhancing fluid collections in cases with abscess. T2-weighted imaging reveals diffuse high signal in areas of cellulitis.[5,6]

Inflammatory lesions of the EAC include cholesteatoma, keratosis obturans, and medial canal fibrosis. The hallmark imaging finding of cholesteatoma, regardless of location, is bony erosion. The typical imaging finding associated with EAC cholesteatoma is a homogeneous, erosive soft tissue mass in the EAC. These masses tend to occur predominantly in the inferior and posterior EAC. CT shows a soft tissue mass, with scalloped bone in the EAC with flecks of bone within the lesion itself (Fig. 135-4).[7] Contrast enhancement is typically not helpful in these cases, but may show rim enhancement in cases with associated inflammation. CT is the study of choice for these lesions.

Keratosis obturans is an abnormal accumulation of keratinous debris within the EAC *without* erosive bony changes.[8] This clinical entity can be confused with cholesteatoma, leading practitioners to perform imaging of the ear. HRCT reveals soft tissue filling the EAC, most typically with an intact tympanic membrane. The bony EAC may be enlarged, without scalloping or erosion of the osseous EAC itself (Fig. 135-5).[9] Enhanced HRCT is not helpful in these cases.

Postinflammatory medial canal fibrosis can be difficult to evaluate in the clinic because the ear canal becomes foreshortened and scarred. This entity is the sequela of chronic inflammation in the EAC, typically resulting from chronic otitis externa, but also can be of autoimmune origin.[10,11] Nonenhanced HRCT with axial and coronal images is most helpful. One typically finds soft tissue in the medial one third to one half of the canal that is indistinguishable from the tympanic membrane without erosion or expansion of the bony ear canal (Fig. 135-6); this often has the appearance of a crescent. In the very early stages, there

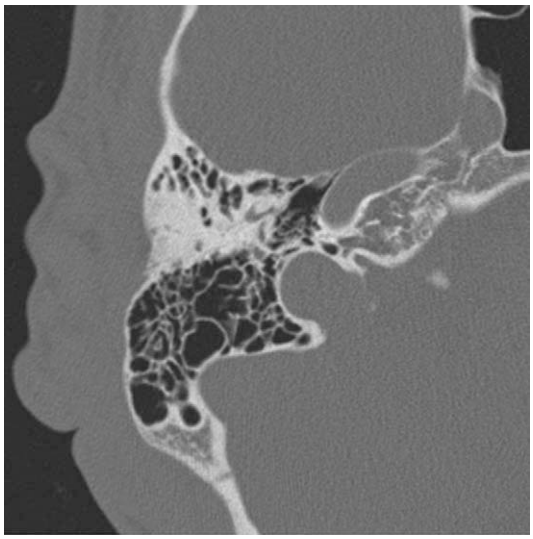

Figure 135-1. Axial noncontrast CT image through the right temporal bone shows a case of external auditory canal (EAC) atresia with membranous and osseous atresia of the EAC, with an abnormal pinna.

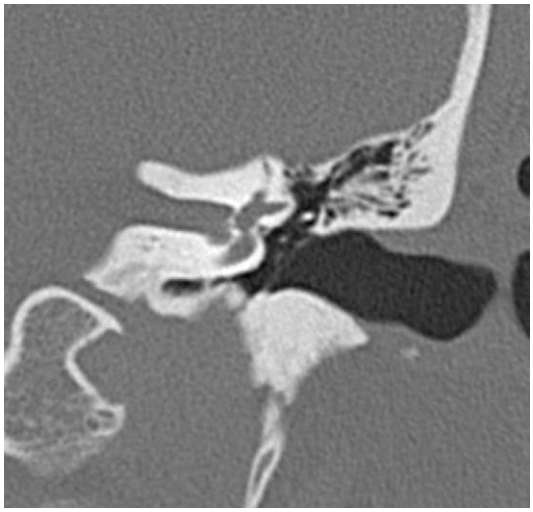

Figure 135-2. Coronal bone algorithm CT image through the left temporal bone in a case of oval window atresia, with a facial nerve tympanic segment overlying the atretic window.

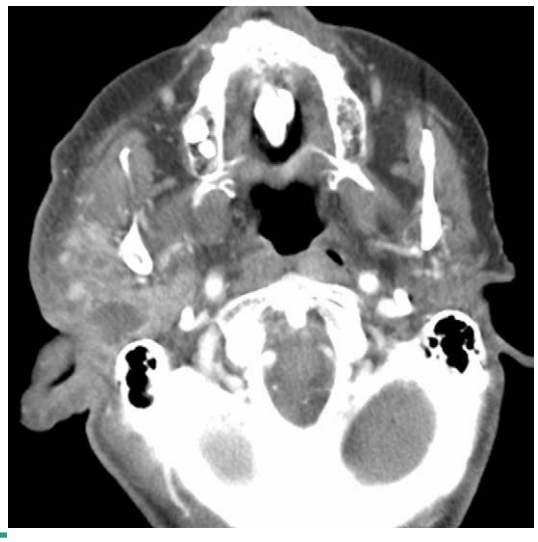

Figure 135-3. Axial postcontrast CT image through the suprahyoid neck shows abnormal patchy enhancement within the right parotid space, below the right external auditory canal secondary to inferior spread of infection.

Figure 135-4. Coronal magnified bone algorithm CT image through the right temporal bone shows osseous destruction of the inferior right external auditory canal (EAC) with bony flecks, consistent with an EAC cholesteatoma.

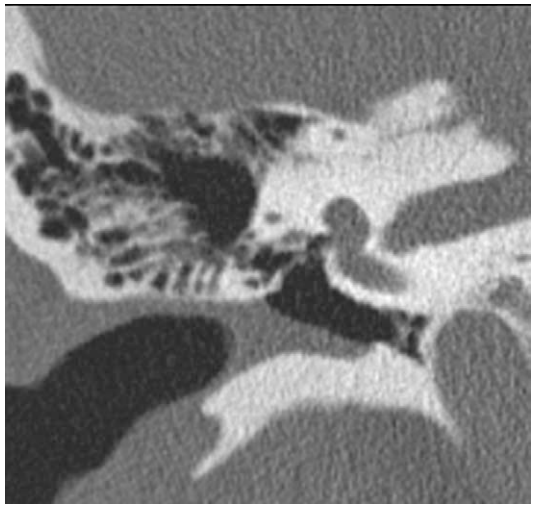

Figure 135-6. Coronal CT image through the right temporal bone shows findings consistent with medial canal fibrosis, with a classic "crescent" of soft tissue adjacent to the intact tympanic membrane.

Figure 135-5. Coronal CT image through the right temporal bone shows classic keratosis obturans findings with benign-appearing soft tissue filling the external auditory canal, without osseous changes.

Figure 135-7. Axial bone algorithm CT image of the right temporal bone shows classic circumferential osseous overgrowth of the osseous external auditory canal, consistent with exostoses or "surfer's ear."

may be thickening of the tympanic membrane only, especially anteriorly. The middle ear and mastoid are not involved.

Benign neoplasms of the EAC include EAC exostoses and osteomas. Exostoses, also known as "surfer's ear," can be diagnosed without imaging, but are frequently seen on temporal bone imaging in some regions where cold water swimming is common. On HRCT, these lesions are typically circumferential bony overgrowths with normal overlying soft tissue that begin past the isthmus of the EAC (Fig. 135-7). These are almost always bilateral, and typically occur at the suture lines. EAC osteomas can be differentiated from these lesions by several distinct features. Similar to exostoses, they have normal overlying soft tissue, but they are typically ovoid in shape and less than 1 cm in size (Fig. 135-8). Usually discovered as an incidental finding, these lesions tend to be isolated, asymptomatic, and unilateral.

Malignant lesions of the EAC are uncommon, and are typically limited to local squamous cell carcinomas and the occasional metastatic carcinoma to the region. The imaging characteristics associated with squamous cell carcinoma are most commonly a soft tissue mass within the EAC with aggressive underlying bony changes. HRCT without contrast enhancement to delineate the bony extent of tumor and MRI with and without contrast enhancement to delineate the extent of soft tissue involvement are recommended for the radiologic evaluation of these lesions because the bony and soft tissue extent of tumor can impact surgical planning.[12,13] HRCT shows the tumor and adjacent bony erosion, which are typically isolated to the EAC (Fig. 135-9). Contrast-enhanced HRCT may show a heterogeneously enhancing mass and spread to adjacent areas. These lesions tend to spread locally to the lining of the EAC and the auricle, sparing the middle ear. Regional metastases to the parotid and neck can be shown as enhancing nodes often greater than 1 cm in size (Fig. 135-10). MRI appearance of these lesions is generally low signal on T1-weighted imaging, which enhances peripherally with contrast medium. T2-weighted imaging commonly shows a heterogeneous high signal invasive lesion.[13]

Middle Ear and Mastoid

Common lesions affecting the middle ear and mastoid include cholesteatoma, glomus tympanicum, and an aberrant internal carotid artery.

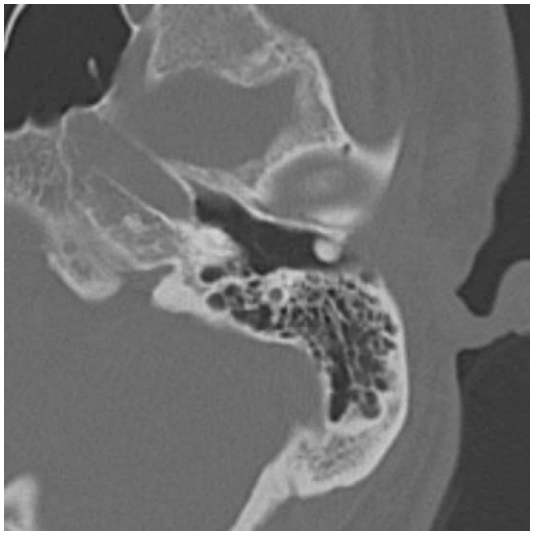

Figure 135-8. Axial CT image through the left temporal bone shows a small osseous lesion near the junction of the membranous and osseous external auditory canal (EAC), consistent with an EAC osteoma.

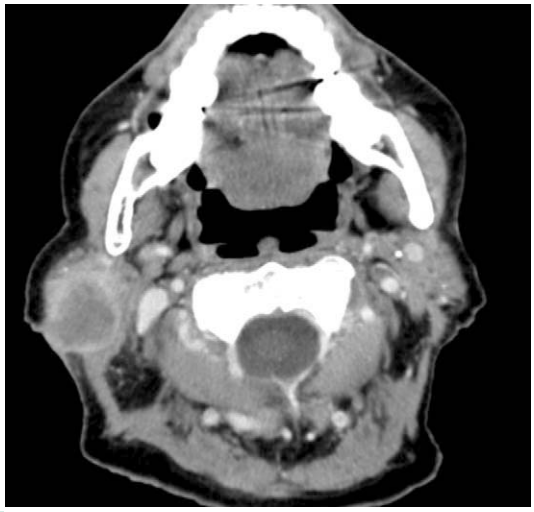

Figure 135-10. Axial postcontrast CT image through the suprahyoid neck shows a large necrotic node within the right parotid gland from an external auditory canal squamous cell carcinoma primary.

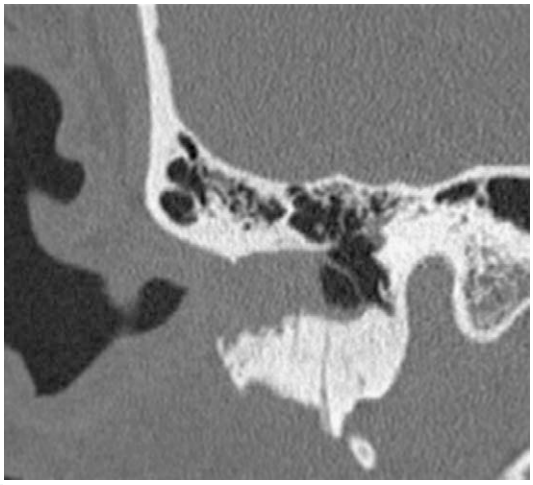

Figure 135-9. Coronal CT image of the right external auditory canal (EAC) shows a destructive lesion of the floor of the EAC, found to be a squamous cell carcinoma.

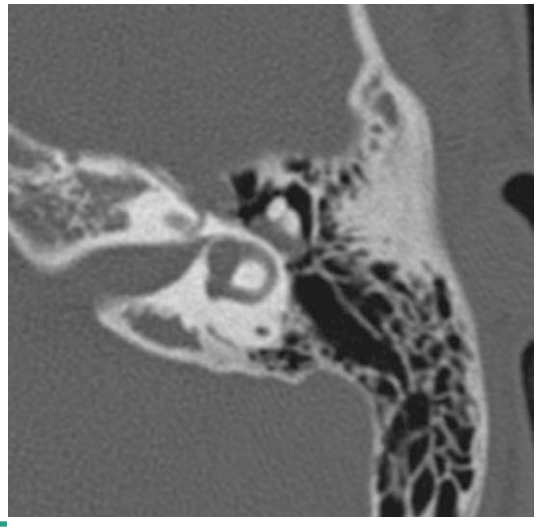

Figure 135-11. Axial CT image through the left middle ear cavity shows a soft tissue mass adjacent to the ossicles with some destruction of the short process of the incus, consistent with a cholesteatoma.

Cholesteatoma, although not strictly a radiologic diagnosis, does have specific radiologic characteristics. Congenital cholesteatomas are by definition found behind an intact tympanic membrane and can be very small, limited to the anterior tympanum, or, more rarely, can fill the entire tympanum and extend into the mastoid.[14] CT without contrast enhancement shows a homogeneous soft tissue lesion, usually in the anterior tympanum adjacent to the eustachian tube with or without adjacent bony erosion (Fig. 135-11). As these lesions enlarge, they may fill the entire middle ear and erode the ossicles (Fig. 135-12), the fallopian canal, the tegmen, or the otic capsule. As the lesion extends posteriorly, it may widen the antrum and obstruct the mastoid air cells, which may be opacified by trapped secretions (Fig. 135-13).[15]

An acquired cholesteatoma has a different CT appearance because it develops in the epitympanum, eroding the scutum and ossicles (Fig. 135-14), and can extend posteriorly to involve the mastoid. MRI of any cholesteatoma is diagnostic because it has a characteristic appearance regardless of location on temporal bone. T1-weighted imaging shows an isointense to hypointense lesion (Fig. 135-15) that does not enhance, but may show a rim of enhancement (Fig. 135-16). T2-weighted imaging shows an intermediate or increased signal intensity lesion, occasionally with high signal secretions in the mastoid cavity (Fig. 135-17). Fluid-attenuated inversion recovery (FLAIR) imaging shows incomplete attenuation, whereas diffusion-weighted imaging shows restricted diffusion (Fig. 135-18).[15] These imaging characteristics are typical of all cholesteatomas within the temporal bone, regardless of location.

An aberrant internal carotid artery is a rare finding, but can be easily confused with a glomus tympanicum if careful attention is not paid to the imaging findings. Nonenhanced HRCT is diagnostic because it shows the characteristic enlargement of the inferior tympanic canaliculus, anterolateral to the jugular bulb, through which the carotid enters the middle ear (Fig. 135-19). From here, the carotid can traverse the middle ear, crossing the promontory and joining the petrous carotid through a dehiscence in the carotid canal. The carotid foramen and the vertical segment of the carotid are absent, with the aberrant carotid taking a more lateral position in the temporal bone.[16] This lesion can be discriminated from a glomus tympanicum by the shape of the

Figure 135-12. Axial CT image of the right middle ear shows a large cholesteatoma with complete ossicular destruction.

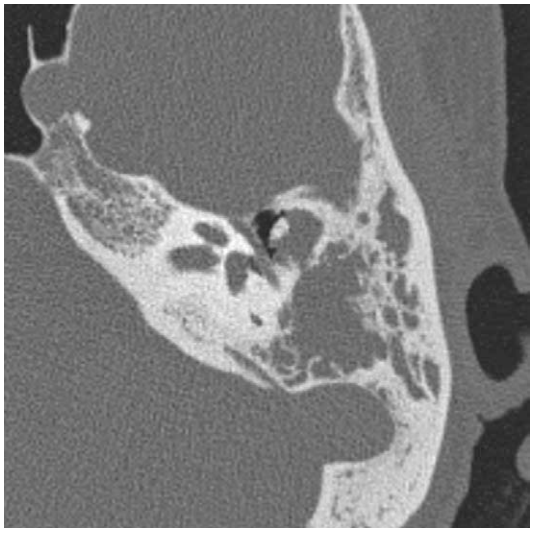

Figure 135-13. Axial CT image of the left middle ear shows destruction of the short process of the incus, and secondary opacification of the mastoid air cells.

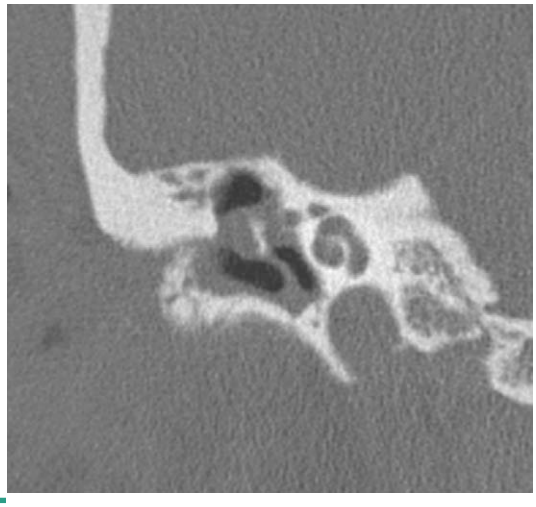

Figure 135-14. Coronal CT image of the right temporal bone shows scutum and ossicle destruction from a cholesteatoma.

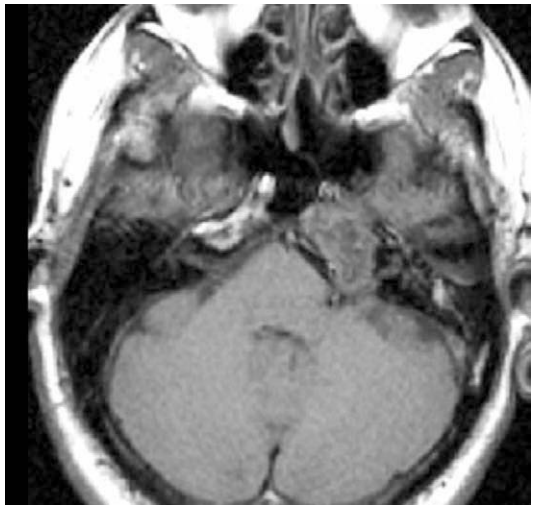

Figure 135-15. Axial T1-weighted noncontrast MR image through the temporal bone shows an isointense mass of the left petrous apex.

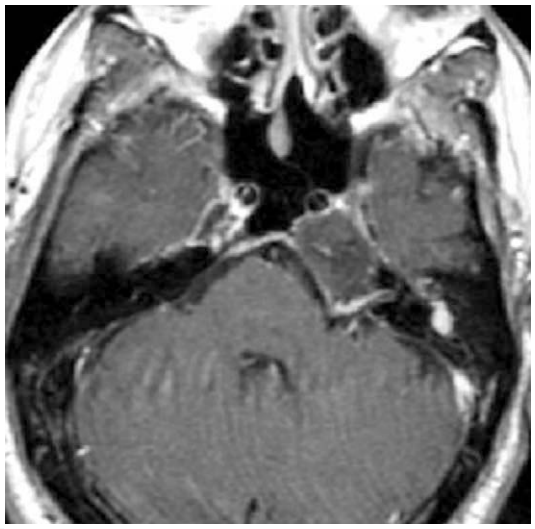

Figure 135-16. Axial postcontrast MR image through the left petrous apex in the same case as in Figure 135-15 shows a nonenhancing lesion with some peripheral enhancement.

middle ear mass (tubular versus ovoid). A glomus tympanicum is limited to the middle ear space (Fig. 135-20). It is imperative to review the images in these cases carefully because the aberrant artery may appear to be an isolated ovoid middle ear mass if visualized only on one cut of the scan. MR angiography is also helpful in the diagnosis of the aberrant artery, showing a more lateral course of a narrowed internal carotid artery (Fig. 135-21).

Inner Ear

Imaging of the temporal bone can produce excellent visualization of the structures of the inner ear. The cochlea, vestibule, and semicircular canals all can be well visualized on HRCT (Fig. 135-22) and high-resolution T2-weighted MRI (Fig. 135-23). The diagnosis of superior semicircular canal dehiscence on imaging has improved significantly as higher resolution scans are acquired with submillimeter cuts and reconstructions in the plane of the superior semicircular canal that show the absence of bone over the canal (Fig. 135-24). In lieu of these reconstructions, the diagnosis is made by visualizing the lack of bone over the canal on three consecutive coronal cuts (Fig. 135-25).[17,18]

Figure 135-17. Axial T2-weighted MR image of the same case shows increased T2 signal intensity within the lesion.

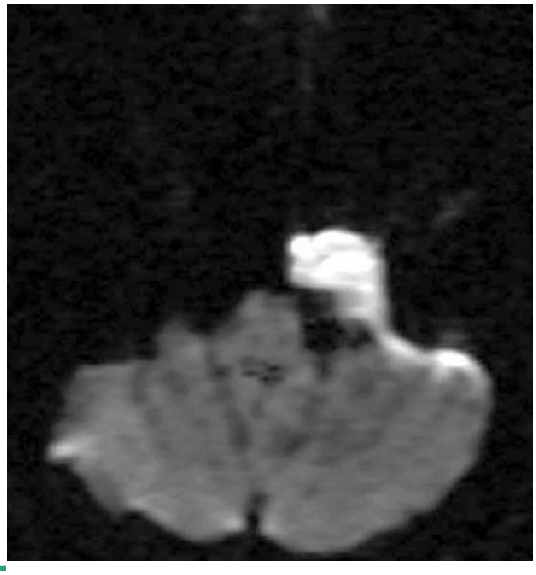

Figure 135-18. Axial diffusion-weighted MR image through the same lesion shows restricted diffusion (bright signal) consistent with a cholesteatoma.

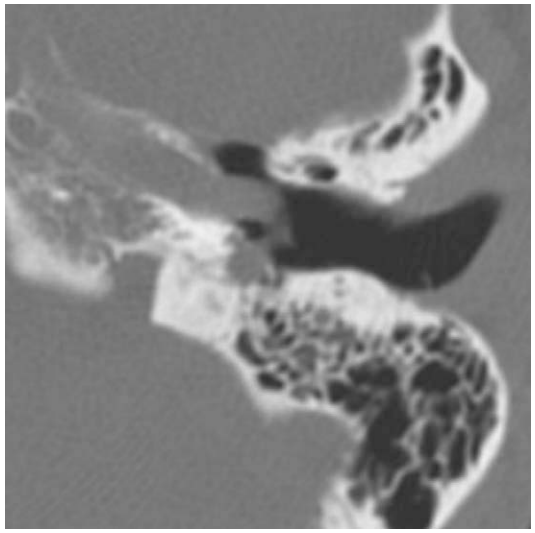

Figure 135-19. Axial CT image through the left temporal bone shows extension of the horizontal segment of the carotid canal into the middle ear, consistent with an aberrant carotid artery.

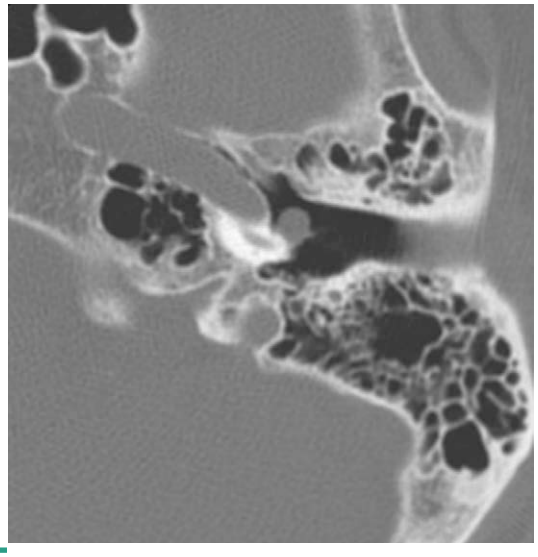

Figure 135-20. Axial CT image through the left temporal bone shows a small mass on the cochlear promontory, separate from the carotid, found to be a small glomus tumor.

Congenital abnormalities of the inner ear can also be well defined using HRCT. Cochlear anomalies such as common cavity and cochlear hypoplasia are readily apparent (Fig. 135-26).

Enlarged vestibular aqueduct can be diagnosed on either MRI or CT, with the characteristic enlargement of the duct leading up to the posterior canal clearly identified on this axial CT image (Fig. 135-27).[19] It is generally accepted that the duct should not measure wider than 1.5 mm in diameter at the midpoint of the bony endolymphatic duct. High-resolution T2-weighted images are necessary to make this diagnosis on MRI (Fig. 135-28).[20,21] Semicircular canal dysplasia is characterized by an abnormal development of the vestibular system during the 6th to 8th week of embryogenesis. This can vary from an enlarged diameter of the semicircular canal to a featureless cavity, and can be diagnosed on HRCT or thin T2-weighted MRI (Fig. 135-29).

In the evaluation of patients with sensorineural hearing loss, the inner ear may be affected by inflammation or neoplasm. These pathologic entities can be difficult to discriminate on imaging, and careful examination must be undertaken. Inflammation in the inner ear associated with labyrinthitis may lead to enhancement of the vestibule or cochlea or both on T1-weighted gadolinium-enhanced images. An intralabyrinthine or intracochlear schwannoma has a similar appearance, but the differentiation can be made on thin T2-weighted images that show evidence of a space-occupying lesion in the area of enhancement with loss of the normal fluid signal (Figs. 135-30 and Fig. 135-31).[22,23] The exception to this is that the late sequela of inflammation in the inner ear, labyrinthitis ossificans, would lead to bone formation within the cochlea or vestibule and lead to a similar appearance. This can be differentiated on CT, which is abnormal in the setting of late labyrinthitis ossificans with increased density within the inner ear (Fig. 135-32).[24]

Fenestral and cochlear otosclerosis (otospongiosis) appears as demineralization of the bone of the otic capsule. HRCT shows osteolytic foci of the otic capsule, surrounding the cochlea or involving the fissula ante fenestram, or both (Fig. 135-33).[25,26] As the resolution of CT

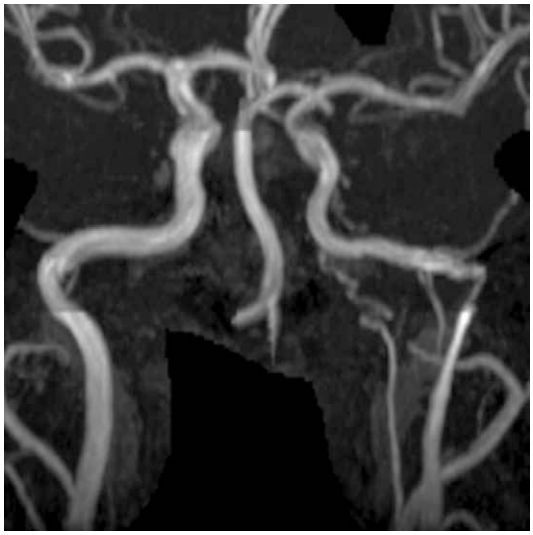

Figure 135-21. Anterior collapsed MR arteriography view shows lateral displacement of the left horizontal segment of the carotid artery, consistent with an aberrant carotid artery.

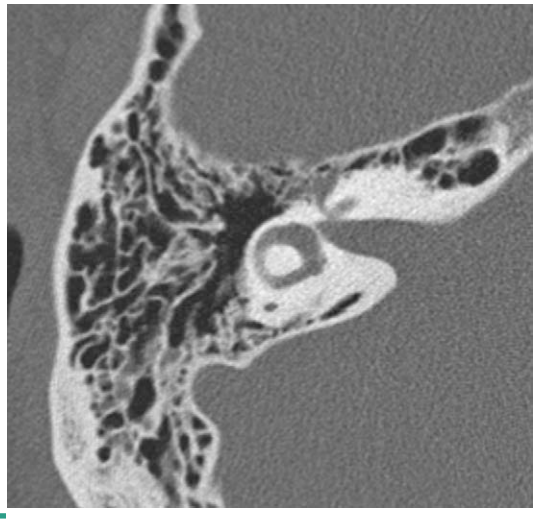

Figure 135-22. Axial CT image through the right temporal bone internal auditory canal shows the normal configuration of the vestibule and lateral semicircular canal.

imaging has increased with multidetector scanners, the ability to diagnose fenestral otosclerosis has improved significantly. The diagnosis of cochlear otosclerosis is possible on MRI, but the sensitivity of this technique is less than that of HRCT. On T1-weighted imaging, the otosclerotic plaque may be visualized as a ring of intermediate signal in the pericochlear and perilabyrinthine regions. On T2-weighted imaging, one may see focal areas of high signal around the cochlea in very large otosclerotic foci. T1-weighted imaging with contrast enhancement shows enhancing foci surrounding the cochlea.[27] HRCT is the most sensitive test to make the diagnosis of otosclerosis.

Petrous Apex Lesions

When clinically faced with a petrous apex lesion, clinicians rely on CT and MRI. Most lesions affecting this area have characteristic imaging features that facilitate the diagnosis (Table 135-1). The most common presentation is the incidental finding on a brain MR image or head CT scan that elicits a consultation with an otolaryngologist. Frequently, the "abnormality" is simply asymmetric marrow in the petrous apex, with

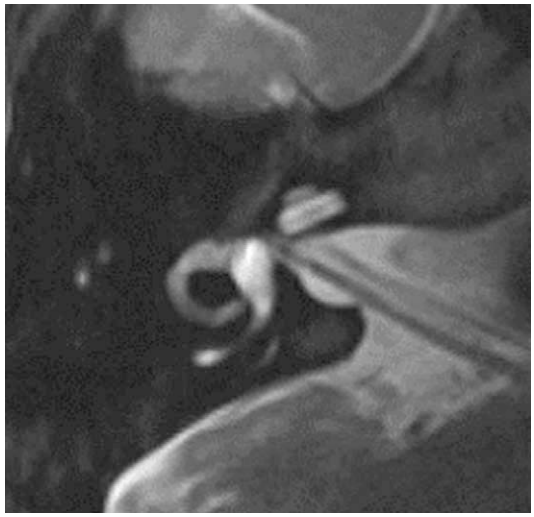

Figure 135-23. Axial thin-section T2-weighted MR image through the internal auditory canal shows the normal bright signal of the cochlea, vestibule, and lateral semicircular canal.

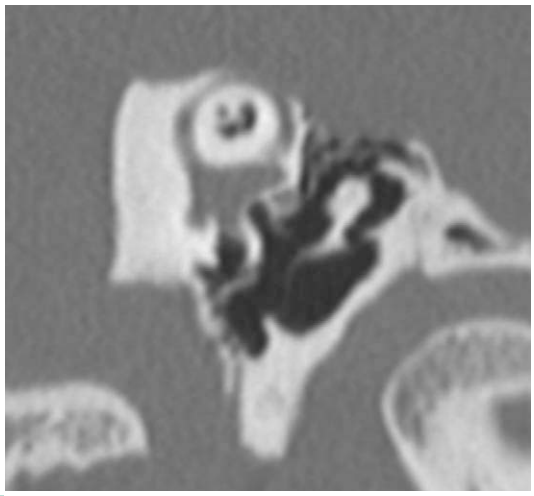

Figure 135-24. Oblique transverse sagittal CT reconstructed image through the left temporal bone shows focal dehiscence of the posterior roof of the superior semicircular canal.

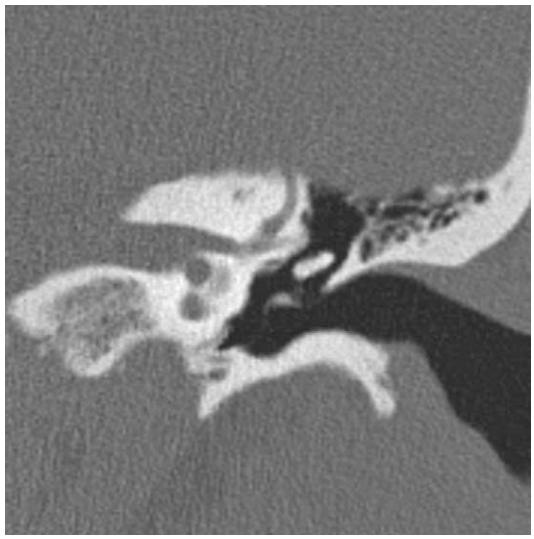

Figure 135-25. Coronal CT image of the left temporal bone shows focal dehiscence of the roof of the superior semicircular canal.

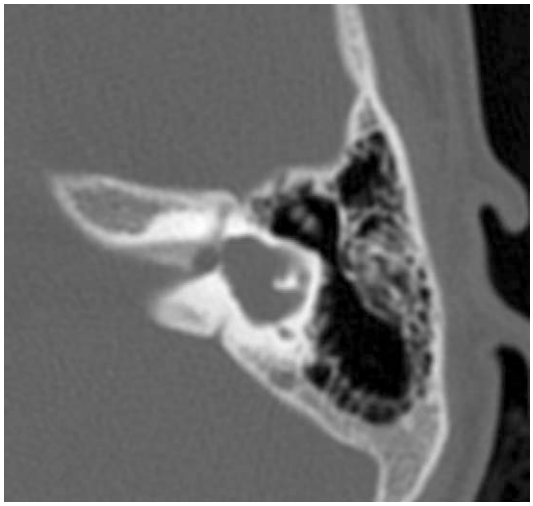

Figure 135-26. Axial CT image of the left temporal bone shows abnormal cystic changes of the left vestibule.

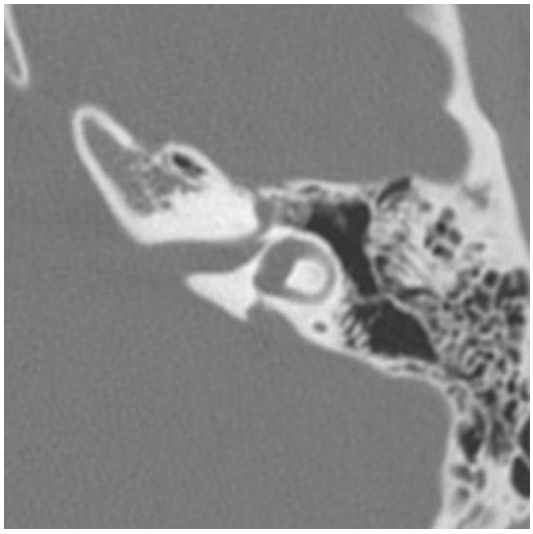

Figure 135-27. Axial CT image of the left temporal bone shows abnormal enlargement of the left endolymphatic duct, posterior to the vestibule.

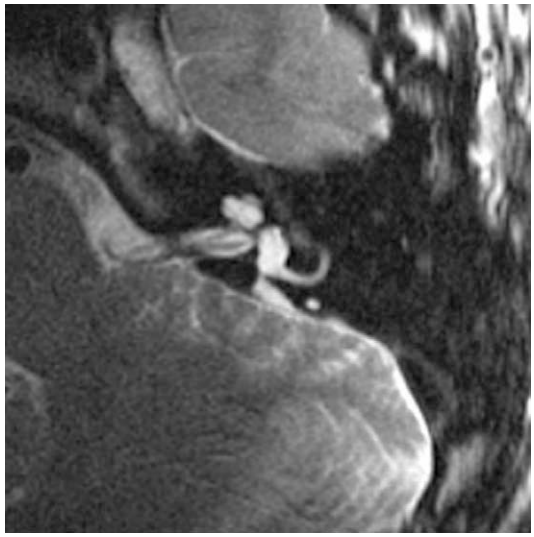

Figure 135-28. Axial thin-section T2-weighted MR image of the left temporal bone in the same case as in Figure 135-27 shows abnormal enlargement of the bright signal intensity of the left endolymphatic duct, posterior to the vestibule.

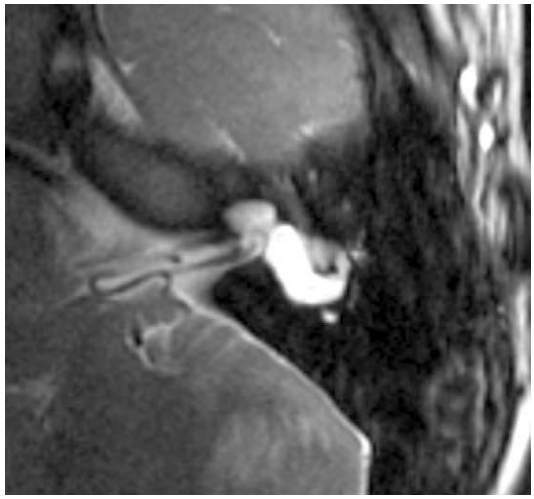

Figure 135-29. Axial thin-section T2-weighted MR image of the left temporal bone shows abnormal increased signal intensity, enlargement of the vestibule, and abnormal configuration of the cochlea.

normal pneumatization on one side and fatty marrow on the other. The bone marrow shows high signal on T1-weighted imaging (Fig. 135-34), which disappears with fat suppression. These lesions may also appear of intermediate signal if the bone marrow has not been infiltrated with fat. T2-weighted imaging shows increased signal in cases with fatty marrow, following the signal of subcutaneous fat. There is no enhancement with the addition of contrast material.

CT of these patients reveals normally aerated petrous apex across from a normal marrow space on the contralateral side (Fig. 135-35). Another commonly found incidental finding is trapped fluid in the petrous apex cells. This trapped fluid appears as a high signal lesion on T2-weighted imaging that has low signal on T1-weighted imaging, but with the preserved bony trabeculae and cortical integrity (Fig. 135-36). Mucoceles of this region show an expansile lesion with trabecular breakdown on CT with low signal on T1-weighted imaging and high signal on T2-weighted imaging. These have rim enhancement on contrast administration.[28]

Cholesterol granuloma is another lesion that is often found incidentally. These granulomas are expansile masses that form within petrous apex air cells that become isolated. As they expand, they can become symptomatic as they come in contact with surrounding structures, such as the IAC, Dorello's canal, and the CPA. On MRI, these lesions typically have smooth, well-circumscribed edges with high signal on T1-weighted imaging (Fig. 135-37) and T2-weighted imaging (Fig. 135-38). The findings on CT are typically an expansile lesion that is well circumscribed and has smooth edges (Fig. 135-39). If the lesion is large, there is associated breakdown of trabeculae and cortical thinning over the lesion. It may extend into the IAC and clivus, and expose the petrous carotid artery.[29]

In contrast, cholesteatoma of the petrous apex has identical signal characteristics as seen in cholesteatoma of the middle ear and mastoid as previously described. MRI shows a smooth, expansile mass with low signal on T1-weighted imaging and high signal on T2-weighted imaging. These lesions also show restricted diffusion on diffusion-weighted imaging (see Figs. 135-15 through 135-18).[30]

Malignant lesions of the petrous apex are uncommon. The most common primary lesion of this region is chondrosarcoma of the skull

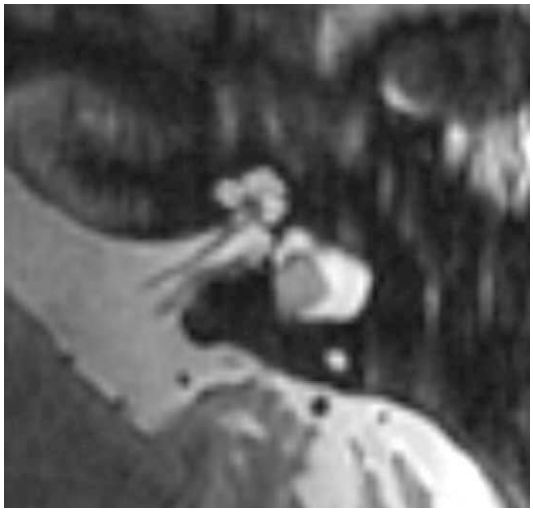

Figure 135-30. Axial thin-section T2-weighted MR image through the left vestibule shows a small focal filling defect within the posterior vestibule, surrounded by normal bright signal intensity of the fluid within the inner ear.

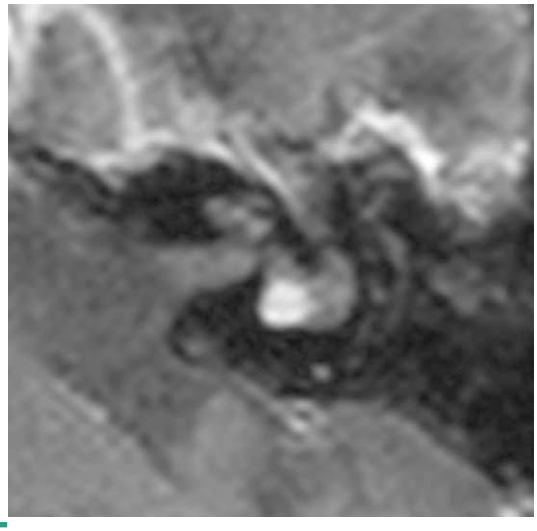

Figure 135-31. Axial postcontrast thin-section MR image through the left vestibule in the same case shows enhancement of this intravestibular schwannoma.

Table 135-1

Imaging Characteristics of Petrous Apex Lesions

Lesion	CT	T1	T2	T1 + Contrast	Notes
Asymmetric pneumatization	Bone marrow filled, no air cells	Hyperintense to intermediate intensity	Hypointense	No enhancement	T1 signal disappears with fat suppression
Retained secretions	Air cell trabecular preservation, nonexpansile	Hypointense	Hyperintense	No enhancement	
Cholesterol granuloma	Air cell trabecular breakdown, expansile	Hyperintense	Hyperintense	No enhancement	
Mucocele	Air cell trabecular breakdown, expansile	Hypointense	Hyperintense	Rim enhancement	
Cholesteatoma	Air cell trabecular breakdown, expansile	Hypointense	Hyperintense	May have rim enhancement if granulation tissue present	DWI does not restrict (bright signal)

DWI, diffusion-weighted imaging.

base. This lesion develops most commonly in the petro-occipital fissure or the basisphenoid. This lesion grows in the medial petrous apex, involving surrounding structures such as cranial nerves III, IV, V, VI, VII, and VIII, and the petrous carotid. A characteristic imaging finding of this lesion is intratumoral chondroid calcification on bone CT (Fig. 135-40). There is bony destruction in greater than 50% of these lesions. There is variable enhancement with the administration of contrast material. The MRI appearance of these lesions shows low to intermediate intensity signal to white matter on T1-weighted imaging. T2-weighted imaging reveals high signal. T1-weighted imaging with contrast enhancement reveals heterogeneous enhancement, with whorls of enhancement within the mass (Fig. 135-41).[31,32]

Facial Nerve

Imaging for facial nerve paralysis becomes necessary when the clinical picture suggests a tumor involving the facial nerve. Although herpetic (Bell's) palsy is the most common cause of acute facial paralysis, it is generally agreed that not all patients with herpetic palsy require imaging. It is important to differentiate cases of viral etiology from cases with a neoplastic origin, however, because enhancement and thickening of the nerves can be seen in cases of herpetic palsy and herpes zoster oticus.[33] In cases of simple herpetic palsy, T1-weighted imaging with contrast enhancement shows linear enhancement of portions of the facial nerve, from the distal IAC through the labyrinthine segment, the geniculate ganglion, and the anterior portion of the tympanic segment (Fig. 135-42). The enhancement pattern varies, and it most commonly involves the facial nerve in the distal IAC and the labyrinthine segment.[34] CT is normal in these cases. Patients with an atypical presentation should be imaged, including patients who (1) present with recurrent ipsilateral paralysis, (2) have no return of function over 6 months, and (3) present with weakness associated with twitching.

Radiologic evaluation for facial nerve tumors employs MRI and CT for complete detail about the facial nerve canal and enhancement in the nerve itself. MRI evaluation for facial nerve tumors requires

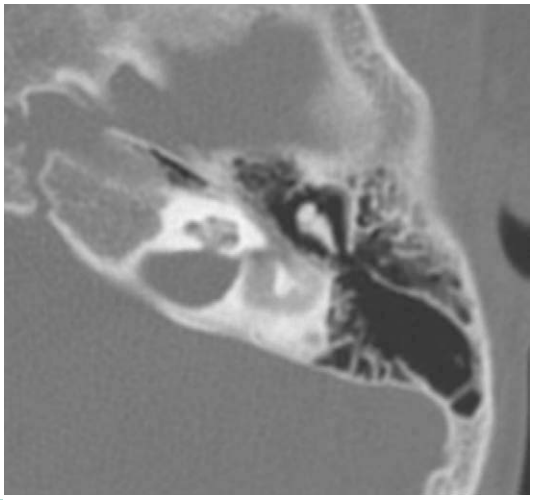

Figure 135-32. Axial CT image through the left temporal bone shows abnormal increased density within the left lateral semicircular canal, consistent with labyrinthitis ossificans.

Figure 135-34. Axial T1-weighted noncontrast MR image through the petrous apexes shows increased signal intensity of the right petrous apex, consistent with normal asymmetric marrow.

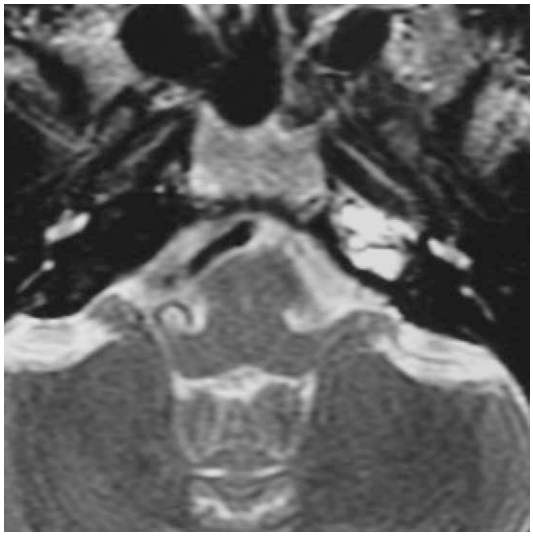

Figure 135-36. Axial T2-weighted MR image shows increased signal intensity within the left petrous apex, consistent with benign petrous apex trapped fluid.

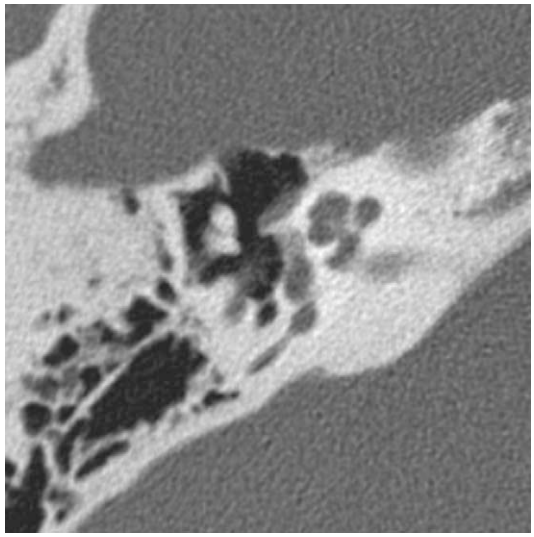

Figure 135-33. Axial magnified CT image of the right temporal bone shows subtle loss of normal bright osseous density of the fissula ante fenestram, just anterior to the lateral basal turn of the cochlea.

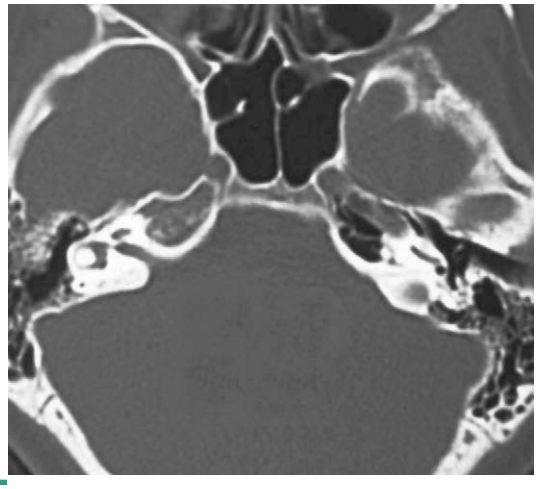

Figure 135-35. Axial bone algorithm CT image through the same level as the prior image shows normal osseous marrow of the right petrous apex, without surrounding aggressive features.

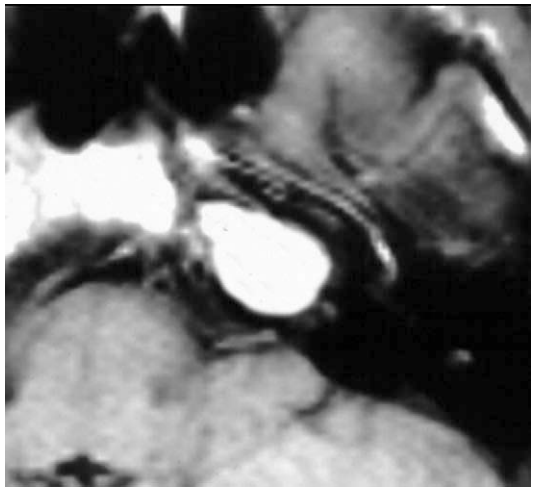

Figure 135-37. Axial magnified T1-weighted MR image of the left temporal bone shows increased signal intensity of the left petrous apex, with slight expansion.

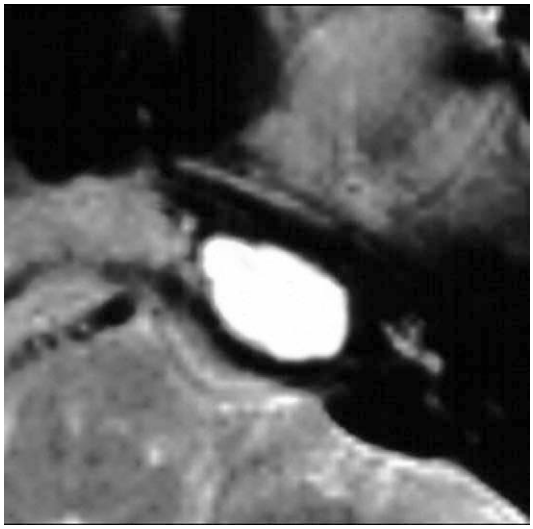

Figure 135-38. Axial magnified T2-weighted image through the same level as the prior image shows correlating bright T2 signal intensity, consistent with a cholesterol granuloma.

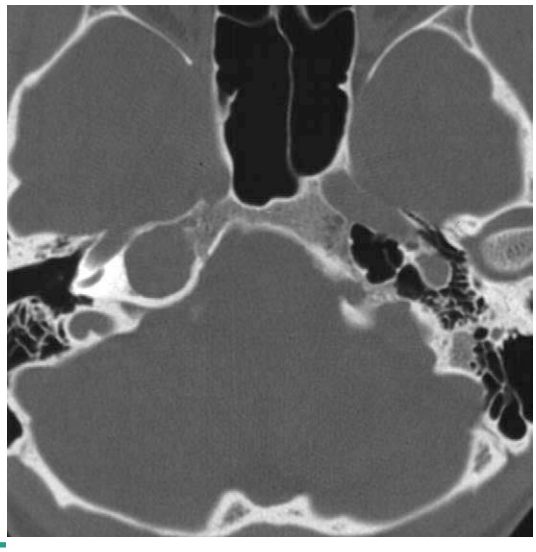

Figure 135-39. Axial bone algorithm CT image through the base of the skull shows benign expansion of a lesion within the right petrous apex, consistent with a cholesterol granuloma.

Figure 135-40. Axial bone algorithm CT image through the base of the skull shows the subtle chondroid calcification matrix at the right petro-occipital suture, consistent with a chondrosarcoma.

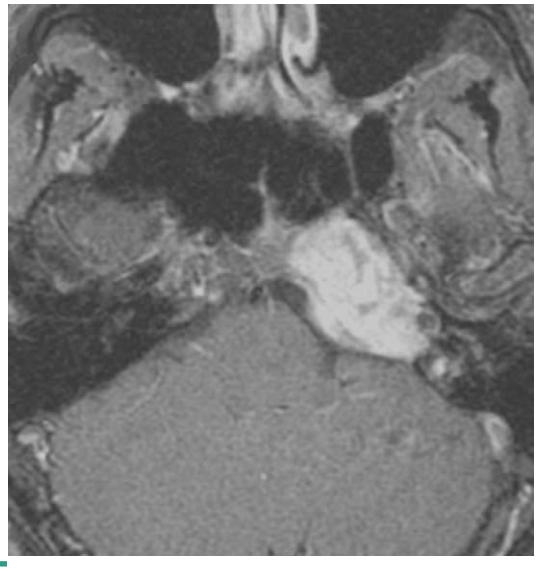

Figure 135-41. Axial T1-weighted postcontrast image through the left petro-occipital suture shows whorls of enhancement, consistent with a chondrosarcoma.

imaging of the facial nerve from the brainstem out to the parotid gland. Malignant parotid tumors may track up the facial nerve and manifest with intratemporal involvement. Intrinsic facial nerve tumors include facial nerve schwannomas and hemangiomas. Facial nerve schwannomas commonly manifest with hearing loss and gradual onset of facial paresis. Imaging in these cases reveals an expansile mass with smooth margins that enhances with contrast medium. T1-weighted MRI shows an isointense lesion in the course of the facial nerve. T2-weighted imaging shows a high signal lesion. T1-weighted imaging with contrast enhancement shows a homogeneously enhancing mass along the course of cranial nerve VII (Fig. 135-43).

The tumor can occur in the IAC, the labyrinthine segment, the geniculate, the tympanic segment, the mastoid segment, and the greater superficial petrosal nerve. Bone windows on HRCT show enlargement of the facial nerve canal in the regions involved, with associated soft tissue mass (Fig. 135-44).[35] Facial nerve hemangiomas frequently manifest with facial nerve paralysis out of proportion to the size of the lesion. These lesions frequently occur at the geniculate ganglion and arise from capillaries around the facial nerve. Typical imaging findings on HRCT are a poorly marginated lesion at the geniculate fossa with "honeycomb" bone within the substance of the tumor (Fig. 135-45). The MRI appearance of a hemangioma shows a mixed signal lesion on T1-weighted imaging with intratumoral low signal corresponding with areas of ossification. T2-weighted imaging shows high signal with areas of low signal, whereas T1-weighted imaging with contrast enhancement shows bright enhancement (Fig. 135-46), and may mimic an acoustic neuroma if the lesion is limited to the fundus of the IAC.[36,37]

Cerebellopontine Angle and Internal Auditory Canal

A common indication for imaging in otology is to rule out retrocochlear pathology. These patients commonly present with unilateral otologic complaints, such as progressive sensorineural hearing loss, sudden sensorineural hearing loss, tinnitus, and occasionally vertigo. The

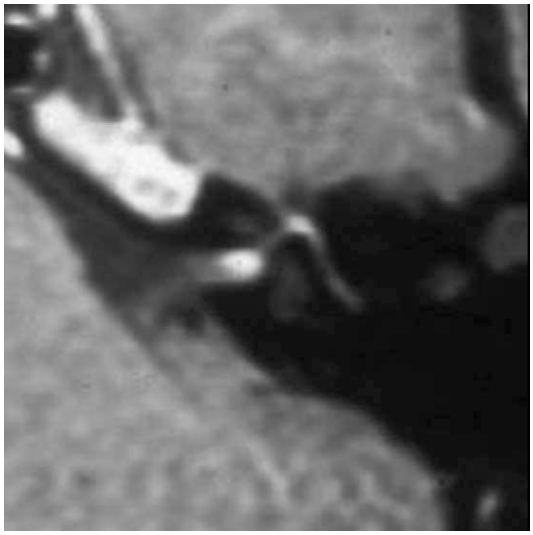

Figure 135-42. Axial T1-weighted postcontrast MR image through the left temporal bone shows abnormal enhancement along the intratemporal course of the facial nerve labyrinthine, geniculate ganglion, and tympanic segments, with a "tuft" of enhancement within the lateral internal auditory canal, consistent with a herpetic, or Bell's, palsy.

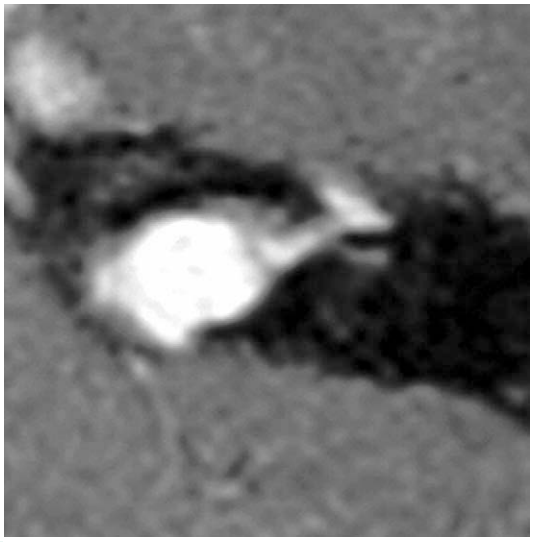

Figure 135-43. Axial magnified postcontrast T1-weighted MR image through the left temporal bone shows avid enhancement within the lateral internal auditory canal, and the labyrinthine segment of the facial nerve, extending into the geniculate ganglion, found to be a facial nerve schwannoma.

evaluation of these patients primarily involves the use of contrast-enhanced MRI. Auditory brainstem response can be a useful clinical adjunct, but it has been shown in the literature that it can miss small intracanalicular lesions.[38] CT scanning is insensitive to the detection of vestibular schwannomas, even when performed with contrast medium.

Contrast-enhanced MRI is the study of choice to detect these lesions, whereas air contrast CT cisternography is reserved for patients who are unable to undergo MRI. Advances in MRI allow the use of screening MRI studies using fast spin-echo (FSE) sequences to acquire submillimeter resolution in the IAC and CPA without the use of contrast material. FSE allows for detection of very small lesions along the seventh and eighth cranial nerve complexes, but misses intra-axial and intratemporal pathology. The cost of these scans approaches that for auditory brainstem response.[39,40]

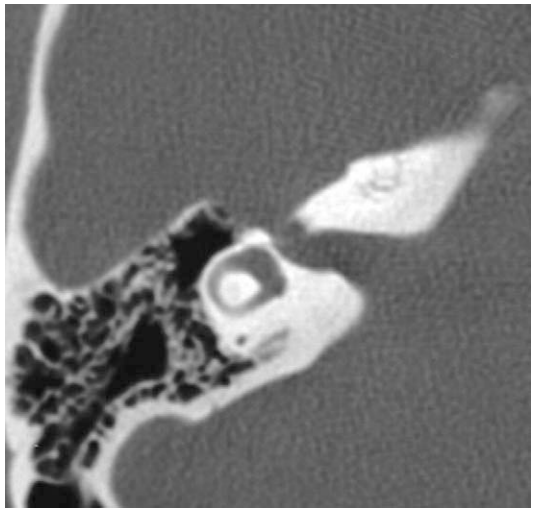

Figure 135-44. Axial CT image of the right temporal bone shows benign enlargement of the labyrinthine segment of the facial nerve from a facial nerve schwannoma.

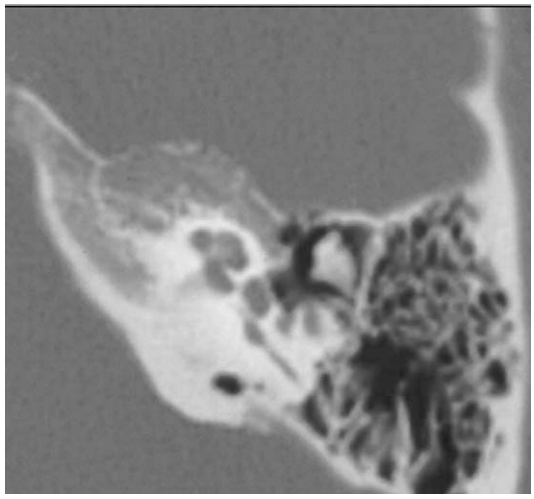

Figure 135-45. Axial magnified CT image through the left temporal bone shows abnormal "honeycombing" osseous changes at the geniculate ganglion, classic for a facial nerve hemangioma.

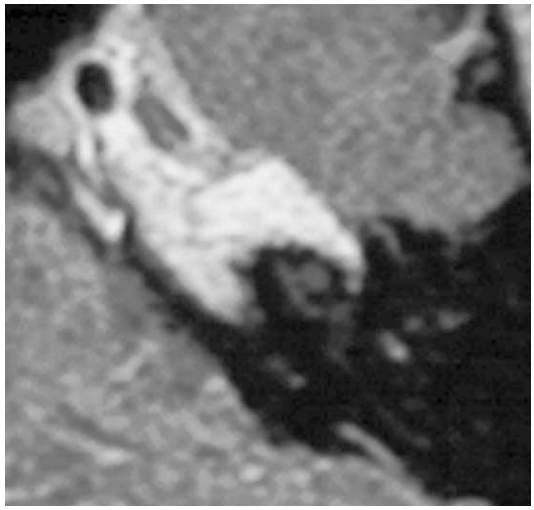

Figure 135-46. Axial magnified postcontrast T1-weighted image through the same level as the prior image shows avid enhancement, classic for a facial nerve hemangioma.

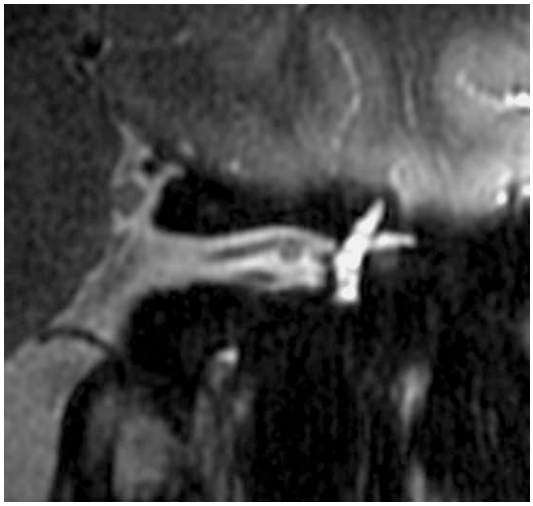

Figure 135-47. Coronal thin-section T2-weighted image through the left internal auditory canal shows a small filling defect within the normally bright cerebrospinal fluid, adjacent to the superior vestibular nerve, consistent with a small vestibular schwannoma.

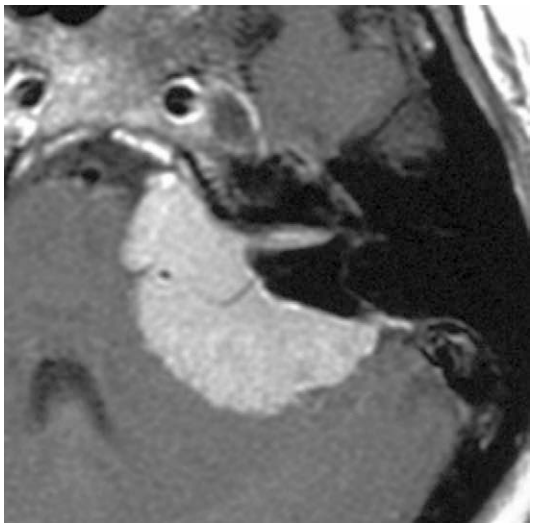

Figure 135-48. Axial postcontrast T1-weighted MR image through the left cerebellopontine angle shows an avidly enhancing lesion with dural tails, consistent with a meningioma.

Vestibular schwannomas are one of the most common extra-axial lesions of the posterior fossa. These lesions enhance avidly with the administration of contrast material on T1-weighted imaging, and are isointense without contrast enhancement. T2-weighted imaging is mildly hyperintense. Vestibular schwannomas may be isolated to the IAC, and high-resolution T2-weighted imaging can show if the tumor originates from the inferior or superior vestibular nerve in small lesions (Fig. 135-47). Larger vestibular schwannomas with extension into the CPA are centered on the IAC, and typically have an IAC component. They typically intersect the dura of the posterior fossa at an acute angle, which can help to differentiate them from meningiomas. Approximately 15% of these tumors have a cystic component.[37]

Meningiomas have a similar appearance to vestibular schwannomas on MRI. These lesions are isointense on T1-weighted imaging, with a variable appearance on T2-weighted imaging. Meningiomas also enhance with administration of contrast material, and have a more "obtuse" relationship to the posterior fossa dura than vestibular schwannomas, with an associated dural tail (Fig. 135-48). The location also helps to differentiate these lesions from vestibular schwannomas because

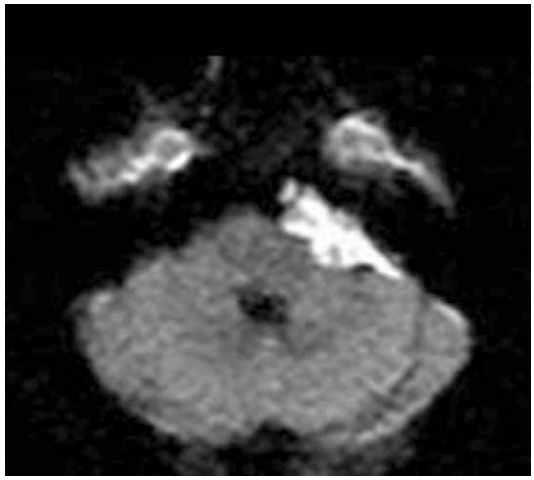

Figure 135-49. Axial diffusion-weighted MR image through the left cerebellopontine angle shows restricted diffusion (bright signal) consistent with an epidermoid tumor.

they tend to arise off center from the IAC, and rarely have an IAC component. These tumors may also have calcification within the lesion, which help to differentiate them from a vestibular schwannoma.[41] Very rarely, meningiomas can arise from the dura of the IAC and can present as an intracanalicular mass.[42]

Facial nerve neuromas may arise in the posterior fossa, and have a very similar appearance to vestibular schwannomas.[43] Occasionally, these can be differentiated from a vestibular schwannoma by identifying tumor extension along the labyrinthine segment of the facial nerve, which is the most sensitive sign of a facial nerve schwannoma. Another imaging characteristic of facial nerve tumors is that the CPA component may be eccentric to the IAC.[44] The involvement of the facial nerve may not be apparent until the time of surgery, however.

Other lesions of the CPA are significantly less common. The MRI characteristics of these lesions aids in their diagnosis (Table 135-2). Epidermoid tumors, which are pathologically identical to cholesteatoma, appear as irregular tumors that are hypointense on T1-weighted MRI and hyperintense on T2-weighted MRI. These lesions do not enhance with the administration of contrast material. Arachnoid cysts have a similar appearance, with hypointense signal on T1-weighted imaging and hyperintense signal on T2-weighted imaging, which follows the signal intensity of cerebrospinal fluid. These lesions do not enhance with contrast material. Arachnoid cysts and epidermoid tumors can be easily differentiated using diffusion-weighted imaging, which shows restricted diffusion when imaging an epidermoid tumor (Fig. 135-49).[45]

Lipomas of the posterior fossa can mimic a schwannoma, and care must be taken to look carefully at the T1-weighted images, which show a hyperintense lesion. Lipomas have an isointense appearance on T2-weighted images. The administration of contrast medium on T1-weighted images does not alter the high signal, and lipomas appear to be "enhancing" if the precontrast images are not taken into consideration. T1-weighted images with fat suppression result in the signal in these lesions being suppressed.[46]

Cochlear Nerve

In the evaluation of children and adults for sensorineural hearing loss, high-resolution MRI is an extremely valuable tool. This imaging modality using FSE sequences can obtain submillimeter resolution of cranial nerves VII and VIII as they traverse the posterior fossa and the IAC. In addition, these images provide excellent detail of the fluid-containing compartments of the cochlea and vestibule. As mentioned previously, this study is an excellent screening modality for vestibular schwannomas.[39]

HRCT has been advocated for evaluation of children with sensorineural hearing loss.[47] HRCT can provide valuable diagnostic

Table 135-2

Imaging Characteristics of Cerebellopontine Angle Lesions

Lesion	T1	T2	T1 + Contrast	Notes
Vestibular schwannoma	Isointense to brain	Slightly hyperintense	Enhances	
Meningioma	Isointense to brain	Hypointense/hyperintense	Enhances	T2 signal depends on calcium content
Arachnoid cyst	Hypointense	Hyperintense	No enhancement	Signal characteristics mirror CSF
Epidermoid	Hypointense	Hyperintense	No enhancement	T2 signal slightly more dense than CSF, DWI does not restrict
Lipoma	Hyperintense	Hypointense	No enhancement	T1 signal disappears with fat suppression

CSF, cerebrospinal fluid; DWI, diffusion-weighted imaging.

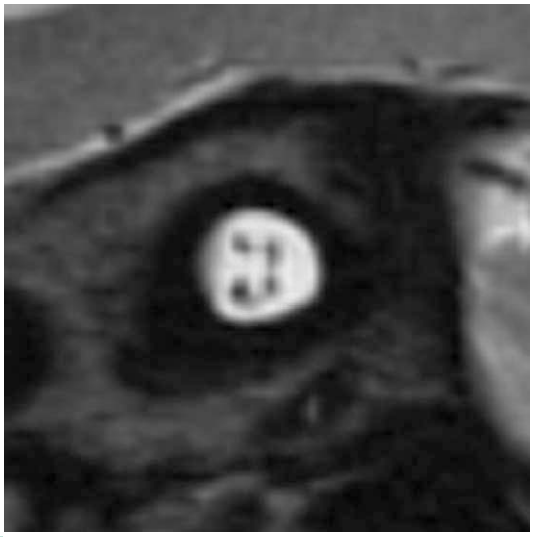

Figure 135-50. Oblique sagittal thin-section T2-weighted MR image through the right internal auditory canal (IAC) shows the normal configuration of the IAC nerves, with the facial nerve superior to the left (anterior), the superior vestibular nerve superior to the left (posterior), the cochlear nerve inferior to the left (anterior), and the inferior vestibular nerve inferior to the right (posterior).

Figure 135-51. Thin-section T2-weighted MR image of the right inner ear shows the normal anatomy of the membranous capsule.

and prognostic information for parents, although it infrequently leads to changes in therapeutic recommendations. The detection of enlarged vestibular aqueduct allows for counseling, however, regarding prognosis and activity modification to avoid head trauma. T2-weighted FSE images may also detect abnormalities in the membranous labyrinth.[48] Older children with suspicion of neurofibromatosis type 2 are best imaged with gadolinium-enhanced MRI.

T2-weighted FSE MRI can also be used for preoperative evaluation of patients for cochlear implantation; oblique sagittal images through the IAC provide excellent detail of the contents of the IAC, allowing visualization of the cochlear, facial, and superior and inferior vestibular nerves (Fig. 135-50), and detection of possible cochlear nerve aplasia. High-resolution T2-weighted imaging has been advocated over HRCT for this reason.[49,50] The detail of the inner ear also allows assessment of the patency of the cochlear duct for implantation (Fig. 135-51).[51] MRI does not provide adequate information, however, about the position of the facial nerve in cases of inner ear malformations, necessitating the addition of HRCT. HRCT can also be valuable in the evaluation of cochlear nerve aplasia if MRI shows two nerves within the canal, but CT shows that there is not a patent cochlear nerve canal entering the cochlea.

Skull Base

Evaluation of patients who present with deficits of lower cranial nerves raises the suspicion of a lateral skull base lesion that involves the jugular foramen, such as a glomus jugulare, meningioma, or schwannoma. Evaluation of these lesions with CT and MRI is diagnostic. Paragangliomas have a characteristic "salt-and-pepper" appearance on T1-weighted MRI, and enhance avidly with contrast medium. T2-weighted imaging shows a hyperintense mass with intervening flow voids ("pepper") (Fig. 135-52). These tumors may extend into the jugular vein and sigmoid sinus, and have a variable involvement of the middle ear and mastoid. Angiography shows a hypervascular tumor that is primarily fed by the external carotid system. HRCT shows erosion of the jugular foramen, with permeative and destructive bony changes, often eroding the jugular spine and involving the vertical segment of the carotid artery (Fig. 135-53).[52]

Jugular foramen meningiomas have unique imaging characteristics that allow them to be differentiated from glomus tumors. The CT

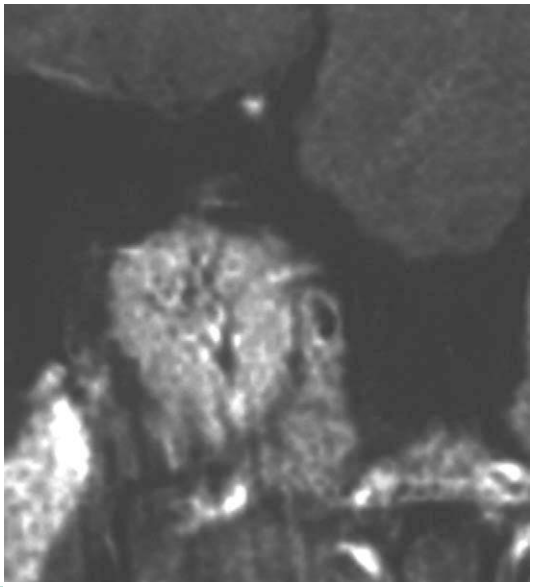

Figure 135-52. Coronal postcontrast T1-weighted MR image through the right jugular foramen shows an avidly enhancing lesion with internal flow voids ("pepper") consistent with a jugular foramen paraganglioma.

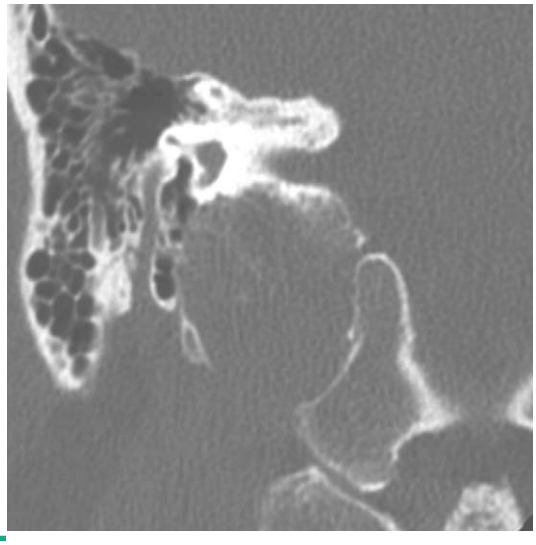

Figure 135-53. Coronal bone algorithm CT image through the same level as the prior image shows correlating permeative changes to the right jugular foramen, consistent with a paraganglioma.

appearance, in particular, shows a more hyperdense mass with intratumoral calcification and a surrounding sclerotic reaction (Fig. 135-54). The T1-weighted MRI appearance shows a hypointense to isointense mass that does not have flow voids. The tumor enhances with contrast medium, with characteristic dural tails. A relative hypointense T2 appearance is very suggestive of meningioma. FLAIR imaging can show adjacent brain hyperintensity reflecting recruitment of pial vasculature.[41] Schwannomas of the jugular foramen show smooth enlargement of the jugular foramen with a thin sclerotic border on CT (Fig. 135-55). Schwannomas are isointense on T1-weighted imaging, are hyperintense on T2-weighted imaging (in contrast to meningiomas), and enhance avidly with the administration of contrast material. There are no flow voids in these lesions, differentiating them from glomus tumors.[53]

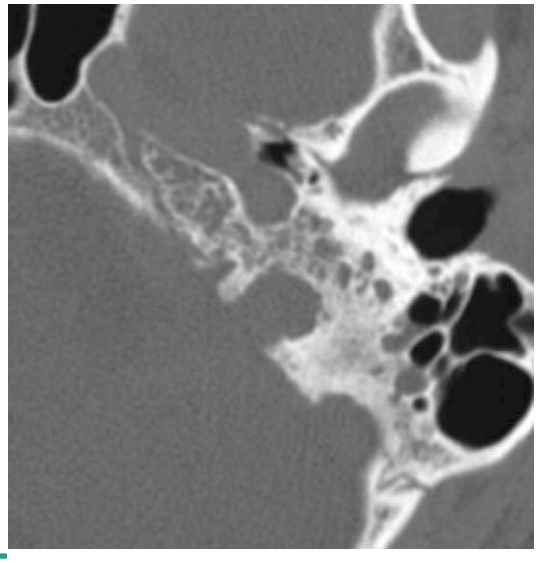

Figure 135-54. Axial bone algorithm CT image through the left jugular foramen shows the subtle osseous sclerotic changes of a left jugular foramen meningioma.

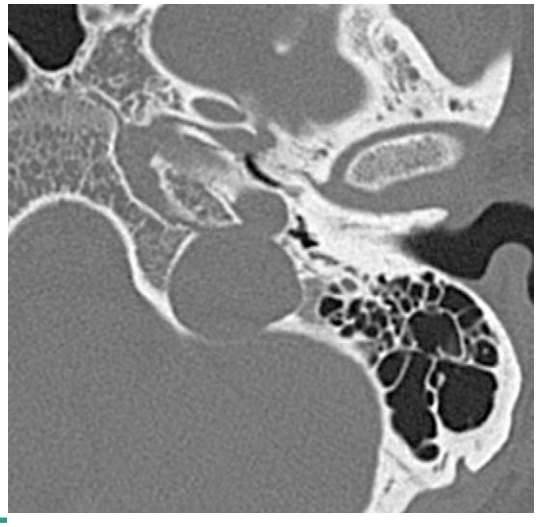

Figure 135-55. Axial bone algorithm CT image of the left temporal bone shows benign scalloped, almost surgical margins of the left jugular foramen from a jugular foramen schwannoma.

CHAPTER ONE HUNDRED AND THIRTY-SIX

Interventional Neuroradiology of the Skull Base, Head, and Neck

Richard E. Latchaw

Sheri L. Albers

Key Points

- Superb equipment to visualize and perform image-guided neurologic interventional procedures is of paramount importance.
- The balloon occlusion test should be accompanied by an imaging procedure to evaluate the effects on cerebral blood flow during carotid occlusion.
- The goal of the interventional procedure must be defined at the outset—presurgical or definitive therapy.
- Preoperative embolization of vascular tumors of the head and neck can be extremely helpful by decreasing the blood loss during surgery.
- Endovascular and image-guided percutaneous techniques can be definitive for epistaxis, arteriovenous malformations, arteriovenous fistulas, pseudoaneurysms, and venous malformations.

Interventional neuroradiologic techniques are essential in the management of certain disorders involving the skull base, face, and neck. These image-guided techniques are used for a variety of purposes, such as to test the potential effects of closing major arteries during surgery for lesions of the skull base, to occlude significant arterial feeders to neoplastic lesions preoperatively, to infuse a chemotherapeutic agent into a metastatic tumor, and to treat a variety of vascular disorders.

Rather than presenting an exhaustive discussion of the management of individual diseases, this chapter introduces the referring clinician to the use of the tools and the basic principles of endovascular and image-guided percutaneous management for lesions of the skull base and the face and neck. This knowledge should not only lead to an appreciation of the sophistication of the interventional techniques, including the capabilities, limitations, outcomes, and possible complications of these procedures, but it also should support the role of an interventionalist when dealing with difficult vascular and neoplastic lesions.

Materials and Techniques

Before performing angiographic or percutaneous therapy, cross-sectional studies such as computed tomography (CT) or magnetic resonance imaging (MRI) are thoroughly analyzed to delineate the precise topography and extension of the lesion and its relationship to nearby structures, including displacements and alterations of blood vessels. It is essential that the goals of an interventional procedure are well defined by the entire therapeutic team to tailor the procedure to the overall treatment of a patient.

Angiographic Equipment

It is essential during endovascular interventional procedures to define the blood supply of a lesion with the highest possible resolution in all projections. Arteries or their collateral channels act as conduits for embolic material to the lesion. Of equal importance is the visualization of the many dangerous collateral vessels leading to the intracranial circulation or to the blood supply of the cranial nerves. Superb visualization and an excellent knowledge of the vascular anatomy are of paramount importance, as is an understanding of the potential clinical symptoms from embolization into an unwanted vascular territory and occlusion of the blood supply to normal tissues.[1]

The anatomic complexity of the neck, skull base, and face makes it essential that sophisticated C-arm positioners be used to allow variable projections of the area of interest. Biplane visualization is helpful for superselective catheterization of the small tortuous channels feeding the lesion. High-resolution techniques, including electronic "road-mapping," are essential. Injection of embolic agents suspended or diluted in contrast material during real-time high-resolution subtracted fluoroscopy (road-mapping) permits visualization of the progressive occlusion of the vessels feeding the lesion. Monitoring the procedure with high-resolution fluoroscopy helps to avoid the complications of reflux of embolic material or flow to collateral branches, thus preserving the blood supply to normal tissues.

Angiographic Catheters

The catheters most commonly used for diagnostic angiography are 4F and 5F polyethylene catheters. Superselective catheterization of tiny arteries feeding tumors, fistulas, and other lesions facilitates the most effective embolization, frequently beyond sites of anastomoses to dangerous collaterals, and is achieved by the use of microcatheters. Wire-directed microcatheters approximately 2F to 3F in size have extremely flexible distal portions that are variable in length. They are used with microguidewires 0.008 to 0.018 inch in diameter. Flow-directed catheters also are used for tortuous vessels feeding high-flow lesions.

If it is impossible to catheterize feeders to a tumor selectively, percutaneous puncture of the hypervascular neoplasm can be per-

formed under image guidance, gaining access to the intratumoral blood supply. Injections of contrast material during digital subtraction angiography are performed to ensure there is no filling of the arterial supply to normal tissues. Injections of the embolic agent are made under low pressure during fluoroscopy with road-mapping or digital subtraction angiography.

Embolic Agents

Several embolic agents are available for the various lesions found at the skull base and in the face and neck. The choice of the embolic material in a given patient depends on the goal of the procedure; the selectivity of the accomplished catheterization; the angioarchitecture and flow dynamics of the lesion; and the proximity of the catheter tip to the blood supply to vital structures such as the brain, cranial nerves, eyes, and skin, or to potential collateral channels to these organs. These embolic agents include particulate materials, metallic coils, liquid agents, and detachable balloons. Each has its own place in the interventionalist's armamentarium.

Two commonly used particulate materials are Gelfoam (Upjohn Pharmaceuticals, Kalamazoo, MI) and polyvinyl alcohol (PVA) (PVA Foam, Cook, Inc., Bloomington, IN; Trufill, Cordis Endovascular Systems, Miami Lakes, FL; Ivalon, Inc., San Diego, CA; Contour Emboli, Boston Scientific/Target Therapeutics, Inc., Fremont, CA).[2,3] Gelfoam breaks down 72 hours after embolization, and this lack of permanence detracts from its efficacy if surgery is not performed within a few days after the procedure. Gelfoam has been used as a preoperative embolization material for neoplasms that are to be operated on within 48 hours, and for patients with epistaxis in whom the goal is to slow the bleeding sufficiently so that the body's normal hemostatic mechanisms stop the hemorrhage. Gelfoam powder always should be used with care because its particles (approximately 50 μm) in solution act as a liquid, easily passing through tiny arteries, which may result in skin necrosis or damage to cranial nerves, or through collateral channels communicating with the intracranial circulation.

PVA is more permanent than Gelfoam, but much of the efficacy of the vascular occlusion is a result of a combination of PVA plus intravascular thrombus. The stellate-shaped particles slow the intravascular flow, and thrombus forms.[2-4] This thrombus may be metabolized before fibrosis occurs, however, resulting in partial or complete recanalization over weeks to months. PVA is easy to use, being supplied as uniform particles within a narrow range of size (150 to 1250 μm). In most patients with neoplasms, the smallest size (150 μm) is used because the particles can be easily injected through a small microcatheter placed selectively into tiny feeding arteries and penetrate into the tumoral vascular bed.

Because of the stellate shape of PVA particles, they do not form a tightly packed embolic mass, allowing recanalization as the interspersed thrombus undergoes lysis. Various types of beads and spheres have been produced to overcome that limitation, such as Embosphere Clear (Biosphere Medical, Inc., Rockland, MA). Their more uniform size and spherical geometry theoretically produce more complete and more permanent vascular occlusion. Similar spheres might also be filled with a chemotherapeutic or other agent for more prolonged treatment of a nonsurgical neoplasm. Microfibrillary collagen (Avitene; Avicon, Inc., Fort Worth, TX) is a hemostatic agent that may be mixed with contrast material for embolization[5] or mixed with other embolic agents such as PVA and ethanol.[6]

There are two broad categories of metallic coils: coils that are pushed from a catheter with a metal coil pusher or guidewire, and coils that are released by breaking a bond between the coil and the pushing wire. The latter is the type used for treating intracranial aneurysms. In head and neck lesions, metallic coils are used for occluding vessels that measure a few millimeters to 1 cm or more in diameter. Their size prohibits their moving more distally into the embolized lesion. They are best used for occluding the feeding artery after particulate embolization; the particles are embolized deeply into the lesion, with the coil producing the final occlusion of the feeding artery. Coils have been used to occlude bleeding vessels, such as in epistaxis or after trauma.

Detachable balloons with a valve mechanism to keep the balloon inflated are currently unavailable in the United States, but should be available again in late 2009. They are used primarily for fistulas with a single artery-to-vein connection. Most experience was with intracranial post-traumatic carotid-cavernous sinus fistulas, but this technique was also used for vertebral artery–vertebral venous fistulas (usually post-traumatic) or for any other type of fistula in the face or neck.[7-9] They were also used for occlusion of a parent artery leading to an unclippable aneurysm, a dissected carotid or vertebral artery producing embolization into intracranial vessels, or a carotid artery to be sacrificed at tumor surgery. Electrolytically detachable coils are used now instead of the currently unavailable detachable balloons. Many coils are usually necessary, however, to do what one balloon could accomplish, increasing the complexity and expense of the procedure.

There are numerous liquid embolic agents, the most commonly used being absolute alcohol (100% ethanol) and various tissue adhesives, including the cyanoacrylates and Onyx (MicroTherapeutics, Inc., Irvine, CA). Absolute ethanol is extremely toxic to the endothelium,[10] and is highly effective at producing sclerosis of vascular lesions, such as venous and lymphatic malformations.[11-13] Although it has also been used to treat arteriovenous malformations and dural arteriovenous fistulas, the problem with these fast-flowing lesions is the need to increase the "dwell time" of the ethanol to interact with the intima, often requiring temporary balloon occlusion more proximally. It has also been used for tumors, via endovascular and percutaneous access, particularly recurrent tumors that are surgically inaccessible.

The injection of ethanol is extremely painful, requiring deep sedation or, more commonly, general anesthesia. It is necessary to see where the embolic agent is going, and so opacification is necessary. Opacification of the ethanol with a liquid contrast agent produces dilution of the ethanol, however, decreasing its effectiveness, which is maximum if used undiluted. Metrizamide powder (Nycomed, Oslo, Norway) was used previously for opacification because a powder does not dilute the ethanol, but provides acceptable opacification. Metrizamide powder is no longer available in the United States, however.

Sodium tetradecyl sulfate (Sotradecol) 3% also is an excellent sclerosing agent, is less painful on injection than ethanol, and may be opacified, although it seems to be less effective than ethanol for venous malformations, and is not considered to be an acceptable alternative. Doxycycline, a tetracycline-like antibiotic, is an effective agent at producing sclerosis of venous, lymphatic, and other slow-flow vascular malformations in which there is an adequate "dwell time." Tetracycline has been associated with darkening of the tooth enamel in young children, so this drug is usually reserved for patients older than 11 years, after the formation of the permanent teeth. Povidone-iodine (Betadine) can also be injected into lymphatic malformations, with less pain than with alcohol and with good success.

Cyanoacrylates such as isobutyl-2-cyanoacrylate (IBCA) or *N*-butyl-2-cyanoacrylate (NBCA) produce polymerization of rapidly flowing blood within seconds. They not only produce immediate thrombosis and have tissue adhesive properties, but they also initiate a giant cell inflammatory reaction of the vessel wall.[14] These embolic liquids are excellent for lesions with rapidly flowing blood, such as an arteriovenous malformation or an arteriovenous fistula. Neoplasms have slow flow, so there is no need to use these agents, which are associated with more risk than particulate materials injected intra-arterially or other agents injected percutaneously.

The newest "liquid" agent is Onyx, which is an ethylene vinyl alcohol copolymer containing dimethyl sulfoxide as the agent facilitating absorption through endothelial barriers.[15] This tissue adhesive is a needed new addition to the armamentarium of the neurointerventionalist because it slowly permeates into tiny vessels feeding a vascular lesion, "creeping" into these feeders during fluoroscopic visualization and control, without the rapid setup time of the cyanoacrylates.[15,16]

Any embolization procedure with a liquid agent should be approached with trepidation because occlusion of the end-arteries to the face, tongue, and cranial nerves may lead to necrosis, and intracranial embolization may occur as the liquid passes through tiny collateral channels to vessels feeding normal structures. Liquid embolization should be performed only when superselective catheterization can be done directly into the direct feeders to the lesion, or with percutaneous puncture of the lesion and direct visualization of the flow of

the agent,[17] to prevent unwanted extension to the blood supply of vital structures.

Provocative Testing to Ensure the Safety of Embolization

Two important techniques help to ensure the safety of vascular occlusion at the skull base. The first involves the injection of lidocaine (Xylocaine) 1% without preservatives into an arterial feeder that is considered a candidate for embolization, to predict the potential of permanent cranial nerve palsy from the embolization procedure.[18] This provocative test anesthetizes the cranial nerve if there is blood supply leading to it from the vessel catheterized. Critics of this test suggest that a false-positive test may occur because a liquid anesthetic can be injected into the capillary bed, whereas particles used for embolization stop short of terminal arterioles so that devascularization is rare. It is likely that a negative test result is truly negative and reassuring.

The second provocative test is the temporary balloon occlusion test (BOT) of the internal carotid or vertebral artery, with the addition of blood flow measurement for precise quantification of the potential effects on cerebral blood flow during temporary or permanent occlusion of the artery during surgery or endovascular therapy. Carotid or vertebral artery occlusion might be necessary during the surgical removal of a skull base tumor, during the temporary occlusion of a major intracranial artery during surgical clipping of an aneurysm, for the thrombosis of an unclippable aneurysm via occlusion of the parent artery, or if carotid occlusion has to be performed to close a carotid-cavernous sinus fistula or any other type of traumatic vascular lesion.

First, a complete angiographic evaluation of all cerebral vessels is performed to evaluate their contribution to the particular lesion and the adequacy of collateral flow via the anterior and posterior communicating arteries. If communicating arteries are present, the traditional BOT is performed, consisting of occlusion of the internal carotid artery (ICA) with a nondetachable balloon catheter placed at the level of the future permanent occlusion. After systemic heparinization, the balloon is inflated, and the patient is evaluated for 30 minutes. Careful neurologic examinations are performed throughout the occlusion period, with special emphasis on the neurologic functions subserved by the vessel that is being tested. If the patient develops a neurologic deficit, the balloon is immediately deflated. If the patient has no neurologic deficit from the carotid occlusion, it is assumed that blood flow is adequate for permanent occlusion to occur. Such a qualitative test does not provide precise quantification of the blood flow to the hemisphere at risk, however. Blood flow values greater than 20 to 25 mL/100 g of tissue per minute allow normal neuronal function, with values less than that precipitating neuronal dysfunction. It is conceivable that blood flow values slightly greater than 20 to 25 mL/100 g/min would leave the patient without symptoms while on the angiography table, but superimposed intraoperative or postoperative hypotension, decreased cardiac output, or decreased oxygenation might precipitate cerebral infarction.

Different methods have been used during temporary occlusion to evaluate the physiologic effects of the BOT on cerebral blood flow to predict the risk of cerebral infarction after definitive occlusion. These methods include electric studies such as evoked potentials or electroencephalography,[19] measurements of arterial stump pressures distal to the site of temporary occlusion,[20] induced hypotensive challenges, and transcranial Doppler studies. Also, several cerebral blood flow imaging methods, including xenon-enhanced CT (Fig. 136-1),[21] single photon emission computed tomography (SPECT), positron emission tomography, and MRI and CT perfusion studies, have been used to evaluate cerebral blood flow during BOT to determine the potential risk of ischemia after permanent occlusion.[22,23] We prefer to use SPECT because it adds little to the basic BOT and easily provides the needed information. After the balloon has been inflated for a short time, the radionuclide is injected intravenously, and the patient is scanned a few hours after the completion of the angiographic study (the radiopharmaceutical "sticks" to the brain tissue during its initial circulation in proportion to the blood flow to that tissue).

Nevertheless, these techniques have turned out to be imperfect predictors of the ischemic risk associated with permanent carotid occlusion. Clinical deficits have been reported after permanent occlusion, even when there has been a negative BOT with accompanying normal physiologic or cerebral blood flow studies. Many, if not most, of these postocclusion deficits probably are a result of marginal cerebral perfusion accompanied by hypotension or decreased cardiac output, clot propagation from the residual stump, or de novo emboli at the time of vascular occlusion.

Endovascular Treatment of Neoplasms

Paragangliomas

Paragangliomas, also known as *chemodectomas* or *glomus tumors,* are neoplasms related to chemoreceptor tissue. They usually are benign, but locally invasive and highly vascularized. Most glomus tumors originate within the temporal bone (48%), including lesions along the promontory of the middle ear (glomus tympanicum tumors) and lesions related to chemoreceptor tissue in the jugular bulb (glomus jugulare tumors). Tumors related to the vagus body (11%) in the high cervical region are called *glomus vagale tumors,* and tumors related to

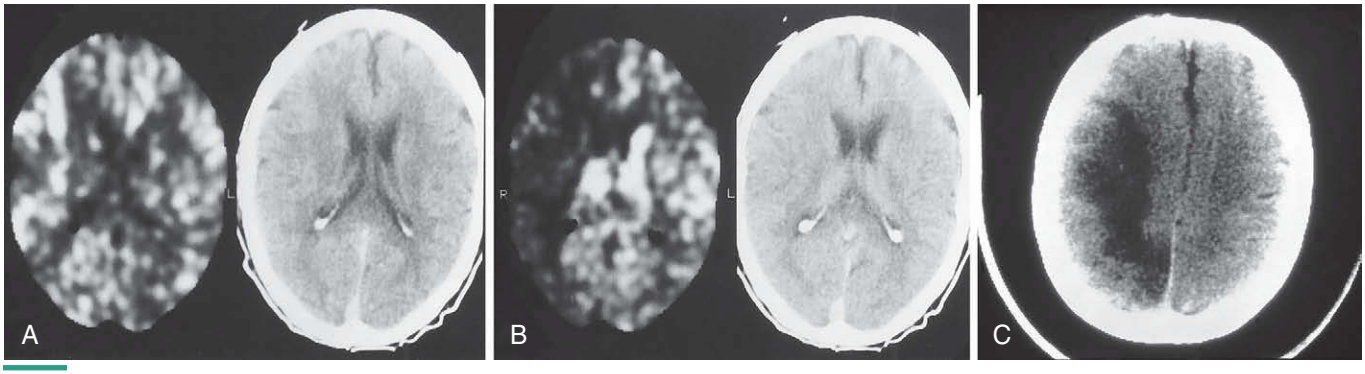

Figure 136-1. Xenon-enhanced CT during balloon test occlusion. This 60-year-old patient with squamous cell carcinoma invading the skull base was to undergo skull base resection and probable permanent carotid occlusion. A Swan-Ganz catheter was placed in the right internal carotid artery. Temporary blockage of the internal carotid flow for 15 minutes did not produce neurologic deficit. **A,** Xenon-enhanced CT scan for the production of a blood flow map *(left)* at the midventricular level *(right)* during balloon deflation reveals symmetric flows to the middle cerebral artery distributions bilaterally. **B,** With the balloon inflated, there is a marked reduction in the blood flow to the right middle cerebral distribution *(left)* relative to the left middle cerebral distribution. Flows to the right middle cerebral distribution are approximately 22 mL/100 g/min. This case was early in the authors' experience, and a bypass procedure was not performed after permanent carotid occlusion during the skull base tumor resection. **C,** Postoperatively, the patient became mildly hypotensive, resulting in infarction in the distribution predicted by the temporary carotid occlusion blood flow test.

the carotid body (35%) at the common carotid artery bifurcation in the neck are called *carotid body tumors*. Multiple tumors are found in approximately 10% of patients (Fig. 136-2), and a familial form exists.[24]

Glomus Tympanicum Tumor

The glomus tympanicum is a tiny tumor that usually manifests with pulsatile tinnitus and otoscopically is seen as a reddish blue mass behind the tympanic membrane. CT scanning allows the differentiation of this small tumor from an extension into the middle ear cavity of a larger glomus jugulare tumor. It also is necessary to exclude an aberrant ICA. In the former, the bony plate between the jugular foramen and the middle ear is destroyed, whereas in the latter, the posterior bony margin of the carotid canal is missing.[25] This tumor is usually small enough for surgery to be performed without embolization.

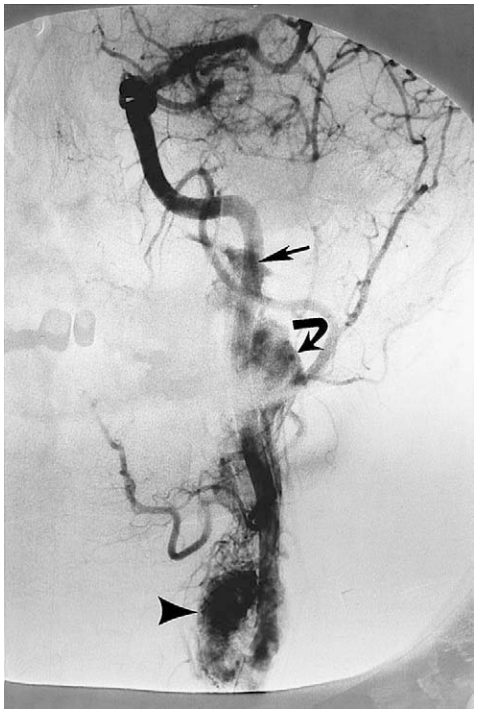

Figure 136-2. Multiple chemodectomas. This 38-year-old woman was one of many members of a family with chemodectomas. There is a small glomus jugulare tumor *(straight arrow)*, a glomus vagale tumor *(curved arrow)*, and extension of tumor along the carotid sheath to end in a carotid body tumor *(arrowhead)*.

Glomus Jugulare Tumor

A patient with a glomus jugulare tumor usually presents with dysfunction of cranial nerves IX, X, or XI, and XII if the tumor is large. Pulsatile tinnitus also is common. Contrast-enhanced CT or MRI usually is the first diagnostic test performed, with the diagnosis generally made and the extension of the tumor shown. The tumor begins in the region of the jugular foramen and may extend inferiorly into the upper neck, superolaterally into the middle ear by destroying bone, posteromedially and posterolaterally into the posterior fossa, and anteriorly to envelop the petrous ICA. Bone destruction can be extensive, simulating a malignant tumor, as the chemodectoma spreads through the skull base. Destruction around the foramen magnum may occur, with compression of the brainstem.[26]

The tumor is fed by multiple external carotid artery (ECA) branches, with each of these arteries feeding a specific compartment of tumor. The ascending pharyngeal (bilaterally at times) and middle meningeal (posterior division) arteries are the most commonly involved, with the stylomastoid branch of the occipital and the posterior auricular arteries providing supply less frequently (Fig. 136-3). If the tumor extends posteriorly around the foramen magnum, supply may be from the anterior and posterior meningeal branches of the vertebral artery. Intradural tumor within the posterior fossa may be fed from the anterior and posterior inferior cerebellar arteries. Tumor surrounding the high cervical or petrous portions of an ICA may parasitize tiny branches of these segments (see Fig. 136-3).[27-29]

The glomus jugulare tumor is highly vascular, which makes surgery difficult in this confined bony area. Embolization may be of great help.[30] Because the diagnosis generally has been made on the basis of CT or MRI before angiography, the patient is prepared with consent forms for angiography and embolization in the same sitting. The arterial feeders are mapped with high-resolution digital subtraction angiography in multiple planes, as previously described (Fig. 136-4). Selective catheterization of the multiple feeders is

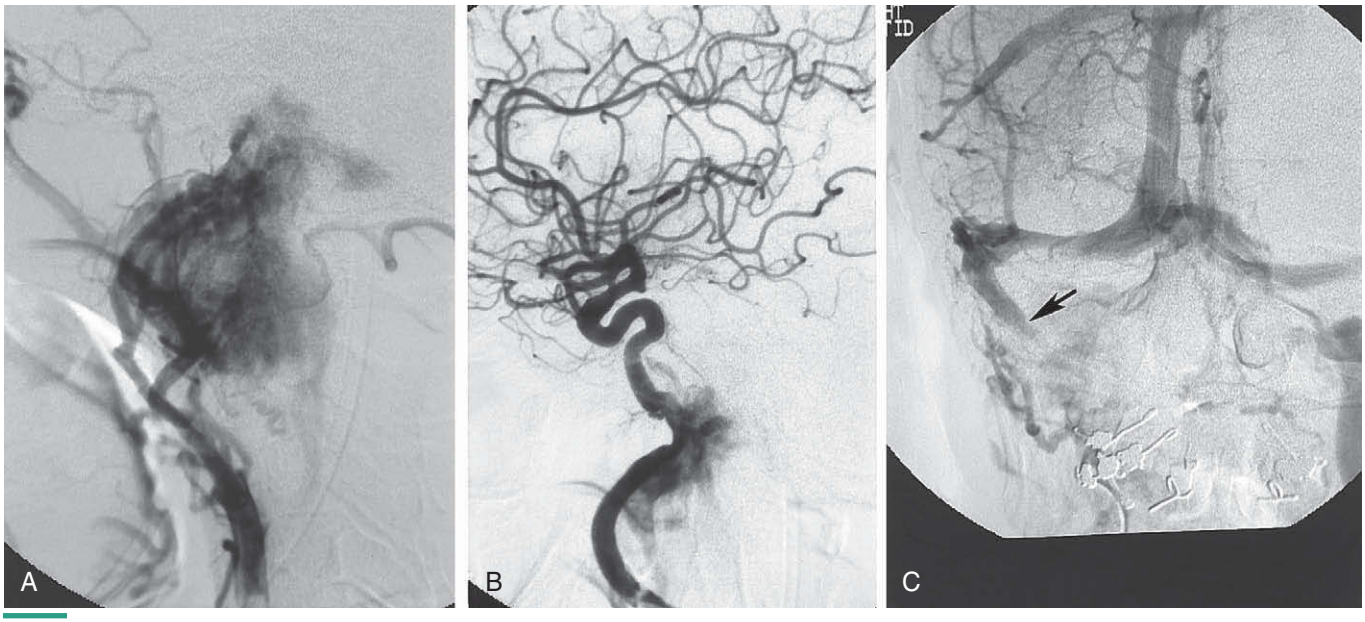

Figure 136-3. Glomus jugulare/vagale tumor. **A** and **B,** Cerebral angiography shows multiple enlarged external carotid branches providing most of the blood supply to this tumor **(A)**, although there is parasitization of the vasa vasora of the high cervical internal carotid artery **(B)** by the circumferential tumor. **C,** There is complete occlusion of the distal sigmoid sinus *(arrow)* and nonopacification of the jugular bulb and vein.

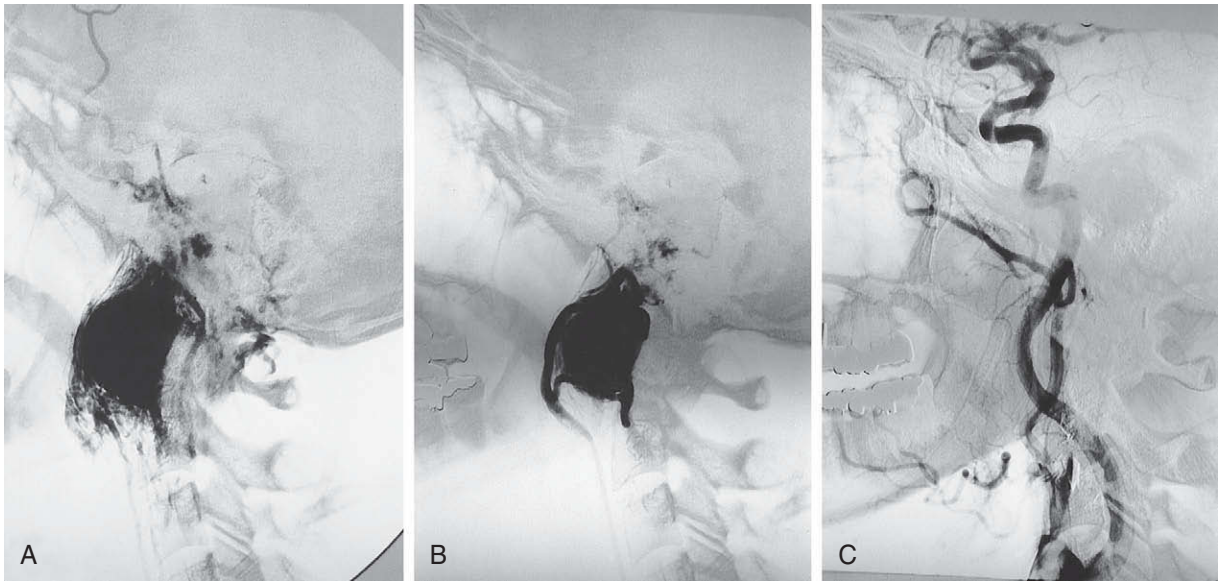

Figure 136-4. Embolization of a glomus jugulare/vagale tumor. **A,** Global external carotid artery injection shows a large homogeneously hypervascular mass lesion within the confines of the petrous bone, extending anteriorly in the region of the carotid canal, and extracranially in the high neck, a position typical for a glomus vagale tumor. **B,** Selective injection of the ascending pharyngeal artery shows filling of most of the tumor from this source. Embolization of this and other branches was performed with polyvinyl alcohol particles measuring 150 to 300 mm. **C,** Common carotid artery injection after embolization shows lack of visualization of the hypervascular lesion, but anterior displacement of the high cervical internal carotid artery typical for the vagale portion of the tumor.

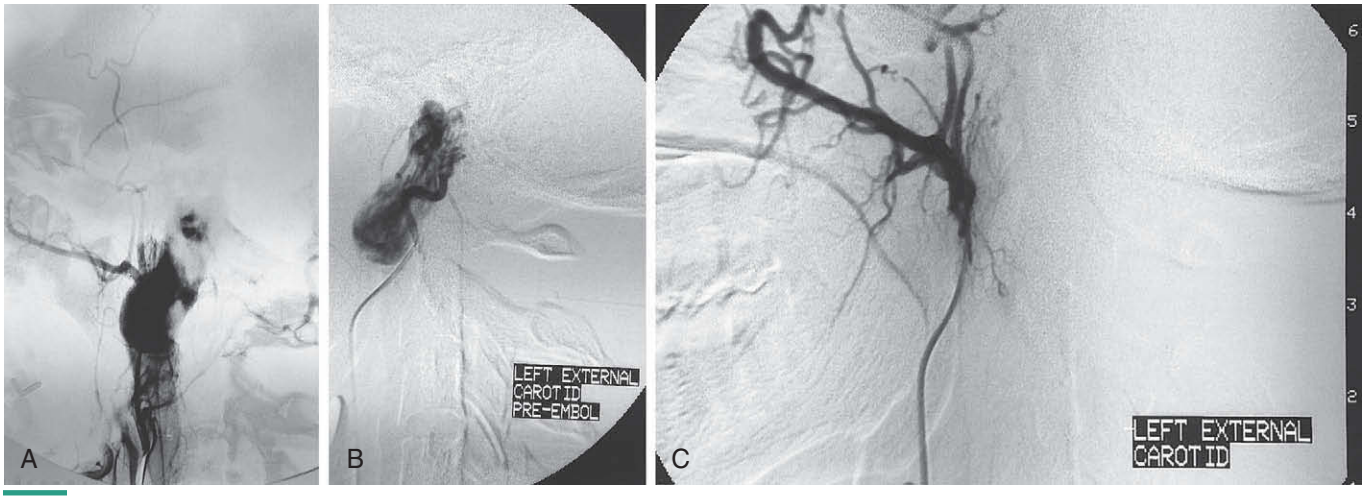

Figure 136-5. Embolization of glomus vagale tumor. Most of this tumor was below the skull base, typical of a glomus vagale tumor, although a small component extended superiorly in the region of the jugular bulb. **A,** Global external carotid artery injection showed the homogeneous hypervascular mass. **B,** Selective injection was made into one branch of an enlarged ascending pharyngeal artery, showing that most of the tumor below the skull base was filled from this vessel. Other branches of the ascending pharyngeal artery were primarily responsible for the intracranial component. All these tributaries were embolized with polyvinyl alcohol particles measuring 150 to 300 mm. **C,** Postembolization global left external carotid injection failed to show the hypervascular mass.

performed, followed by embolization of particulate material, most commonly PVA of small size (e.g., 150 μm) (see Fig. 136-4). Before injecting external carotid branches that may supply cranial nerve VII, particularly the stylomastoid artery, 1% lidocaine is injected as a provocative test to ensure that the cranial nerve is not devascularized during the embolization procedure, as previously discussed.[18]

Glomus Vagale Tumor

The glomus vagale tumor originates from the vagus body high in the neck at the C1-2 level. The tumor may extend superiorly so that differentiation from a glomus jugulare tumor is difficult and may be moot. The typical appearance is that of anterior displacement of the high cervical ICA. Blood supply is from multiple branches of the ECA, particularly the ascending pharyngeal artery. The arterial supply is mapped as for the glomus jugulare tumor, although there generally are fewer sources of supply (Fig. 136-5). Potential supply from ascending and deep cervical branches of the thyrocervical and costocervical trunks and of neuromuscular branches from the ipsilateral vertebral artery also should be evaluated. The feeding vessels are catheterized and embolized to the point of fluoroscopic devascularization, particularly with tiny PVA particles (see Fig. 136-5). The lidocaine provocative test is used

if there is any question regarding potential cranial nerve insult during the procedure.

Carotid Body Tumor

A carotid body tumor is a highly vascular mass occurring in the crotch between the origins of the internal and external carotid arteries, splaying them apart. There are commonly many tiny feeders from the distal common carotid and proximal internal carotid arteries that are too small to be catheterized selectively to the degree necessary to avoid reflux of particles into the ICA, although there usually are major feeders from the ECA, particularly the ascending pharyngeal, superior thyroidal, lingual, facial, and carotid body arteries (Fig. 136-6). These can be selectively catheterized, and much of the tumor may be appropriately embolized with tiny PVA particles to make surgery easier with less blood loss (see Fig. 136-6). Some surgeons do not want preoperative embolization, believing that a potential secondary inflammatory reaction from embolization makes it more difficult to define tumor planes for removal.[31]

Juvenile Angiofibroma

The usual history of angiofibroma is that of recurrent epistaxis and nasal obstruction in an adolescent boy. The tumor has a typical location adjacent to the nasal choana and within the nasopharynx and pterygopalatine fossa. The tumor may extend anteriorly through the nasal cavity or superiorly into the sphenoid sinus. Occasionally, it extends into the subtemporal fossa. Bone destruction of the lateral wall of the sphenoid sinus or of the anterior temporal fossa allows it to enter the intracranial cavity.

Typically, blood supply is from the ascending pharyngeal artery (which may be bilateral and may require common carotid rather than

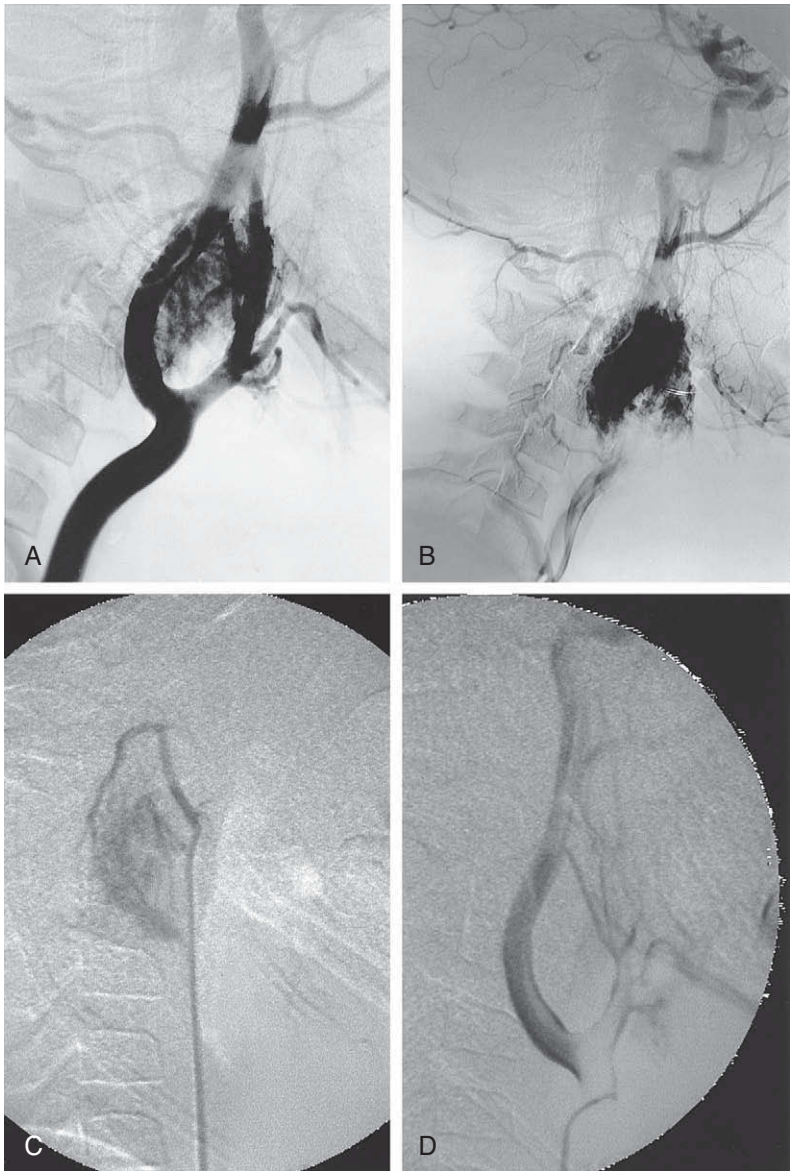

Figure 136-6. Embolization of carotid body tumor. This 8-year-old child had MRI evidence of a carotid body tumor. No other family members were known to have a chemodectoma. **A,** Common carotid artery injection showed the classic separation of the internal and external carotid trunks because of the hypervascular mass between them. There were multiple twigs from the internal and external carotid arteries supplying this tumor. **B,** No other chemodectomas at or above the skull base were shown. **C,** Selective catheterization of the artery to the carotid body during online digital fluoroscopy showed a large blood supply to the tumor from this vessel, which was subsequently embolized with polyvinyl alcohol particles measuring 150 to 300 mm. Two other smaller branches of the external carotid artery were also embolized. **D,** After embolization, a common carotid artery injection during digital subtraction fluoroscopy failed to show the hypervascular mass.

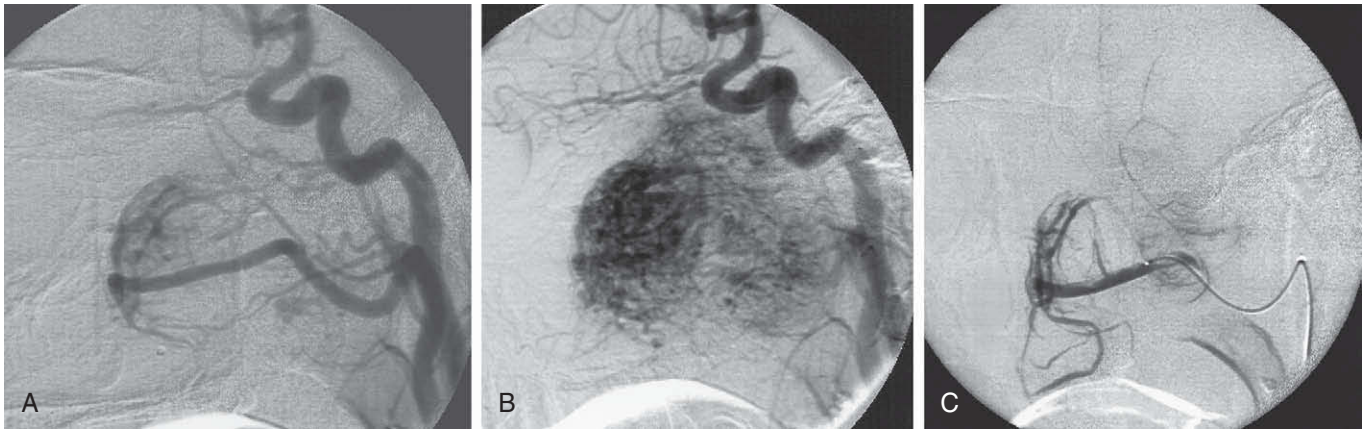

Figure 136-7. Embolization of angiofibroma of the nasopharynx. This 15-year-old boy was seen with nasal bleeding. **A** and **B,** Common carotid artery injection **(A)** showed the classic appearance of an angiofibroma of the nasopharynx, fed primarily by the internal maxillary artery, with a dramatic degree of vascularity of the tumor **(B)**. Catheterization of the internal maxillary artery was performed beyond the middle meningeal and accessory meningeal arteries, for embolization with polyvinyl alcohol particles, initially by use of 150 μm for the tiniest peripheral tumor branches, followed by 300 to 500 μm for the larger feeders. **C,** Embolization resulted in a dramatic decrease in vascularity of the tumor on follow-up angiography.

ECA injections to visualize because of the possible origin of this vessel near the common carotid bifurcation), and the internal maxillary artery and its branches, particularly the ascending and descending palatine arteries (Fig. 136-7). Tumor may remain extracranial and receive supply from collaterals of the petrous and cavernous segments of the ICA.[32-34] Intracranial extension may be supplied from the middle meningeal and accessory meningeal branches of the internal maxillary artery, and from branches of the petrous and cavernous internal carotid arteries. Because the middle meningeal, accessory meningeal, and foramen rotundum arteries supply cranial nerves within the cavernous sinuses,[33] it is preferable to catheterize the internal maxillary artery beyond the origin of the accessory meningeal artery for particulate material embolization (150 μm) of tumors that are purely extracranial (see Fig. 136-7). Supply from the middle meningeal and accessory meningeal arteries should be embolized with care, usually preceded by a lidocaine test. Other arteries are catheterized and embolized as necessary. Such embolization usually dramatically decreases the blood loss at the time of surgery.[32-35]

Meningiomas

Meningiomas are the most common intracranial nonglial tumors, accounting for approximately 20% of all primary intracranial tumors. They originate from the arachnoid, occur most often in patients 30 to 69 years old, and predominate in women. Their most common locations are over the cerebral convexities and in the parasagittal and parafalcine regions (50%), but meningiomas originating from various sites along the skull base and tentorium account for at least 40% of the cases.

Meningiomas derive their primary blood supply from arteries supplying the meninges. External carotid branches, such as the middle meningeal and ascending pharyngeal arteries, play a significant role in this supply, but dural branches of the intracranial carotid, ophthalmic, and vertebral arteries also are significant. As meningiomas grow, they may parasitize pial branches of the cerebral circulation.

Whether to embolize a meningioma in a given location depends on the risk-to-benefit ratio of the intervention and the ability to catheterize the appropriate blood supply selectively.[36,37] Frontobasal meningiomas involve the orbital roof, the olfactory groove, and the planum sphenoidale. Their blood supply is primarily from ethmoidal branches of the ophthalmic arteries. Because of the potential risk to vision, selective catheterization of an ophthalmic artery and subsequent embolization usually is not performed. Sphenoid wing and middle cranial fossa tumors may derive significant blood supply from the middle meningeal artery. If so, selective embolization of the middle meningeal artery, taking care to place the microcatheter above the origins of the branches supplying the cranial nerves, may be a valuable preoperative intervention, especially because the location of this tumor may make control of the blood supply difficult at surgery.

Cavernous sinus meningiomas have various potential sources of blood supply from branches supplying the dura in this region. The inferolateral trunk from the C4 portion of the ICA frequently represents a major supply to meningiomas in this region, and, if enlarged, may be selectively catheterized with a microcatheter. If catheterization is impossible, a nondetachable balloon may be placed in the ICA above the origins of the dural branches, and embolization with tiny particles performed.[38,39] Other sources of blood supply include the accessory meningeal and the middle meningeal arteries. Both of these latter vessels provide blood supply to the cranial nerves, so there is the potential of cranial nerve injury if these vessels are embolized. Provocative testing with the use of 1% lidocaine can be performed, and catheterization beyond the origins of the cranial nerve blood supply.

If a microcatheter with an inner diameter of 0.014 inch is used, 150-μm particles can be used to penetrate the meningioma; these particles usually are too large to penetrate the vessels supplying the cranial nerves. Gelfoam powder with particles of 40 to 60 μm behaves more like a liquid, and has a greater potential of producing cranial nerve palsies and passing through dangerous anastomoses. True liquids, such as cyanoacrylates and ethanol, carry too high a risk for cranial nerve injury or passage into anastomotic channels to be used as a preoperative agent. Occasionally, for patients with recurrent, nonoperative tumors requiring shrinkage for palliation of mass effect, absolute ethanol can be used, acknowledging the higher risk of cranial nerve injury (Fig. 136-8). Meningiomas in this region may infiltrate the ICA or middle cerebral artery. If en bloc resection of the tumor, including the ICA, is contemplated, preoperative occlusion of the ICA with a detachable balloon may be performed.[39]

Posterior fossa meningiomas include lesions in the clival, petroclival, and paraclival regions, and lesions involving the petrous bone, cerebellopontine angle, jugular foramen, and foramen magnum. The dural blood supply depends on their location, and these tumors may be embolized in the same manner as described for supratentorial tumors.

Other Neoplasms

Hypervascular solid masses involving the face and neck, other than those previously discussed, are uncommon. Occasionally, a hypervascular thyroid tumor receiving its blood supply from the superior and inferior thyroidal arteries is amenable to embolization. The inferior thyroidal artery is a branch of the thyrocervical trunk, and the superior thyroidal artery usually is the first branch of the external

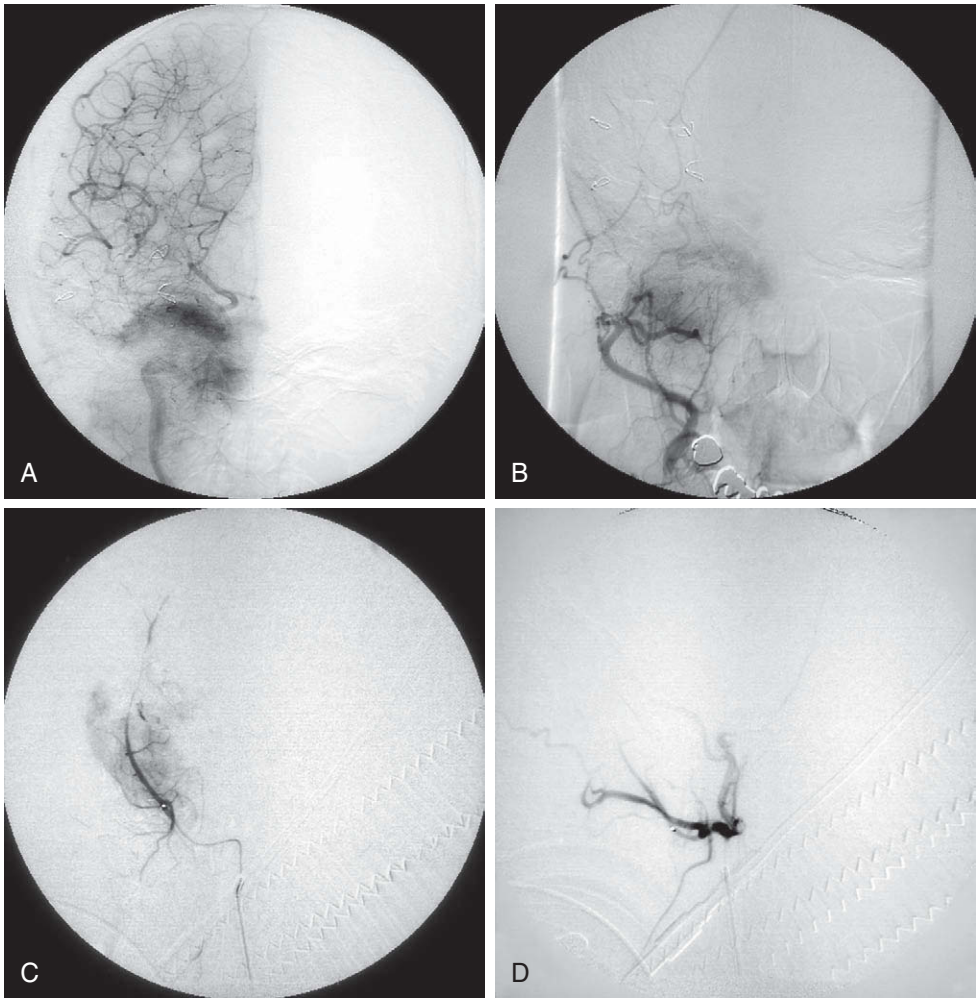

Figure 136-8. Embolization of a recurrent intracranial meningioma with alcohol. A 65-year-old woman had recurrence of a meningioma around the right middle cerebral artery. **A,** Right internal carotid artery angiography showed the "stain" of the meningioma wrapping around the middle cerebral artery and deriving blood supply from tiny feeders from that vessel. **B,** Right external carotid artery study showed a significant supply from the right middle meningeal artery. **C,** Selective catheterization of the right middle meningeal artery was performed, and angiography revealed its selective supply. **D,** To stop the tumor from occluding the middle cerebral artery, it was elected to perform embolization of the tumor. Small amounts of absolute alcohol were slowly infused into the tumor, which produced occlusion of the tiny feeding branches over a 15-minute period. An alternative therapy might have been gamma knife irradiation to stop the tumor growth.

carotid; both generally are easy to catheterize. Selective lingual or facial angiography and injections into the thyrocervical and costocervical trunks should be done to evaluate tumor extension or other sources of blood supply. Embolization usually is performed with particulate materials.

Intra-arterial Chemotherapy

Endovascular techniques permit the selective perfusion of high concentrations of chemotherapeutic agents directly into a tumor, while minimizing systemic side effects. This technique has been used for advanced primary head and neck tumors, and metastatic tumor to cervical lymph nodes.[40] A new delivery technique involves intra-arterial injection of ethylcellulose microspheres containing chemotherapeutic agents. These biodegradable microspheres can remain in the tissue for weeks while they slowly release their anticancer drugs.[41]

Lesions of Vascular Etiology

Epistaxis

Epistaxis may result from trauma, tumor, coagulopathy, or a congenital vascular malformation, such as in hereditary hemorrhagic telangiectasia (or Osler-Weber-Rendu disease). The most common cause is spontaneous bleeding, with or without hypertension, from small vessels along the nasal septum and superior margins of the nasal cavity. Spontaneous bleeding from the anterior aspect of the nasal cavity usually is self-limited and does not require endovascular therapy, but posterior nasal hemorrhage (20%) is more inaccessible and more difficult to manage clinically. Cautery, ligations of the internal maxillary arteries, and nasal packing may be ineffective. Nasal packing may be associated with pulmonary or cardiac problems in elderly patients; embolization may be an effective and rapid therapy.

In all patients, bilateral selective internal and external carotid angiography should be performed to visualize the feeders to the bleeding site (Fig. 136-9).[42,43] Superselective catheterization of internal maxillary artery, facial, and ascending pharyngeal vessels is performed with a microcatheter for angiography. If a bleeding site is found, all feeders and potential collaterals to the site are embolized by moving the microcatheter distal to branches potentially feeding cranial nerves such as the middle meningeal and accessory meningeal arteries. If no bleeding site is found, distal internal maxillary artery and facial artery embolization is performed bilaterally to ensure hemostasis (see Fig. 136-9).[32,44-47] Particles 150 μm provide excellent hemostasis, and there is no risk of devascularizing normal facial tissues. Distal rather than proximal vascular occlusion decreases the chance of recurrent bleeding from col-

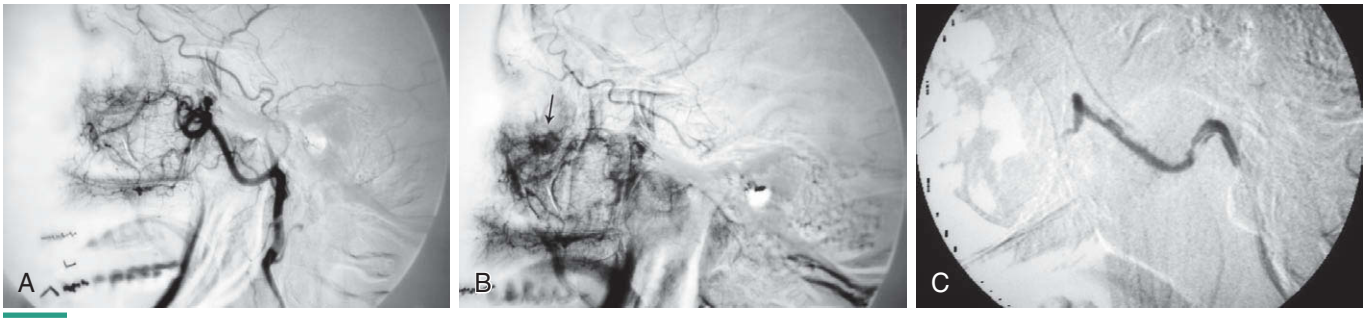

Figure 136-9. Embolization for epistaxis. A 69-year-old woman had recurrent epistaxis requiring nasal packing. **A** and **B,** Selective left external carotid artery injection **(A)** showed a hypervascular area in the region of the superior aspect of the left side of the nose (*arrow* in **B**). Embolization of polyvinyl alcohol particles, 150 µm, was performed under the control of digital subtraction angiography road-mapping. **C,** Postembolization study showed occlusion of the distal internal maxillary artery and no site of bleeding. Clinically, there was no recurrent epistaxis.

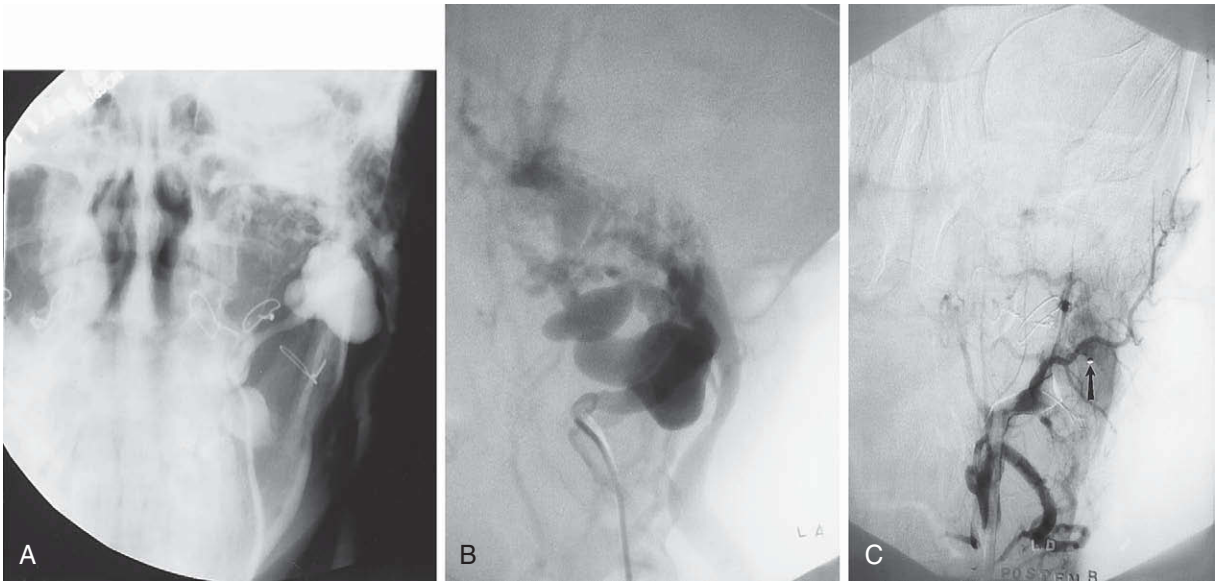

Figure 136-10. Iatrogenic facial arteriovenous fistula with embolization. Surgery had been performed on the left maxillary antrum for chronic sinus disease. One month postoperatively, a large pulsatile mass was noted below the left temporomandibular joint. **A** and **B,** Selective left internal maxillary artery injection showed an arteriovenous fistula with a large venous varix. **C,** A detachable balloon was placed at the site of the fistula (*arrow* denotes metallic marker on balloon) to produce complete occlusion of the fistula.

lateral circulation. With the development of coaxial microcatheter systems and the heightened awareness of functional facial vascular anatomy, success rates of 91% to 97% with complication rates of 0% to 3% have been reported.[46]

Facial Arteriovenous Fistulas

Arteriovenous fistulas may occur after direct facial trauma or from iatrogenic trauma such as facial surgery or image-guided biopsy.[48] Temporomandibular joint or maxillary sinus surgery may result in an arteriovenous fistula (Fig. 136-10). Arteriovenous fistulas also may be congenital in origin. Whatever the cause, selective angiography defines the site of the fistula, which generally is easy to occlude with an appropriately sized detachable balloon (see Fig. 136-10),[7] or with detachable coils. Metallic coils also may be used to pack the venous and arterial sides of a fistula via superselective arterial or venous approaches. To do so, a catheter with a nondetachable balloon is introduced from one femoral artery and placed proximal to the fistula, to be inflated to provide flow control so that the coils do not get swept downstream. A second catheter is introduced via the other femoral artery and placed proximal to the fistula. This second catheter is a guiding catheter with a lumen that accommodates a microcatheter that is manipulated across the fistula into the venous side. Coil occlusion is performed during proximal balloon inflation, progressively pulling the microcatheter back to occlude the arterial side.

Dural Arteriovenous Fistulas

Dural arteriovenous fistulas represent direct communications between small arterial channels within the dura and the underlying dural sinus or veins draining into that sinus. Two types of dural arteriovenous fistulas are considered: fistulas that involve the transverse and sigmoid sinuses and fistulas involving a cavernous sinus.

Transverse and sigmoid sinus dural arteriovenous fistulas are acquired lesions, probably resulting after sinus thrombosis and increased venous pressure, which opens tiny arteriovenous shunts in the dura, with or without subsequent sinus recanalization.[49] Increased flow in the transverse and sigmoid sinuses produces a subjective bruit. The prolonged high flow may lead to intimal hyperplasia of the sinus wall, stenosis, and recurrent occlusion. Persistent or recurrent occlusion of the transverse and sigmoid sinuses produces increased outflow in the contralateral sinuses. Compromise of this venous drainage produces retrograde flow into cortical venous channels, venous hypertension, and tissue congestion, resulting in neurologic deficits.[50] Further venous hypertension may lead to intraparenchymal or subarachnoid hemorrhage.[51] The arterial supply to a transverse and sigmoid sinus dural

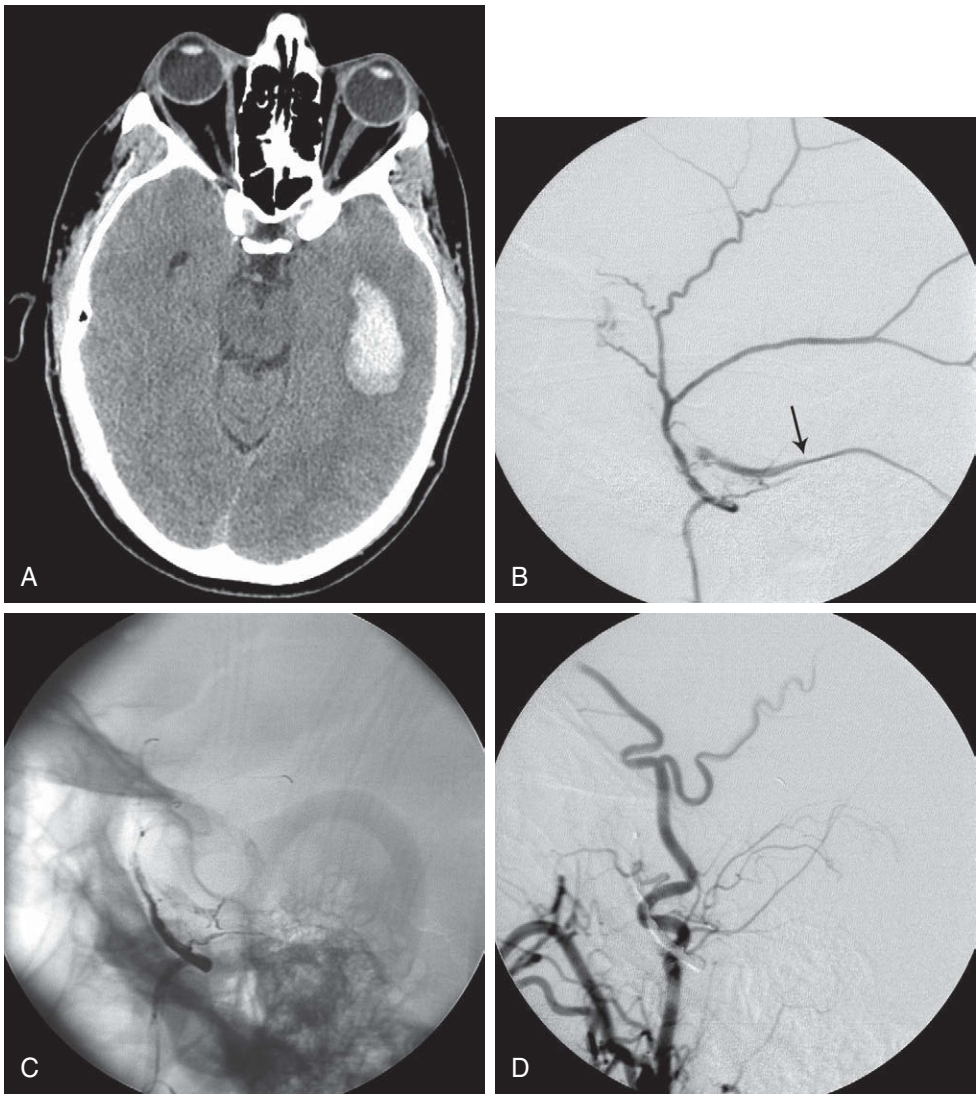

Figure 136-11. Anterior temporal fossa dural arteriovenous fistula treated with intra-arterial Onyx infusion. **A,** A 52-year-old man presented with a spontaneous hemorrhage in the left temporal lobe. The differential diagnosis was a "cryptic" arteriovenous malformation or a dural arteriovenous fistula, such as from the superior petrosal sinus. **B,** Selective middle meningeal artery injection showed early filling of the vein of Labbé *(arrow)* from multiple middle meningeal artery feeders. As a soccer goalie, this patient might have had a skull base fracture and a traumatic arteriovenous fistula. **C,** Onyx was infused into the middle meningeal artery, leaving a "cast" of the tantalum-containing compound. **D,** Subsequent external carotid angiogram did not show the fistula; it was not shown on follow-up angiography 1 year later.

arteriovenous fistula is from multiple ECA branches bilaterally, particularly the occipital arteries and the tentorial branches of the internal carotid arteries. Meningeal branches of the vertebral arteries also may be involved.[52]

If the patient complains of only a mild bruit but is otherwise asymptomatic, the risk-to-benefit ratio does not warrant treatment. In patients in whom the bruit has become so severe that the patient is incapacitated, treatment may be undertaken. The presence of cortical venous outflow, with or without neurologic deficit, indicates a high-risk lesion that should be managed with endovascular techniques. Lesions producing neurologic deficit, dementia, and previous hemorrhage require management.

Arterial embolization alone may be only palliative, with multiple other dural sources increasing in size as the primary feeders are occluded. Embolization with particles is particularly discouraging; if only the arterial side is embolized, a tissue adhesive such as Onyx (Fig. 136-11), or alcohol, may be very effective. Another solution is a combination of arterial and venous approaches. After decreasing the arterial flow rate with particle embolization, coils are deposited in the transverse and sigmoid sinuses via a transvenous approach (usually transfemoral venous catheterization of the jugular bulb with a large guiding catheter, through which a smaller catheter is manipulated into the transverse sinus for coil deposition along the length of the transverse and sigmoid sinuses).[53] If transfemoral venous access is impossible, intraoperative exposure of the sinus for coil packing may be necessary. Some transverse and sigmoid sinus dural arteriovenous fistulas are complex; recurrences are frequent, and therapy may require the combined expertise of the interventionalist and the surgeon over multiple sessions.

The etiology of cavernous sinus dural arteriovenous fistulas is unclear. They are most common in elderly women and manifest with symptoms of proptosis, chemosis, conjunctival injection, decreased vision, and occasionally cranial nerve palsies. The blood supply is from the external carotid and ICA branches to the dura of the cavernous sinus. These lesions behave differently than transverse and sigmoid sinus dural arteriovenous fistulas because they may close spontaneously or after angiography, or subsequent to air travel with its barometric changes. Intermittent compression of the ipsilateral carotid artery may produce closure of the fistula. Progressive loss of vision or cortical venous drainage requires therapeutic intervention. ECA embolization with particles may lead to closure, in contrast to transverse and sigmoid

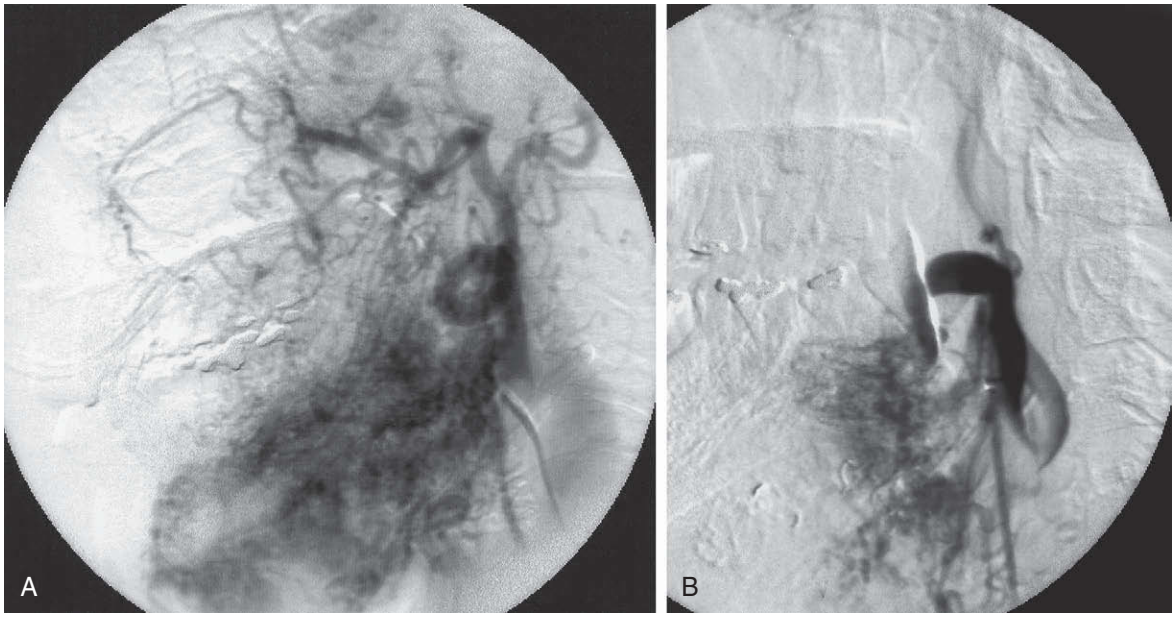

Figure 136-12. Facial arteriovenous malformation (AVM) embolized with intra-arterial alcohol. This 38-year-old woman had a long history of a bilateral facial AVM, and had undergone multiple embolization procedures in the past. **A,** Left external carotid artery study showed an enormous AVM involving the soft tissues of the mandibular region. Two balloons were placed for flow control, one in the external carotid artery and one in the left facial artery. The latter was a balloon surrounding a catheter with a lumen, through which 100% alcohol was injected. The balloon in the facial artery kept the alcohol in contact with the AVM endothelium, whereas the proximal balloon prevented reflux into other external carotid artery branches and into the internal carotid artery. **B,** Postembolization study showed a marked reduction in visible AVM. Three more procedures on the left and three on the right were performed over the subsequent 9 months, markedly reducing the facial deformity.

sinus dural arteriovenous fistulas. Inferior petrosal vein catheterization via a transvenous femoral approach permits the deposition of coils or rarely a tissue adhesive into the cavernous sinus, which is highly effective management with a low complication rate.

Facial Vascular Malformations

Venous malformations of the face manifest as bluish lesions that may distend with the Valsalva maneuver. Although they are congenital, they usually are dormant until some type of factor, such as local trauma, causes them to enlarge.[54,55] MRI studies show lesional hyperintensity on T2-weighted sequences, and the size and the extent of the lesion. Management is for cosmetic purposes. Percutaneous puncture allows the deposition of sclerosing agents. Absolute ethanol is more effective than sodium tetradecyl sulfate, but produces more swelling and is much more painful on injection, requiring deep sedation or anesthesia.[10-13]

Arteriovenous malformations of the face are rare. If surgery or irradiation of a facial arteriovenous malformation is impossible for cosmetic reasons, embolization may be undertaken as a palliative treatment. In such a case, ethanol can be injected intra-arterially, particularly with flow control to keep the agent in proximity to the endothelium for as long as possible (Fig. 136-12). The major complication is flow of the ethanol into the tiny arteries feeding the skin and cranial nerves, producing necrosis. Even with flow control, the rapid flow in the arteries feeding the malformation usually sweeps the ethanol into the venous system for dilution, preventing such complications.

Hemangiomas of the Face and Neck

Hemangiomas have a proliferative phase followed by involution, so that 90% of hemangiomas that are present at birth regress by early childhood.[55] Therapy for infantile or early childhood hemangioma is necessary only if there is airway obstruction, such as from hemangioma of the tongue or subglottic tissues. Even if the hemangioma is in the periorbital region and interferes with normal eye function, time should be allowed for regression, followed by eye muscle and cosmetic surgery. In adolescents or adults, problems may be simply cosmetic, although the hemangioma may infiltrate surrounding tissues such as the alveolar ridge, resulting in hemorrhage when eating, or narrow the airway or esophagus. If there is a slow arterial component, embolization with PVA particles can be performed. If there is primarily a capillary or venous component, direct puncture of the lesion with the instillation of a sclerosing agent, such as absolute ethanol or sodium tetradecyl sulfate, may be effective. In most patients, embolization is followed by surgical removal.

Pseudoaneurysms

Cranial trauma resulting in cavernous carotid artery laceration usually produces a carotid-cavernous sinus fistula, although a pseudoaneurysm may be formed instead, with enlargement over time, erosion into the sphenoid sinus, and rupture, producing massive life-threatening epistaxis. Emergency balloon occlusion of the ICA may be necessary because the lack of a true arterial lining of the pseudoaneurysm predisposes to recanalization after intra-aneurysmal coil or balloon placement.

Rapid hyperextension of the neck with contralateral head rotation forces the high cervical ICA against the lateral mass of C2, or stretches a vertebral artery at C1-2 between its contained segments within the C2 foramen transversarium and the dura at the foramen magnum,[56] resulting in arterial dissection and subsequent pseudoaneurysm formation. Surgical repair may be difficult, necessitating the use of endovascular techniques. Because the pseudoaneurysm lacks a true arterial wall, frequently has a wide neck, and may contain semisoft clot of variable age, successful occlusion with intra-aneurysmal balloons or coils usually is impossible. The endovascular placement of a stent across the neck of a pseudoaneurysm is the preferred method of management; the combination of stenting and intra-aneurysmal coil placement may be even more successful. If necessary, occlusion of the parent artery with balloons[57] or coils placed above and below the aneurysm is definitive, but should be preceded with the BOT and assessment of cerebral blood flow after carotid occlusion via collateral channels.

Inadvertent biopsy of an aberrant carotid artery in the middle ear cavity has been reported, leading to severe otorrhagia and massive epistaxis. These lesions generally are best handled by trapping with balloons or coils proximal and distal to the aneurysm (Fig. 136-13).[58]

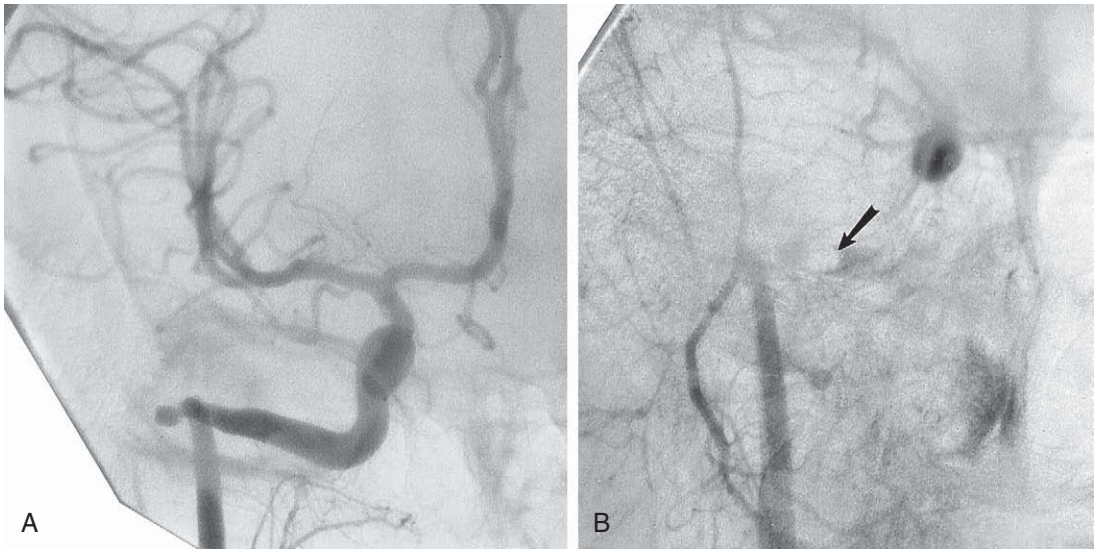

Figure 136-13. Pseudoaneurysm of an aberrant right internal carotid artery after biopsy with balloon occlusion. This 6-year-old child had a reddish mass behind the tympanic membrane. A biopsy of the mass was performed by an otolaryngologist, producing rapid blood loss through the myringotomy. The ear was packed, and the patient was sent for evaluation. **A,** Right common carotid angiography showed the arcuate appearance of the petrous portion of the right internal carotid artery characteristic of an aberrant internal carotid artery extending into the middle ear cavity, with a pseudoaneurysm extending laterally representing the site of biopsy. **B,** A releasable balloon was placed above the aneurysm in the horizontal portion of the petrous segment (*arrow* marks distal margin of balloon). A second balloon was placed in the high cervical carotid artery for trapping of the aneurysm. Excellent cross-flow from left to right through the anterior communicating artery prevented neurologic sequelae after carotid occlusion.

Tinnitus-Producing Fibromuscular Dysplasia of the Carotid Artery

Fibromuscular dysplasia of the ICA, which usually occurs at the level of C2, is one of the many causes of pulsatile tinnitus. Vascular webs that characterize this entity may be stretched by angioplasty,[59] and stent placement may be necessary to prevent recurrence.

External Ear

CHAPTER ONE HUNDRED AND THIRTY-SEVEN

Infections of the External Ear

Joel Guss

Michael J. Ruckenstein

Key Points

- The external ear and ear canal are affected by various bacterial, fungal, and viral infections, and noninfectious inflammatory conditions.
- Meticulous débridement of the ear canal is a crucial first step in managing all infections.
- Most cases of external otitis should be managed with topical medications.
- Infections that have spread beyond the confines of the ear canal skin require culture-directed systemic antibiotics.
- Malignant or necrotizing otitis externa is a life-threatening infection that requires a high index of suspicion and proper selection of radiographic and nuclear studies for prompt diagnosis.
- Infection of the auricular cartilage can lead to significant cosmetic deformity and requires aggressive treatment with systemic antipseudomonal antibiotics and, in many cases, surgical débridement.
- Viral infections of the ear canal include zoster oticus and, most likely, bullous myringitis; both may be associated with sensorineural hearing loss.
- Keratosis obturans and external auditory canal cholesteatoma are two poorly understood disorders marked by accumulation of squamous debris and bony remodeling of the ear canal; both are treated by débridement, but occasionally require aggressive surgical management.

Applied Anatomy

The external ear consists of the auricle and the external ear canal. The auricle, with the exception of its lobule, is formed by a framework of elastic cartilage. The perichondrium is tightly bound to the cartilage on its lateral surface and more loosely bound to its medial surface. Sebaceous glands and hair follicles are found in the subcutaneous layer of the auricle. Adipose tissue is generally restricted to the lobule. Keratinizing squamous epithelium covers the auricle. The ear canal measures approximately 2.5 cm in length, with the anterior portion being approximately 6 mm longer than the posterior wall. The lateral one third of the canal possesses a cartilaginous skeleton, a subcutaneous layer containing hair follicles, sebaceous and apocrine glands, and a squamous epithelial surface layer. The hydrophobic, slightly acidic (pH 6.0 to 6.5) cerumen is formed by glandular secretions and sloughed epithelium in this portion of the canal.

Transverse slits on the floor of the cartilaginous canal (the fissures of Santorini) allow for spread of infection or neoplasms from the external canal to the soft tissues surrounding the ear canal. The osseous portion of the canal begins at the narrow isthmus and is formed mostly by the tympanic portion of the temporal bone and a thin layer of squamous epithelium continuous with the lateral surface of the tympanic membrane. It lacks a subcutaneous layer.

The skin of the ear canal possesses a unique, self-cleansing mechanism. The sloughed keratinous layer of tympanic membrane migrates in a centrifugal fashion to the ear canal. This migratory process continues from the medial to lateral portions of the osseous canal, where the sloughed epithelium is deposited into the cartilaginous portion of the canal and is extruded as a component of cerumen.

Otitis Externa

Definition

Otitis externa is an inflammatory (typically infectious) disorder of the external ear canal.

Incidence and Epidemiology

Acute otitis externa affects approximately 4 of every 1000 children and adults per year.[1] Approximately 80% of cases occur in the summer, particularly in warm, humid environments.[2] Other predisposing factors include anatomic obstructions of the ear canal (e.g., stenosis, exostoses, impacted cerumen), hearing aid or ear plug use, self-induced trauma (e.g., by cotton swabs), and swimming.

Pathogenesis

Bacterial

The initiating event is believed to be an abrogation of the hydrophobic ceruminous coating of the external canal.[3] This event exposes the underlying epithelium to water and other contaminants, leading to edema and excoriation of the epithelial layer. These violations of the epithelium allow for bacterial infection. The resulting infection and inflammatory response lead to progressive erythema and edema of the epithelial and subcutaneous layers. These pathologic changes are associated with the symptoms of itching, pain, and otorrhea.

Fungal

Fungal infections of the external canal are generally considered to be opportunistic, occurring after treatment of bacterial infection.

Figure 137-1. Otomycosis. This florid infection with *Aspergillus flavus* has infected the deep canal, with tufts of fungus crowned by white conidiophores.

Superficial infection of the ear canal by yeast (*Candida* sp) can be seen in patients who use hearing aids. *Aspergillus* sp may induce a more aggressive infection, involving the epithelial and subcutaneous tissues (Fig. 137-1).

Chronic

Chronic otitis externa represents different disease states with distinct etiologies, as follows:

- Allergic otitis externa may result from an allergic reaction to topical agents, most commonly neomycin. It manifests as a maculopapular eruption on the skin of the conchal bowl and ear canal.
- A contact dermatitis can result from contact with various agents, including hairsprays, shampoos, and hearing aid molds.
- Psoriasis or systemic dermatitides such as seborrhea can involve the ear canal. The chronic inflammatory reaction typically results in hyperkeratosis and lichenification of the ear canal skin.
- Granular otitis externa is thought to result from chronic infection of the ear canal by bacteria or fungi or both. The ear canal skin and tympanic membrane manifest granulation and excoriation.

Microbiology

Roland and Stroman[2] evaluated the microbiology of otitis externa. The results of their study are summarized in Table 137-1. *Pseudomonas aeruginosa* was the most common bacteria responsible for infections. *Staphylococcus* sp were the next most common pathogens. Fungi were responsible for only 2% of cases, but may be more prominent in cases of persistent or chronic infection.

Clinical Manifestations

Pain is a common symptom associated with bacterial infection. The pain may be severe and is exacerbated by manipulation of the auricle or the tragus. Itching may be experienced in early bacterial infections, and in fungal infections and in all forms of chronic otitis externa. Aural fullness and decreased hearing may be experienced in any case of otitis externa resulting in accumulation of debris in the ear canal. Otorrhea is more common in bacterial infections.

Examination of the canal may reveal the following findings:

1. An erythematous canal with scant discharge in cases of early bacterial otitis externa
2. An edematous canal filled with purulent-squamous debris in cases of well-established bacterial otitis externa
3. An accumulation of white debris sprouting hyphae best seen with the otologic microscope, typical of candidal otitis externa
4. An accumulation of a moist white plug dotted with black debris ("wet newspaper") typical of *Aspergillus niger*
5. A maculopapular eruption on the conchal bowl and in the ear canal consistent with an allergic reaction to a topical agent (e.g., neomycin)
6. A thickened, erythematous canal associated with an allergic or contact dermatitis
7. Granulation tissue in the canal and on the tympanic membrane caused by chronic infection

Table 137-1

Microbiology of Otitis Externa

Organism	%
Pseudomonas aeruginosa	40
Staphylococcus epidermidis	9
Staphylococcus aureus	8
Other *Staphylococcus* sp	8
Coryneform (diphtheroids)	9
Other gram-negative rods	9
Streptococcus, Enterococcus	4
Aspergillus, Candida	2

From Roland PS, Stroman DW. Microbiology of acute otitis externa. *Laryngoscope*. 2002;112:1166-1177.

Investigations

Investigations are rarely required for cases of otitis externa. Cultures for bacteria and fungus are indicated in cases of persistent or refractory infection, particularly to identify fungal infection. Special reference must be made to the value of sensitivities of the infectious organism to various antibiotics provided by laboratory culture tests. These sensitivities are based on expected tissue levels of systemically administered antibiotics. Sampling of otorrhea after administration of topical preparations has shown a concentration of antibiotic several orders of magnitude greater than can be obtained by systemic administration, however, even 8 hours after dosing.[4] Organisms listed as "resistant" to a particular antibiotic are likely to be susceptible to the antibiotic when it is given topically. This is true for so-called resistant cases of *Pseudomonas* sp or methicillin-resistant *Staphylococcus aureus*. As long as the topical drop can reach the infected site, systemic antibiotics are unnecessary even in cases of infection by "resistant" bacteria.

Biopsy of the external auditory canal should be undertaken in cases of presumed otitis externa that do not respond to appropriate antimicrobial therapy. Biopsy is done to exclude malignancy, most commonly squamous cell carcinoma of the ear canal skin, which may manifest with otalgia and otorrhea and may be misdiagnosed as infection.

Treatment

Careful débridement of the ear canal in any case of otitis externa is crucial to facilitate clearance of the infectious organism and to allow topical medications to reach the target tissue. If the ear canal is so edematous that topical medication would not reach its medial extent, an ear wick may be inserted. Classically, the physician made these from

strands of cotton. Currently available Merocel wicks (Medtronic, Inc., Jacksonville, FL) offer better absorption of the drug, however, and expand when wet to decrease canal edema substantially. Although unpopular in North America, good results can also be obtained by packing the ear canal with antibiotic-impregnated ribbon gauze.[5]

Acidification of the ear canal is toxic to many bacteria (including *Pseudomonas*) and fungi, and effectively treats many early infections. A homemade mixture of equal amounts of white vinegar and rubbing alcohol acidifies and dries the ear canal. Commercial solutions of acetic acid (VoSol) or acetic acid with aluminum acetate (Domeboro) also are available. Acidifying solutions may also be used prophylactically by at-risk patients, such as after swimming. A hair dryer on a low heat setting may be used to dry the ear canal gently.

Antibiotic drops remain the mainstay of treatment for otitis externa. The ideal drops possess the following properties:

1. Broad-spectrum coverage for pathogenic bacteria (see Table 137-1)
2. An acidic vehicle
3. No potential for ototoxicity, which is an important property in the case of a perforated tympanic membrane
4. No potential for allergic reactions
5. No deposition of precipitate from the drop
6. Low cost
7. A steroid to decrease edema more rapidly and, perhaps, alleviate pain more rapidly

No current drop possesses all these properties. For many years, the mainstay of treatment was a combination solution of polymyxin, neomycin, and hydrocortisone (PNH) (Cortisporin). This combination is available in solution and suspension, and is produced by various manufacturers. Polymyxin provides coverage against *Pseudomonas*; polymyxin and neomycin are effective against *S. aureus* and other gram-negative organisms.

Quinolone antibiotics are available in otic and ophthalmic solutions. They offer single-agent coverage for pathogenic bacteria, with virtually no risk of contact dermatitis or ototoxicity. Ofloxacin (Floxin) is available for treatment of external and middle ear disease and is equal to PNH in efficacy.[6,7] Its main disadvantages are a neutral pH (6.2 to 6.8), the absence of a steroid, and expense. Ciprofloxacin is available as an otic preparation combined with hydrocortisone and as a newer formulation combined with the more potent dexamethasone (Cipro HC and Ciprodex). These solutions are acidic and contain a steroid. The hydrocortisone in Cipro HC may leave a precipitate in the canal, and both solutions are expensive.

When choosing a topical treatment of otitis externa, there is currently minimal clinical evidence to support the use of one solution over another. Existing literature is difficult to interpret because studies differ in their outcome measures and in the degree of aural toilet used. A systematic review of topical treatments by Rosenfeld and colleagues[8] reached the following conclusions: (1) topical antimicrobial and topical antiseptic drops were superior to placebo; (2) a topical antiseptic (with a steroid in most cases) was as effective as a topical antibiotic; (3) topical quinolone and nonquinolone antibiotics were equally effective except in achieving a bacteriologic cure, where the quinolones were more effective; and (4) a topical antibiotic is as effective as a topical antibiotic and steroid preparation. Chapter 138 contains further information on costs and emerging resistance with quinolone ototopicals.

Fungal otitis externa can be treated with meticulous débridement and acidification of the ear. As with bacterial infection, topical treatment cures most cases, although recurrence rates are high. Clotrimazole 1% solution (Lotrimin) is available over the counter and provides broad-spectrum antifungal activity. Cresylate otic and ketoconazole ointment are effective as well.[9] An alternative popular treatment is painting the canal and tympanic membrane with dyes that possess antifungal properties (e.g., gentian violet). Tolnaftate (Tinactin) solution can be used safely in the presence of a tympanic membrane perforation.[10,11] Finally, persistent *Aspergillus* infections associated with considerable canal edema or infections failing to respond to topical treatment may require the administration of oral itraconazole. The senior author has found that virtually all cases of fungal otitis externa can be quickly resolved by débridement of the canal and then filling the canal with a combination cream—Lotrisone (clotrimazole and betamethasone). The cream is loaded into a 3 cc syringe and passed through an angiocath into the ear canal.

Contact or allergic dermatitis should be treated by elimination of the offending agent, débridement, and the administration of a topical corticosteroid solution/lotion.[12] Chronic granular otitis externa can be difficult to treat. This is most frequently seen in individuals who are dependent on their hearing aids. Minimizing or alternating hearing aid use is crucial to the success of the treatment regimen. Culture of the ear for bacteria and fungus may provide evidence of the causative organisms. Repeated débridement, cauterization of the granulations, and filling the canal with topical antibiotic or antifungal creams can be effective. Topical gentian violet may also be effective at drying the ear canal and eliminating the chronic infection. Surgical therapy may be required.

In patients with long-standing inflammation of the ear canal that does not respond to traditional ototopical treatments, we have found that filling the ear canal with a mixture of equal parts of bacitracin and polymyxin ointment, clotrimazole cream 1%, and betamethasone 0.05% cures most patients.[13] This mixture of an antibiotic, antifungal, and steroid is inexpensive and is easily instilled using a syringe and an 18-gauge angiocatheter tip. The ointment can be débrided after 1 week and reapplied as needed.

Complications

Cellulitis, perichondritis, and chondritis may result from otitis externa. In adults, the presence of these complications should prompt the administration of a systemic quinolone antibiotic. In children, in the case of a cellulitis, an oral antistaphylococcal drug may be initiated; however, if *Pseudomonas* is detected on ear culture, parenteral administration of antipseudomonal antibiotics is required. Specific treatment of perichondritis and chondritis is addressed in a subsequent section.

Medial canal fibrosis represents a thick fibrous scar at the medial end of the ear canal, just lateral to the tympanic membrane, and is the end stage of chronic otitis externa.[14] Physical examination reveals what appears to be a lateralized tympanic membrane and an absence of typical landmarks (Fig. 137-2). Surgical treatment of this disorder can be challenging. The affected portion of the canal lining is resected, bony canalplasty is performed, and the canal is relined with split-thickness skin grafts. In more favorable cases, a space remains between the fibrous scar and the tympanic membrane, avoiding the need for tympanoplasty.

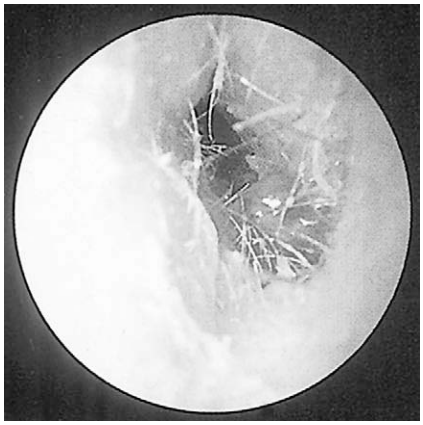

Figure 137-2. Chronic external otitis. The hallmarks are atrophy of the skin of the canal and stenosis caused by chronic irritation. This patient used cotton swabs in the ear, and debris from the canal with cotton fibers has been pushed medially against the tympanic membrane.

When the tympanic membrane is involved, however, a total-drum tympanoplasty is required. Meticulous technique is required to avoid blunting the anterior tympanic sulcus. Recurrence after surgical treatment is common.

Tympanic membrane perforation is particularly common with fungal otitis externa caused by *Aspergillus* sp. Elimination of the offending fungus allows for a high rate of spontaneous healing of these perforations.[15]

Malignant Otitis Externa

Definition

Malignant otitis externa is an aggressive and potentially fatal infection originating in the external canal, with progressive spread along the soft tissues and bone of the skull base, ultimately involving intracranial structures.[16] It is also (more accurately) known as necrotizing otitis externa.

Incidence and Epidemiology

Malignant otitis externa is a rare disorder occurring predominantly in immunocompromised patients. Elderly individuals with diabetes mellitus are the most commonly affected patients,[16,17] although malignant otitis externa has been reported in various other immunocompromised states, including myeloid malignancies, pharmacologic immunosuppression, and HIV/AIDS.[18-20] It has also been reported to occur in immunocompetent patients.[21-23]

Microbiology

Most cases are caused by *P. aeruginosa* followed by *S. aureus*.[16,24,25] Case reports have implicated other organisms. *Aspergillus* sp are the most common fungal pathogens to cause this disorder,[24] but infections by more exotic molds have also been reported. Fluoroquinolone-resistant *Pseudomonas* is an increasing problem,[24,25] and is particularly frustrating because the fluoroquinolones are the only enterally administered antibiotics with antipseudomonal activity.

Clinical Manifestations

Patients are initially seen with long-standing otalgia, which can be severe, and otorrhea. The hallmark finding is granulation tissue protruding through the floor of the ear canal at the bony-cartilaginous junction (Fig. 137-3).[16] In its initial stages, the infection is confined to the skin and soft tissues of the ear canal.[26] As it progresses, the infection involves the bony structures of the temporal bone. At its most advanced stages, it extends beyond the temporal bone along the skull base or intracranially or both.[26] The facial nerve is the most common cranial nerve involved, with paralysis resulting from involvement at the stylomastoid foramen. Further progression leads to involvement of the lower cranial nerves at the jugular foramen and hypoglossal canal. Intracranial spread results in headaches, fever, neck stiffness, and altered levels of consciousness.

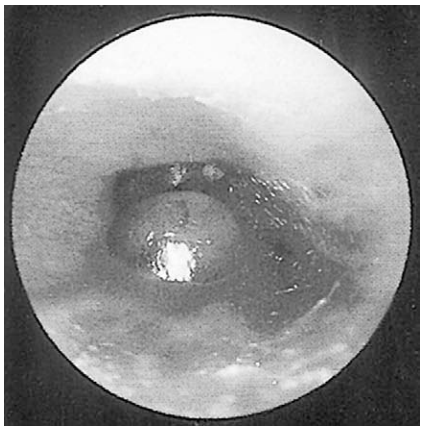

Figure 137-3. Malignant otitis externa. A nubbin of granulation tissue sits on the floor of the ear canal at the junction of the bony and cartilaginous portions.

Investigations

When malignant otitis externa is suspected, bacterial and fungal cultures of otorrhea should be obtained at the time of initiation of treatment. Early diagnosis of malignant otitis externa requires a high index of suspicion and use of appropriate imaging modalities, as follows.

- High-resolution computed tomography (CT) scans are readily obtainable and relatively inexpensive. The CT scan shows even small cortical erosion of the tympanic bone and is a useful first-line test.[27-30] Disadvantages of CT include an underappreciation of the soft tissue and intracranial extent of disease, and the inability to distinguish infection from malignancy.[27] Because normalization of bony changes may never occur despite resolution of the infection, CT is also limited in following the response to treatment.

- Although magnetic resonance imaging (MRI) misses subtle bony erosion, it is superior in detecting soft tissue changes and may show dural enhancement.[27,29] These are more likely to resolve with treatment, making MRI more useful in following the course of disease.[27]

- Technetium-99m bone scanning shows areas of osteoblastic activity and is highly sensitive for bony infection. Traditional planar imaging or single photon emission computed tomography (SPECT) can be used. SPECT provides good anatomic localization and may highlight areas of bony involvement before the CT scan shows structural changes, making it particularly useful when the clinical suspicion for malignant otitis externa is high, but the CT scan is negative.[28] Because bony repair persists long after the infection has resolved, the technetium bone scan is not used to follow response to treatment.

- Gallium-67 citrate and indium-111–labeled leukocyte scans show areas of inflammatory cell activity. These tests are sensitive, and uptake values return to normal quickly with resolution of infection, making them useful in following response to treatment.[28] These are expensive and time-consuming tests to perform, and false-positive results may occur secondary to inflamed soft tissues surrounding bone. A greater degree of diagnostic accuracy (and expense) may be afforded by the simultaneous acquisition of a SPECT technetium-99m bone scan and indium-111–labeled leukocyte scan.[31]

Treatment

Cure of this infection is predicated on early diagnosis and aggressive medical therapy. Administration of antipseudomonal antibiotics is the cornerstone of treatment. Early infections may be treated solely with an oral fluoroquinolone (most commonly ciprofloxacin) except in cases of resistant organisms.[25,32] In more advanced stages, parenteral antibiotics may be indicated initially, with discharge of the patient home on oral fluoroquinolones. Total duration of treatment is typically 6 weeks, or as indicated by the results of radiologic studies and clinical response. Although hyperbaric oxygen therapy has been used as an adjuvant resulting in cure of some advanced cases,[33-35] it has never been tested in a randomized controlled study.[36]

The role of surgical treatment for this disorder has never been critically evaluated. Surgical débridement of nonviable sequestra of bone has been mentioned; however, it remains unclear when surgical resection is mandated. Involvement of bone occurs along the skull base, so traditional mastoidectomy should theoretically not be effective in débriding the infection. Similarly, because the facial nerve is involved in the region of the stylomastoid foramen, facial nerve decompression of the proximal segments would seem to be inappropriate. Medical therapy for this disorder seems paramount. Surgical resection should be reserved for cases in which bone involvement is resistant to therapy. In addition, surgical resection should be incorporated in more heroic efforts to abort a rampant or progressive infection. In these cases, surgical intervention would include a wide resection of the bony skull base, including the stylomastoid foramen and jugular bulb, together with the

Figure 137-4. Herpes zoster. Note the infectious vesicles with erythematous margins involving the concha, and a crusted older lesion over the mastoid.

introduction of viable, vascularized tissue (e.g., temporalis muscle flap or microvascular free tissue transfer) into the bed.

Herpes Zoster Oticus

Herpes (or varicella) zoster virus can cause a recrudescent infection involving the external ear. It is an uncommon infection that more frequently affects immunosuppressed patients or elderly individuals in whom immunity to the virus has waned.[37] Other stimuli for viral reactivation involve various physical and psychological stressors. Often, no precipitating event is identified. After primary infection (chickenpox), varicella-zoster virus is harbored in a latent state in sensory ganglia, and reactivates with infection spreading along dermatomes. When the ear is involved, virus is most commonly believed to be harbored in the geniculate ganglion and spreads along the sensory fibers of the facial nerve.[38] Other sensory ganglia have also been implicated, including the fifth and eighth cranial nerves.[39]

Clinical manifestations include a prodrome of otalgia, which may be severe. A vesicular eruption is seen in the canal and concha (Fig. 137-4). Ultimately, these vesicles rupture and form crusts. A subgroup of patients manifest Ramsay Hunt syndrome, defined by facial paralysis in the presence of herpes zoster oticus. If cranial nerve VIII is involved, sensorineural hearing loss or vertigo or both may be present. Treatment is empiric and not based on many scientific studies. It includes local ear care, the administration of topical antibiotic/steroid drops, and the administration of an antiherpetic agent at the onset of the syndrome (e.g., valacyclovir, 1000 mg three times daily for 7 days).[40] High-dose steroids (e.g., prednisone, 1 mg/kg/day) should be added in the presence of facial paralysis or sensorineural hearing loss or both.[41] Particular attention should be directed to eye care, and ophthalmologic consultation should be obtained with any evidence of a herpetic keratitis. Postherpetic neuralgia can be a significant problem. Universal vaccination of infants against varicella-zoster virus and the U.S. Food and Drug Administration approval of a zoster vaccine for older adults may result in a decreased incidence of zoster infections. These vaccines are not indicated for treatment of zoster or postherpetic neuralgia.[37]

Bullous Myringitis

Bullous myringitis is an inflammatory/infectious condition involving the lateral surface of the tympanic membrane and the medial portion of the canal wall. It typically occurs in association with upper respiratory infections and is more common in winter. The etiology is believed to be primarily viral; however, *Mycoplasma* has been identified in some cases.[42-44] Clinical manifestations include acute, severe otalgia; serosanguineous otorrhea; and hearing loss. Physical examination reveals bullae on the tympanic membrane that are filled with serous or serosanguineous fluid (Fig. 137-5). Spontaneous rupture of the bullae leads to the observed discharge. Primary care practitioners frequently mistake this disorder for acute otitis media. A serous otitis media is a frequently associated finding in 30% to 40% of cases.[43-46] More significant is the association of this disorder with a sensorineural hearing loss. Sixty-five percent of patients manifest a sensorineural or mixed hearing loss, with the sensorineural component recovering completely in approximately 60%.[45,46]

Figure 137-5. Bullous myringitis. The deep ear canal and tympanic membrane are acutely inflamed. A large bulla is seen over the posterior tympanic membrane.

Treatment includes analgesics, topical antibiotic/steroid drops to prevent bacterial superinfection, and lancing the bullae, which may result in some pain relief. Because *Mycoplasma* sometimes can be associated with this infection, the administration of a macrolide or quinolone antibiotic may be prudent. The role of systemic steroids has not been established.

Cellulitis

Cellulitis of the ear typically results from a spreading otitis externa or a penetrating injury. It is distinguished from perichondritis by the lack of induration. It manifests as an erythematous ear. Treatment is with systemic, antistaphylococcal antibiotics.

Erysipelas

Erysipelas is a dermal infection that may involve the skin of the head and face, including the ear, caused by β-hemolytic streptococcus. The involved tissue is erythematous, indurated, and tender. The hallmark of the infection is that it spreads along a well-demarcated border (Fig. 137-6). Treatment is with oral systemic antibiotics (e.g., penicillin).

Perichondritis and Chondritis

Perichondritis and chondritis represent infections of the auricular perichondrium or cartilage. They result from blunt or penetrating trauma to the ear or by direct extension from an otitis externa. In the case of a blunt trauma, a hematoma on the lateral surface of the pinna that becomes infected is the initiating event. Penetrating trauma may result from various injuries, including ear piercing, assaults, bites, and iatrogenic injuries. Increasingly popular piercing of the ear cartilage as opposed to the lobule may predispose to infection, and outbreaks have been reported.[47] *Pseudomonas* is the most frequent causative organism.

Physical examination reveals a tender, erythematous, indurated pinna. Fluctuance indicates the presence of an abscess and possible chondritis. Treatment of perichondritis consists of elimination of any foreign bodies and the administration of an oral quinolone antibiotic. An abscess must be drained, and any necrotic cartilage must be resected. The wound can be packed with antibiotic-impregnated ribbon gauze, or, when cartilage is resected, a through-and-through Penrose drain may be placed. A permanent deformity of the cartilage ("cauliflower ear") may result. Recurrent or bilateral auricular swelling should prompt a rheumatologic workup for relapsing polychondritis.

Figure 137-6. Erysipelas. Note the diffuse erythema and swelling of the auricle and the advancing margin of cellulitis involving the face. The line of demarcation between involved and uninvolved areas is clearly defined.

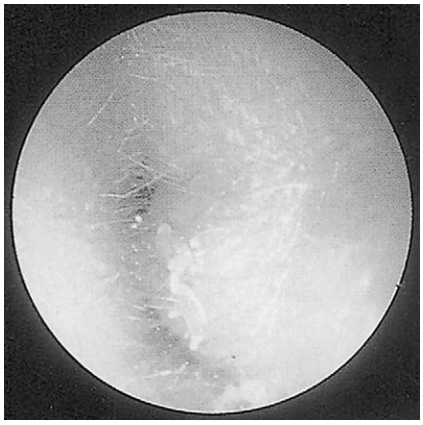

Figure 137-7. Furuncle of the ear canal. The small abscess forms a localized swelling at the entrance of the ear canal. The furuncle is pointing and has begun to rupture.

Furunculosis

A furuncle (abscess or boil) is a walled-off collection of pus that is seen as a painful, firm, or fluctuant mass (Fig. 137-7). It arises from the hair follicles of the lateral ear canal. The causative organism is typically *S. aureus*. Clinical manifestations include localized pain, particularly to touch. Early manifestations include a nodular swelling that proceeds to fluctuance. Treatment includes the application of warm compresses and topical antibiotic ointment. Antistaphylococcal oral antibiotics should be administered. A fluctuant lesion should be incised and drained under local anesthetic.

Keratosis Obturans and External Auditory Canal Cholesteatoma

Keratosis obturans and external auditory canal cholesteatoma are two conditions marked by the abnormal accumulation of keratin in the medial portion of the ear canal. Although the two terms were long used interchangeably, they are now generally held to represent separate disease entities.[48]

Keratosis obturans represents a diffuse disorder of the entire circumference of the medial external auditory canal skin. Affected patients accumulate a dense plug of keratin that can completely occlude the auditory canal and cause a conductive hearing loss. Frequently, such patients have severe pain from an aggressive secondary external otitis. Both ears are frequently involved, although not always to the same extent. If the condition is neglected, the pressure exerted by the keratin plug can cause widening of the bony ear canal or formation of an "automastoidectomy" cavity. Thickening and mucosalization of the tympanic membrane may occur, as can blunting of the periannular canal skin from chronic inflammatory scarring. Rare cases of tegmen dehiscence, facial palsy, and lateral semicircular canal erosion have been reported.[49]

The condition primarily affects adults, usually 30 to 60 years old. Corbridge and colleagues[50] documented faulty epithelial migration patterns of the epithelial layer of the tympanic membrane and external auditory canal skin in affected patients, whereas others have proposed that excessive production of epithelial cells underlies the disease.[51] The factors responsible for these alterations are unknown.

The treatment is atraumatic removal of the epithelial debris. Occasionally, preliminary softening with otic drops or even general anesthesia is necessary. After cleaning, follow-up visits are scheduled to clean the canals and remove debris prophylactically before inflammation and infection can occur. Over time, the interval between cleanings can increase. The condition frequently ameliorates, although lifelong débridements may be necessary.

External auditory canal cholesteatoma is rare and seems to represent a distinct clinical entity. Ulceration of the canal skin and necrosis of the underlying bone develop at the inferior-posterior portion of the bony ear canal just lateral to the anulus. It is unclear whether invasion of the bone by squamous epithelium with subsequent necrosis begins the process, or whether a focus of injured bone (secondary to trauma or infection) with invasion of epithelium from the margins of the overlying ulcer is the initiating event.[51] The focal nature of the disease distinguishes it from keratosis obturans, which circumferentially affects the ear canal. Patients typically present with signs and symptoms of an external otitis including otorrhea. On examination, granulation tissue may be seen at the edge of a bony crater filled with infected keratin debris.

Treatment is to resolve the granulation tissue and external otitis with cleaning, removal of debris, and medications. Follow-up visits are scheduled to try to prevent flare-ups by periodic cleaning and topical agents. Surgery may be necessary in refractory cases, and entails removal of the cholesteatoma matrix and necrotic bone followed by placement of a fascial graft in the cavity to promote healthy re-epithelialization.[51]

CHAPTER ONE HUNDRED AND THIRTY-EIGHT

Topical Therapies of External Ear Disorders

Joyce Colton House

Daniel J. Lee

Key Points

- An understanding of the efficacy and side-effect profile of prescription and nonprescription topical therapies of external ear disorders is important for successful management of a patient who presents with otitis externa.
- Débridement under binocular microscopy in the otolaryngologist's office is diagnostic and therapeutic for common conditions involving the external ear.
- Most ototopical therapies are safe for the management of uncomplicated infections of the outer ear, provided that the tympanic membrane is intact.
- Aminoglycosides and acidifying agents should be avoided when a tympanic membrane perforation is present because of the possible risk of ototoxicity.
- An emphasis on meticulous ear hygiene and avoidance of self-manipulation is crucial to avoid recurrent or chronic infections.
- Systemic therapy should be considered in severe or chronic infections or in patients who are immunocompromised.
- Persistent infections should be cultured, and biopsy specimens of suspicious or diseased tissue should be obtained to exclude the possibility of a malignancy.
- Dermatologic and rheumatologic evaluations should be considered in refractory or bilateral cases of eczematoid otitis externa.

Topical therapies for external ear disorders are among the most commonly prescribed medications for pediatric and adult patients who present to an otolaryngology office. The local delivery of antibiotic and anti-inflammatory medications to the external ear has several advantages over systemic therapies, including (1) ease of patient use, (2) increased concentration of drug levels in the affected region, (3) decreased systemic side effects, and (4) lower cost. Ototopical antibiotics in particular avoid the selection of resistant organisms in the gastrointestinal and respiratory tracts that can be seen with systemic therapy. Disadvantages include the difficulty of using topical medications in an edematous or occluded external auditory canal, hypersensitivity or allergic reactions, and a theoretical risk of injury to the inner ear when the tympanic membrane is perforated or tympanostomy tubes are present. This chapter provides an evidence-based discussion of topical therapies for external ear disorders based on disease categories. These categories include bacterial otitis externa (OE), fungal OE, myringitis, eczematoid OE, viral infections of the external ear, cerumen impaction, and chronic draining ear.

History

Topical therapies have been used to manage external ear disorders for thousands of years. According to Myer,[1,2] mixtures including red lead, tree resin, olive oil, frankincense, goose grease, cream from cow's milk, crushed soda, vermilion, cumin, ass ear, and hatet oil were used to treat chronic draining ears 3500 years ago. A process known as "ear candling" dates back more than 1000 years and was originally adopted as a method of removing cerumen from the canal. In this process, a hollow candle is lit on one end creating a vacuum at the other end that, when inserted into the ear, draws out debris from the canal. Contemporary studies have shown that ear candling is largely ineffective, and this technique can deposit hot candle wax into the canal, resulting in burns.[3] In the 1800s, "rattlesnake oil" (turpentine, camphor, menthol, and sassafras) was marketed as a cure for otorrhea.

By the early 1900s, astringents and alcohols were introduced, and the acidity and high alcohol concentration made these preparations effective if given early in the course of an infection. They had no targeted antimicrobial activity, however. Topical antibiotics and antifungals against the most common pathogens associated with OE and otitis media were not developed until the mid-20th century.[1,2] In particular, ototopical aminoglycosides have been available for more than 20 years and are still frequently prescribed; newer fluoroquinolone agents are gaining in popularity because studies have shown potentially less ototoxicity associated with their use.[3,4]

Mechanism of Action

The external auditory canal is lined with squamous epithelium, providing a natural barrier against the environment. The successful delivery of topical medications requires penetration across this barrier, and the stratum corneum (the most superficial layer of the epidermis) provides the greatest resistance to the permeation of drugs.[5] Passive diffusion allows for most of the transport across the stratum corneum, and the degree of absorption is related to the properties of the agent being used.[5] Two routes of passive diffusion across the stratum corneum have been proposed: transappendageal and epidermal.[6] Because only 0.1% of skin

area is composed of appendages such as hair follicles and sebaceous glands, the epidermal route is thought to be the more important route of drug permeation.[5,6] Topical medications can diffuse through the epidermis transcellularly or intercellularly.[6] Transcellular transport is used by hydrophilic drugs, whereas intercellular diffusion occurs with lipophilic compounds.[5,6] The agent or vehicle used in a particular ototopical agent will affect its absorption and diffusion across the epidermis.

Topical Antibiotics

Extremely high local concentrations (3000 µg/mL for a 0.3% otic solution) of ototopical antibiotics can be achieved in the external canal. The minimum inhibitory concentrations (MICs) for antibiotics against common pathogens associated with external ear infections are typically less than 100, but can be in the mid-200's for resistant *Pseudomonas*.[7,8] The local concentrations associated with ototopicals are significantly higher than MICs for all pathogens that have been isolated from external ear infections, including resistant organisms.[7,8] In contrast, the local concentration of antibiotics in the *middle* ear after *oral* administration of amoxicillin, erythromycin, azithromycin, or cefixime (given in standard adult doses) may not be more than the MICs for the offending organisms, ranging from 1 to 15 µg/mL, although the concentration can be 35 µg/mL for intravenous ceftriaxone.[7,9-11] These levels were observed 4 hours after oral administration in human subjects and were measured in middle ear fluid samples obtained using tympanocentesis. No studies have examined the concentrations of antibiotics given systemically in the *external* ear; however, it is unlikely that they would be vastly different from the concentrations observed in the middle ear.

Topical Anti-inflammatories

The most commonly used prescription anti-inflammatories for external ear conditions also include an antibiotic or antifungal, although occasionally an otolaryngologist may prescribe a topical steroid alone for chronic pruritus or eczema. Most of the current understanding of how the steroid component of these preparations is absorbed regionally through topical application can be found in the dermatologic literature. The efficacy of a particular steroid preparation is associated with the inherent potency of the compound and its ability to penetrate the epidermis.[12] Lipophilic (nonpolar) preparations are transported across the stratum corneum more effectively than hydrophilic (polar) molecules.[12] The stratum corneum can also act as a reservoir for topical steroids, allowing for a prolonged regional effect after therapy is stopped.[5,12] Vehicles such as ethanol or propylene glycol increase the solubility of a topical agent to enhance permeability.[12] The hydration of the stratum corneum can also be enhanced by using occlusive vehicles such as ointments that improve drug penetration.[12]

Acute Bacterial Otitis Externa

See Chapter 137 for a definition and description of acute bacterial OE.

Topical Therapy Options for Acute Bacterial Otitis Externa

The most common bacterial pathogen is *Pseudomonas aeruginosa,* followed by *Staphylococcus aureus,* gram-negative bacteria, and anaerobes.[13-15] Treatment of acute OE often involves topical antibiotic preparations, with or without steroids. In mild acute or chronic OE, or as a preventive measure, acidifying agents may be used. Systemic antibiotics are indicated in severe or refractory cases, or in patients who are immunocompromised. Regardless of the therapy chosen to treat acute OE, removal of debris from the external canal and evaluation of the status of the tympanic membrane is crucial before using any ototopicals,[14,16-18] and oral analgesics are often needed in moderate or severe cases. Repeat débridement of the canal under binocular microscopy is essential to improve an infection that remains refractory to ototopical therapies.

In cases where the canal is extremely edematous, it may be impossible to visualize the tympanic membrane—care should be taken in this instance to avoid the use of ototopicals with potential ototoxic side effects.[16] Significant swelling and edema also requires wick placement to ensure proper delivery of ototopical antibiotics medially in the canal (Fig. 138-1). The wick should be changed or removed within 3 to 5 days of its insertion. If the canal is patent, tragal massage helps deliver the medication to the medial external auditory canal, and holding the head in a dependent position for several minutes allows for sufficient filling of the infected cavity.

Ototopical Antibiotics

Ototopical antibiotic preparations, with or without steroids, are the most common agents used to treat acute OE in the otolaryngology office. These preparations achieve local tissue concentrations approximately 1000 times that of systemic antibiotics, have a favorable side-effect profile, and show a lower incidence of bacterial resistance compared with systemic antibiotics.[7,14] The American Academy of Otolaryngology–Head and Neck Surgery Foundation (AAO-HNSF) developed a Clinical Practice Guideline in 2006 for the treatment of OE. The group made firm recommendations to use "topical preparations for initial therapy of diffuse, uncomplicated [acute OE]; [systemic] antimicrobial therapy should not be used unless there is extension outside of the ear canal or the presence of specific host factors that would indicate a need for systemic therapy" (e.g., diabetes, prior radiotherapy, or immunocompromise).[16]

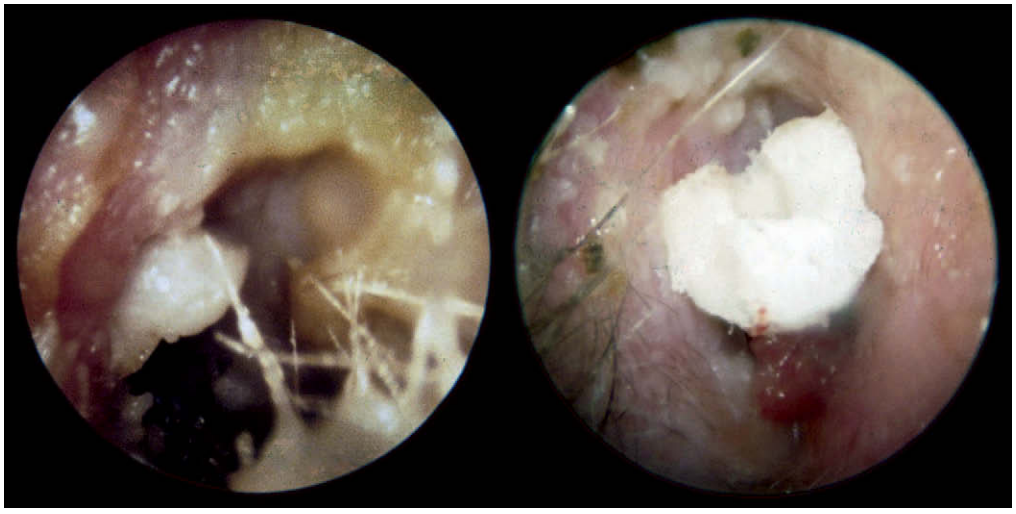

Figure 138-1. Acute otitis externa. Erythema, edema, and copious purulent debris are seen in the *left image*. In some cases, an edematous canal with granulation tissue (*right image*) necessitates the placement of an ear wick to assist topical drug delivery in the acute setting. *(Courtesy of John House, MD.)*

The following are commonly used preparations for the topical management of acute OE:

1. Cortisporin otic suspension and solution (neomycin + polymyxin + hydrocortisone 1%) have antibacterial and anti-inflammatory properties. The suspension is a milky white agent and has been a popular choice for uncomplicated bacterial acute OE for many years because of its efficacy, patient tolerance, and low cost. The suspension and solution each contain a 3.5-mg neomycin base, 10,000 polymyxin B units, and 10 mg of hydrocortisone 1% per mL. The suspension vehicle ingredients include cetyl alcohol, propylene glycol, polysorbate, and water; ingredients of the solution include cupric sulfate, glycerin, hydrochloric acid, propylene glycol, and water (Package insert, Cortisporin Otic Solution, 2003; Package insert, Cortisporin Otic Suspension, 2003, both from DSM Pharmaceuticals, Inc., Greenville, NC). The suspension has a less acidic pH (3.0 compared with 2.0 for the solution), and is better tolerated. Neomycin has been in use more than 40 years and is one of the oldest aminoglycosides. *Pseudomonas* has developed resistance to neomycin,[8,19] with less than 20% of *Pseudomonas* retaining sensitivity.[8] Polymyxins are cationic detergent antibiotics that disrupt the bacterial cell membrane. They work well against gram-negative rods, especially *Pseudomonas.* Although neomycin and polymyxin have ototoxic potential in animal studies, human data are equivocal.[14,20-23] The manufacturer recommends that Cortisporin otic should not be used in patients with tympanic membrane perforations (package insert, Cortisporin Otic Solution, 2003; package insert, Cortisporin Otic Suspension, 2003).

2. Ofloxacin (Floxin otic solution—ofloxacin 0.3%; benzalkonium chloride 0.0025%; sodium chloride 0.9%; water, pH 6.5) is a topical fluoroquinolone commonly used in acute OE. It can be used with tympanic membrane perforations and ventilation tubes because it has no known risk of ototoxicity,[4,24,25] making ofloxacin a reasonable choice for ear surgery prophylaxis. Ofloxacin otic is approved by the U.S. Food and Drug Administration (FDA) for use in patients with suppurative otitis media and perforated tympanic membranes (package insert, Floxin Otic, 1995, Daiichi Sankyo, Inc., Edison, NJ). Similar to all fluoroquinolones, ofloxacin acts by inhibiting DNA synthesis and bacterial growth by binding to DNA gyrase and topoisomerases. Commonly reported side effects include pruritus and bitter taste if used with a perforated tympanic membrane. Clinical cure rates for acute OE after treatment with ofloxacin have been shown to be greater than 80% in adults and greater than 95% in children.[24]

3. Ciprofloxacin + hydrocortisone (Cipro HC Otic—ciprofloxacin 0.2%; hydrocortisone 1%; benzyl alcohol as preservative) is a topical fluoroquinolone that also contains a steroid agent. It has broad-spectrum coverage, including *Pseudomonas,* although it has no activity against anaerobes. Ototoxicity has not been shown to be a concern with topical ciprofloxacin, and it is believed to be safe for use with tympanic membrane perforations.[26,27] Although many physicians use Cipro HC otic in the presence of tympanic membrane perforations, the manufacturer recommends against this because the bottle is nonsterile (package insert, Cipro HC Otic, 2002, Alcon Cusí, S.A. El Masnou, Barcelona, Spain, Alcon Laboratories, Fort Worth, TX).

4. Ciprofloxacin + dexamethasone (Ciprodex—ciprofloxacin 0.3%; dexamethasone 0.1%) also combines ciprofloxacin with a steroid for anti-inflammatory properties. It is safe for use with tympanic membrane perforations, and is FDA approved for use in patients with patent tympanostomy tubes (package insert, Ciprodex Otic Suspension, 2002, Alcon Laboratories, Fort Worth, TX). Ciprodex has been shown in randomized clinical trials to be more effective at resolving acute OE than neomycin/polymyxin/hydrocortisone,[28] and has been shown in a large randomized blinded study to be superior to ofloxacin in treating acute otitis media with otorrhea through tympanostomy tubes.[29] There is no study directly comparing Ciprodex with Cipro HC otic suspension in humans, although Sobol and colleagues[30] showed in an animal model that Ciprodex was superior to Cipro HC at treating granulation tissue in the external and middle ear.

5. Tobramycin + dexamethasone (Tobradex—tobramycin 0.3%; dexamethasone 0.1%; benzalkonium chloride 0.01% as a preservative) is an ophthalmic preparation with antibacterial and anti-inflammatory activity. Tobramycin is an aminoglycoside that binds to the 30S and 50S ribosomal subunits leading to a defective bacterial cell membrane. It should be avoided in patients with tympanic membrane perforations or tympanostomy tubes because of possible ototoxicity.[31-33]

6. Gentamicin (Garamicin Ophthalmic—gentamicin 0.3%, pH 7) is another ophthalmic solution that can be used in acute OE, especially when additional gram-negative coverage is needed. Gentamicin should be avoided with tympanic membrane perforations because of concerns of ototoxicity.[31-33]

Evidence-based Data on Ototopical Antibiotics in Acute Otitis Externa

Roland and colleagues[28] performed one of the few randomized multicenter studies comparing ototopical antibiotics. The clinical efficacy of 1 week of ciprofloxacin/dexamethasone (Ciprodex) or neomycin/polymyxin B/hydrocortisone (Cortisporin) was studied in 468 adults and children with acute OE and intact tympanic membranes. Ciprofloxacin/dexamethasone showed higher bacterial eradication rates and more rapid symptom improvement compared with neomycin/polymyxin B/hydrocortisone. Rahman and coworkers[34] also compared the efficacy of Ciprodex and Cortisporin drops in 1072 adults and children with acute bacterial OE in a multicenter, randomized, prospective, blinded trial. Cortisporin dosed three times daily and Ciprodex dosed twice daily for 7 days resulted in a 98% cure rate at 18 days for Ciprodex and a 97% cure rate for Cortisporin. The time to cure was 0.6 days shorter for Ciprodex.[34]

van Balen and associates[35] performed a randomized clinical trial of ototopical therapies that compared acetic acid alone, acetic acid and corticosteroid, and antibiotic and corticosteroid for acute OE. In 213 adults with acute OE, patients who received preparations that included steroids (either acetic acid or antibiotics) had significantly higher cure rates compared with acetic acid alone.[35] The acetic acid–alone group also had higher recurrence rates of OE.[35] Schwartz[36] performed a randomized multicenter blinded study in which patients with acute OE received either ototopical ofloxacin administered *once* daily or neomycin/polymyxin/hydrocortisone administered *four* times daily. In 278 pediatric patients with pseudomonal OE, both agents were *equally* effective at eradicating disease and had similar safety profiles.[36] Given the decreased ototoxic potential of ofloxacin and the easier dosing schedule, the authors concluded that ofloxacin might be a better first-line agent,[36] although neomycin/polymyxin/hydrocortisone is significantly less expensive than ofloxacin. The same conclusion was reached by Simpson and Markham[24] in a meta-analysis of the literature concerning ofloxacin use for acute OE.

Rosenfeld and colleagues[37] found 18 studies concerning ototopical therapy for acute OE that compared any of the following groups: antimicrobial versus placebo, antiseptic versus antimicrobial, fluoroquinolone antibiotic versus antibiotic, steroid/antimicrobial versus antimicrobial, or antimicrobial/steroid versus steroid. Clinical cure rates were 65% to 80% within 10 days of therapy with all of the above-mentioned ototopical antibiotics, and there was no statistical difference in *clinical* cure rates among any of the treatment groups.[37] Fluoroquinolones did have an 8% higher *bacteriologic* cure rate compared with nonquinolone ototopicals; however, the clinical cure rate and rates of adverse side effects were the same as those of the other preparations.[37] The addition of a steroid to fluoroquinolone agents decreases the symptomatic period by approximately 0.8 days[1,3] As discussed subsequently, however, steroids do have a small risk of causing a hypersensitivity reaction.

Resistance Associated with Ototopical Antibiotic Therapy

Weber and colleagues[38] found that there is overall grade B evidence (at least fair scientific evidence suggests that the benefits of the clinical service outweigh the potential risks) that no significant antibiotic resistance develops from the use of ototopical antibiotic therapy. Cantrell and colleagues[19] examined the susceptibility of isolates from acute OE to neomycin/polymyxin and ofloxacin. The MICs of each antimicrobial drug for the major pathogens (*Pseudomonas* and *Staphylococcus aureus*), bacterial eradication, and clinical efficacy were studied from 1995-1996 and from 1999-2000.[19] The MICs for all pathogens increased above the breakpoint for polymyxin B in the data from 1999-2000, but the MICs of all isolates for ofloxacin remained similar between the two time periods, indicating that resistance developed to neomycin/polymyxin, but not to ofloxacin.[19] In 2003, Wai and Tong[25] noted that minimal resistance had been documented against ofloxacin since its initial use in the 1980s, and mentioned that only two strains of *Pseudomonas* have been shown to have slight resistance to ofloxacin. Contrary to these findings, Jang and Park[39] examined 88 patients with chronic suppurative otitis media that was refractory to treatment with topical ciprofloxacin and found that *Pseudomonas* isolates in all cases were resistant to topical ciprofloxacin. There is still ongoing concern and debate over the possibility of bacterial resistance to Cortisporin *and* ofloxacin drops, and this is an area that needs to be studied further in years to come. At this time, owing to extremely high local concentrations achieved with topical therapies that far exceed even the highest MICs for resistant *Pseudomonas,* it is unlikely that resistance would be a large factor in the choice of ototopical antibiotics.

Acidifying Agents in Acute Bacterial Otitis Externa

Acidifying agents may be used in mild acute or chronic cases of OE where there is minimal otalgia, but their main usefulness is in the preventive care of patients prone to developing recurrent acute or chronic OE (e.g., swimmers, hearing aid users). Alkaline pH has been shown to be a risk factor for the development of acute and chronic OE[40,41]; restoring the natural acidity of the external canal can inhibit the growth of bacteria responsible for OE. The acidic pH of these preparations may also limit patient compliance because of pain and local irritation.[18] These agents are contraindicated if a tympanic membrane perforation or tympanostomy tube is present because of possible ototoxicity.[3,42]

The following are commonly used acidifying solutions for treatment of mild OE, treatment of chronic OE or preventive care of the external canal:

1. Alcohol-vinegar solution contains ½ alcohol, ¼ white vinegar, and ¼ distilled water. Typically, several drops (4 to 5) are used in the affected ear two to four times daily until symptoms resolve and can be easily delivered with a syringe. This solution is contraindicated in patients with tympanic membrane perforations or ventilation tubes, or if the patient has a hypersensitivity to any of the components.

2. Acetic acid in aluminum acetate drops (Domeboro) may be used in mild cases of OE to help acidify and dry the canal. Five drops are applied to the affected ear two to four times daily. This solution should not be used if a tympanic membrane perforation or ventilation tube is present (package insert, Bayer Corp, West Haven, CT, 1995).[42]

3. Propylene glycol and acetic acid otic solution (VoSol) and hydrocortisone 1% propylene glycol acetic acid otic solution (VoSol HC) also work well in superficial infections. The acetic acid has antibacterial properties, whereas the hydrocortisone helps reduce inflammation and pruritus. Both of these preparations are quite viscous and have a pH of approximately 3. Two to four drops are applied two to four times daily. This solution should not be used in the setting of a tympanic membrane perforation or ventilation tube because of concern for ototoxicity (package insert, Wallace Labs, Cranbury, NJ, 1999).[43]

Table 138-1

Considerations if Acute Otitis Externa Fails to Respond to Initial Ototopical Therapy

Self-instrumentation trauma
Malignant external otitis
Contact dermatitis
Failure to adhere to preventive measures such as avoiding water in the ear
Improper administration of ototopical
Immunosuppression resulting from diabetes, or prior radiotherapy
Inadequate penetration of ototopical owing to debris or thickened canal skin
Misdiagnosis such as psoriasis, cancer, or tuberculosis
Organism resistant to ototopical choice

Systemic Therapy for Acute Bacterial Otitis Externa

The AAO-HNSF recommends adding a systemic antibiotic in patients with OE and a history of prior radiation therapy, diabetes, or immunocompromised state.[16] Patients with concomitant parotitis or cellulitis extending to the auricle, face, or neck, and patients with concurrent otitis media without tympanic membrane perforation or tympanostomy tube also should receive oral antibiotics. Finally, patients who fail to respond to a full course of ototopicals may benefit from oral antibiotics.[7,15,16,18] It may be prudent to obtain a culture in patients with refractory OE before starting oral antibiotics, or before starting topical therapy in patients with underlying immunocompromise.

Special Considerations in Chronic Bacterial Otitis Externa

When initial therapy fails to treat acute OE, the physician should consider not only the possibilities of improper administration or ineffectiveness of the ototopical, but also other possible diagnoses, such as malignant OE, underlying canal cholesteatoma, keratosis obturans, contact dermatitis, and malignancy (Table 138-1).[14] Symptoms lasting longer than 3 months may indicate chronic OE. This condition can be the result of inadequately treated infectious OE, but noninfectious causes should also be considered and are discussed subsequently in the section on eczematoid OE.[14,44] In chronic OE, topical antibiotic therapies may not be as effective in resolving long-standing inflammation. Daily irrigation with an acidifying or dehydrating agent and use of a hair dryer on a low, cool setting after water exposure help to optimize daily ear hygiene. Dry powder preparations (discussed subsequently) are a reasonable alternative to topical drops because continued moisture from long-term ototopical use can contribute to maceration of the external canal skin and chronic infection. Topical steroid creams have been used with topical antibiotics to improve the efficacy of treatment in chronic OE.

Ototoxicity Associated with Topical Antibiotics

The possible risk of ototoxicity with the use of topical antibiotics, particularly aminoglycosides (gentamicin, neomycin, streptomycin), continues to be a concern. Free radicals are generated by aminoglycosides in the inner ear that can injure vestibular and cochlear hair cells. Two mutations in the mitochondrial 12S ribosomal RNA gene have been reported to predispose carriers to aminoglycoside-induced ototoxicity.[31] The vestibulotoxic and cochleotoxic side effects were initially recognized after systemic use of aminoglycosides, and subsequent research has examined their toxicity when used in topical form. Animal studies performed since the 1950s have consistently confirmed the ototoxic potential of topical aminoglycosides. Wright and Meyerhoff[20] showed near-total destruction of all the hair cells in the inner ear of the chinchilla with only a single application of neomycin, polymyxin, or chloramphenicol.

No large randomized controlled trials examine the issue of ototoxicity from topical antibiotic therapy in humans. The data that do exist from human studies are equivocal, and the incidence of topical aminoglycoside–associated ototoxicity may be only approximately 1 in 10,000 patients.[4,45] Possible explanations for this difference in ototoxicity between humans and animals are that humans have thicker round window membranes, a deeper round window niche (providing greater protection), and often a pseudomembrane (mucous membrane) overlying the round window that may minimize topical absorption.[7] Polymyxin, a component of Cortisporin otic drops, has ototoxic properties in animal studies (even more so than neomycin), and may have ototoxic potential in humans in the presence of tympanic membrane perforations.[20,46] In contrast to aminoglycosides and polymyxin, no ototoxicity from fluoroquinolones has been reported in animals or humans.[25]

In 2007, the Clinical Audit and Practice Advisory Group of the British Association of Otolaryngologists–Head and Neck Surgeons (ENT-UK) reviewed the literature with the goal of establishing a clinical guideline for the use of aminoglycosides in acute OE in humans. They found no convincing data regarding the ototoxicity of topical aminoglycosides, but recommended that these agents should be used only in the presence of obvious infection and for no longer than 2 weeks.[47]

Linder and associates[48] examined 134 patients who were evaluated for possible ototopical antibiotic–related ototoxicity, and found only two patients with significant sensorineural hearing loss attributable to excessive administration of framycetin-containing and polymyxin-containing ear drops in the presence of tympanic membrane perforations. Matz and colleagues[49] performed a review of the literature and found 14 articles that dealt directly with the evaluation of either hearing loss or changes in vestibular function after the use of ototopical antibiotic drops. Although most articles were in the level 3 to 3b evidence category (*opinions* of respected authorities based on clinical experience, descriptive studies, or reports of expert committees), two were in the 1b category (evidence obtained from at least one properly designed randomized controlled trial). Fifty-four cases of gentamicin-induced vestibular toxicity were documented, and cochlear toxicity was noted in 24 of these patients. Eleven cases of cochlear toxicity and 2 cases of vestibular toxicity associated with neomycin-based ototopicals were also observed.[49]

Berenholz and coworkers[50] performed a retrospective review of 500 patients who received Cortisporin drops after ventilation tube placement. They found no cases of new-onset sensorineural hearing loss, and noted that Cortisporin drops were less than half as expensive as topical fluoroquinolones. A Cochrane Database article in 2006 addressed the safety concerns of ototopicals and found no adequate evidence to suggest ototoxicity for either Cortisporin or fluoroquinolone drops.[51]

A consensus panel of the AAO-HNSF made recommendations in 2004 on the use of topical aminoglycosides in the middle ear or in the presence of tympanic membrane perforation.[4] The panel determined that, whenever possible, "topical antibiotic preparations free of potential ototoxicity should be used in preference to ototopical preparations that have the potential for otologic injury if the middle ear or mastoid are open." They pointed out that aminoglycoside topical agents are not FDA approved for use in the middle ear, and warning labels from the manufacturer state that they should not be used if the tympanic membrane is perforated. The panel did agree that the potential ototoxic side effects of aminoglycosides are quite infrequent, and that the data from human trials are equivocal, but determined that because antibiotics without any known ototoxic potential are available and are efficacious, they should be considered as a first-line treatment.[4] Finally, evidence exists that combining aminoglycoside ototopicals with steroids (i.e., TobraDex) results in significantly less ototoxicity than using the aminoglycoside alone,[52] indicating that the combination drops may be a better option if an aminoglycoside is indicated.

Hypersensitivity Associated with Ototopical Antibiotics

In addition to the potential for ototoxicity, the possibility of drug hypersensitivity reaction may help to guide the selection of antibiotic preparations for treatment of OE. Patients who present with a hypersensitivity reaction complain of pruritus and tenderness of the ear associated with clear otorrhea. Examination often reveals an erythematous, maculopapular rash associated with edema and thickening of the external auditory meatus and conchal bowl where pooling of the topical preparation has occurred. Neomycin is the most common sensitizer, followed by gentamicin.[53] Smith and coworkers[54] showed an incidence of 32% neomycin hypersensitivity in patients with chronic OE. Other studies report a lower incidence ranging from 5% to 18%.[14,55]

Millard and Orton[22] found that in 45 patients with documented drug-induced hypersensitivity reactions, 76% of those were due to neomycin, followed by framycetin and gentamicin. Holmes and colleagues[56] performed patch testing on 40 patients with chronic OE and found that 35% had a medication-induced allergic contact dermatitis. Neomycin, framycetin, clioquinol, and gentamicin were the major sensitizers in this study.[56] Finally, aminoglycosides are capable of cross-sensitization, so careful selection of alternative therapies should be made when a patient develops a reaction to one member of this class.

Hypersensitivity to steroid preparations has also been documented, but is significantly less common (<0.1% for hydrocortisone). Lauerma[57] performed patch testing using three different corticosteroids on 727 patients, and found that 3.9% reacted to tixocortol pivalate, 1.4% to hydrocortisone butyrate, and 0.4% to hydrocortisone. Preservatives such as benzalkonium chloride, thimerosal, and propylene glycol (which also increases the solubility of the drug in the epidermis) can also incite local sensitization and should be considered as possible culprits if topical therapy does not resolve otorrhea.[14,18,55]

Fungal Otitis Externa

For a definition and description of fungal OE, see Chapter 137.

Topical Therapy Options for Fungal Otitis Externa

The treatment of choice for fungal OE includes thorough débridement followed by topical application of antifungal agents.[58-60] As with bacterial OE, acidification of the external canal with ototopical preparations is effective at clearing mild cases of otomycosis. The acidification helps inhibit bacterial and fungal growth. Re-establishing a dry external auditory canal with routine hygiene, water precautions, and maintenance irrigations with acetic acid or mild alcohol solutions (in the setting of an intact tympanic membrane) is important to prevent recurrent fungal OE. Refractory fungal OE may require more specific antifungal preparations.

Acidifying Agents for Fungal Otitis Externa

Aluminum acetate otic drops (Burow's solution), acetic acid/propylene glycol/hydrocortisone 1% (VoSol HC), acetic acid (Domeboro Otic), and boric acid solution all are acidifying agents that are commonly used to treat uncomplicated otomycosis. Acidifying agents have been shown to treat most mild cases of fungal OE successfully, especially when combined with thorough débridement of the external canal. Ho and colleagues[58] found that aluminum acetate drops were greater than 80% effective in mild cases of fungal OE. del Palacio and associates[61] also confirmed that boric acid solution was as effective as antifungal 11% ciclopirox olamine cream (or 1% solution) in treating patients with otomycosis, but that the boric acid group had significantly more discomfort. Kiakojuri and colleagues[62] showed in a prospective study that acidification of the canal in combination with topical antifungals (miconazole) did not improve efficacy compared with miconazole alone.

Topical Antifungals for Fungal Otitis Externa

The following are commonly used antifungal preparations for the topical management of fungal OE:

1. Clotrimazole (Lotrimin, Mycelex) cream: Ologe and Nwabuisi[59] showed a 96% symptom-free rate after a single application of clotrimazole cream following débridement of the canal. Complications were rare, and included a recurrence rate of less than 3%. The one-time application required is tolerated well by most patients and

is cost-effective. Stern and colleagues[60] showed that clotrimazole 1% cream was effective against all common fungal pathogens in vitro when measuring zones of inhibition of various antifungals. Similar to Stern and colleagues,[60] Maher and coworkers[63] showed that clotrimazole was effective against the large variety of fungi isolated from clinical otomycosis specimens. Greater than 94% of the 59 fungus species had MICs less than 0.1 μg/mL, and for the remaining 6% MICs were between 0.4 μg/mL and 1 μg/mL.[63]

2. Miconazole 2%: Kiakojuri and colleagues[62] showed in a prospective trial that miconazole was effective at treating otomycosis, and that the addition of acidifying drops (acetic acid 3% + alcohol 97%) did not significantly improve outcome.

3. Ketoconazole: Ho and colleagues[58] showed that ketoconazole had a better efficacy and lower recurrence of otomycosis compared with Cresylate otic and aluminum acetate.

4. Tolnaftate (Tinactin): Maher and coworkers[63] showed in an in vitro study the efficacy of tolnaftate and clotrimazole. The MIC for each of the drugs was <1 μg/mL for all 59 species of fungi tested from patients with otomycosis.

5. Nystatin is a polyene antifungal agent that damages fungal membranes by altering permeability. It can be used as a topical suspension, cream, or powder. Stern and colleagues[60] found that nystatin had the widest range of activity against a variety of pathogens when measuring the zones of inhibition of various antifungals.

6. Ciclopirox olamine 0.77% antifungal cream or solution: del Palacio and associates[61] in a randomized prospective trial showed ciclopirox olamine 0.77% to have equal efficacy compared with boric acid, but was better tolerated by patients.

Topical Antiseptics for Fungal Otitis Externa

The following are commonly used topical antiseptics for the management of fungal OE:

1. Cresylate otic drops 25%: Ho and colleagues[58] determined Cresylate otic drops to be greater than 80% effective.

2. Gentian violet: Gentian violet is useful in refractory cases, but should be avoided with perforated tympanic membranes.

3. Merbromin (Mercurochrome): Chander and associates[64] found merbromin to be more effective than clotrimazole or miconazole.

4. Silver nitrate gel 1%: van Hasselt and Gudde[65] found in a prospective randomized trial that a single application of 1% silver nitrate gel cured 92% of ears with refractory otomycosis within 1 week.

Ototoxicity Associated with Topical Antifungal Therapy

Ototoxicity of topical antifungal therapies has not been well studied. Tom[23] showed that clotrimazole, miconazole, and tolnaftate had no ototoxic effects when applied to the middle ear of guinea pigs compared with normal controls and animals that received topical neomycin (an agent known to cause ototoxicity) applied to the middle ear. Nystatin likewise had no ototoxicity, but did leave a persistent residue at the round window niche. Gentian violet was found to be extremely ototoxic.[23] Marsh and Tom[66] observed that preparations containing acetic acid or propylene glycol caused elevation of brainstem response thresholds when applied to the middle ear of guinea pigs, whereas clotrimazole and tolnaftate had no ototoxic effects.

Myringitis

Definition

Myringitis is an inflammatory condition of the tympanic membrane and can be acute or chronic. Acute bullous or hemorrhagic myringitis can be the consequence of a bacterial infection, such as *Streptococcus pneumoniae* or *Staphylococcus* species, or a viral infection, such as influenza or herpes zoster. Fungal myringitis, eczematoid myringitis, and granular myringitis may also occur.

Topical Therapy Options

Treatment of myringitis depends on the etiology. For acute primary bacterial myringitis, or myringitis associated with acute otitis media, oral antibiotics are the primary therapy. Systemic antibiotics should be directed against the most common pathogens associated with otitis media, *S. pneumoniae* and *Haemophilus influenzae.* For individuals with acute OE, standard therapy includes topical antibiotic and steroid ear drops. The topical preparations mentioned earlier are effective in treating external canal disorders with associated myringitis. Kaga and Ichimura[67] performed a small pilot study examining the efficacy of ofloxacin on infantile myringitis and chronic otitis media. Treatment with twice-daily ofloxacin eradicated the causative pathogen in most of the 21 patients examined in their cohort.[67] For fungal infections involving the tympanic membrane, the topical antifungals mentioned earlier are the mainstay of treatment. Treatment for chronic myringitis may include antibiotic ear drops, but may also respond to acetic acid ear canal irrigations followed by application of steroid cream.

Granular myringitis is a chronic inflammatory condition of the epidermal layer of the tympanic membrane and may be treated with surgical removal, chemical cauterization, or vinegar irrigations—although no large randomized controlled studies address this question.[68] Jung and colleagues found a 96% reduction in granular myringitis recurrence with daily dilute vinegar irrigations in a sample size of 15 patients.[68a]

Eczematoid Otitis Externa

See Chapter 137 for a definition and description of eczematoid OE.

Management Options in Eczematoid Otitis Externa

When identified, offending agents (i.e., lotions, jewelry, foods, ototopicals) related to eczematoid OE should be avoided, but there are often significant delays in diagnosis because of the similarities in presentation between infectious and noninfectious causes of OE. Careful débridement of the affected ear under microscopy and management of any associated infection are crucial; it is also crucial to use appropriate ototopical antibiotics when a superimposed bacterial infection is present (and when the possibility of sensitivity to a previously used ototopical has been eliminated).

If the elimination of possible sensitizing agents and ear hygiene are unsuccessful in managing eczematoid OE, anti-inflammatory medical therapy is warranted. Topical glucocorticoids are the gold standard for management of eczematous OE. Many steroid preparations are available and are frequently prescribed to help reduce inflammation and skin flaking and to decrease pruritus. Refractory cases may warrant systemic steroids and a referral to a dermatologist and a rheumatologist.

Steroids for Eczematoid Otitis Externa

Jacobsson and colleagues[69] performed a double-blinded study of 60 patients with eczematoid OE who were randomly assigned to a placebo group or a treatment group in which they received therapy with budesonide (a glucocorticoid). The treatment group had significant improvement of erythema, edema, and drainage compared with the placebo group.

No clinical trials have explored the efficacy of the different steroid preparations in the treatment of eczematoid OE; however, it may be possible to extrapolate findings from the dermatology literature. Juhlin[70] performed a randomized, double-blind, parallel-group study of 120 patients to examine the efficacy of fluticasone propionate cream 0.05% and hydrocortisone butyrate cream 0.1% in the treatment of eczema. Both preparations had minimal side effects, and there was no statistically significant difference in efficacy at reducing the severity of eczema. James[71] performed a randomized, double-blind trial of 125 patients to compare the same two preparations (fluticasone propionate cream 0.05% and hydrocortisone butyrate cream 0.1%) in the treatment of psoriasis. In this study, fluticasone propionate cream was superior to

hydrocortisone butyrate cream. Ashton and coworkers[72] compared 0.25% and 0.05% desoxymethasone, 0.1% betamethasone valerate, and 1% hydrocortisone creams in the treatment of eczema in a randomized controlled trial of 96 patients. The 0.25% desoxymethasone cream was the most effective treatment, hydrocortisone was the least effective, and 0.05% desoxymethasone and 0.1% betamethasone were of intermediate effectiveness.

Fluocinolone acetonide oil 0.01% (DermOtic Oil) is currently the only FDA-approved treatment for chronic pruritus of the external ear. The manufacturer states that the peanut oil vehicle moistens the ear canal and loosens cerumen, and the corticosteroid reduces irritation and inflammation. It is approved for patients older than 2 years, and twice-daily usage for 2 weeks is recommended. In clinical studies sponsored by the manufacturer, 90% of patients had near-resolution of their symptoms within 2 weeks.[73]

Generally, it is reasonable to start with a readily available, over-the-counter mild topical glucocorticoid such as hydrocortisone 1% for a patient with eczematous OE. If the initial treatment regimen fails, changing to a more potent glucocorticoid is a reasonable option.

Classes of Topical Steroids

The strength of a steroid is determined by a standardized test that measures the extent to which it can cause blood vessels to constrict in the upper dermis. Table 138-2 lists some popular steroids in each class in order of decreasing potency.

Ototoxicity Associated with Ototopical Steroid Use

Ototoxicity has not been documented from the topical use of glucocorticoids. Multiple studies have shown that they may have a protective effect on inner ear function. Ye and coworkers[74] and Kiefer and colleagues[75] showed that round window application of triamcinolone has no ototoxic effect in a gerbil model, and that intracochlear application via a cochleostomy resulted in an increased recovery of cochlear function after surgical trauma. Intratympanic injections of high-dose steroids such as dexamethasone or methylprednisolone are used to treat idiopathic sudden sensorineural hearing loss.[76-78] Kiliç and associates[79] showed in a prospective randomized controlled trial of 37 patients that intratympanic injection of methylprednisolone improved hearing results in patients who failed a trial of oral steroids for sudden sensorineural hearing loss. Xenellis and colleagues[80] confirmed these results in their randomized controlled prospective trial of 37 patients with sudden sensorineural hearing loss who also failed oral steroid treatment. These studies are small, but many in vitro and in vivo studies have supported an otoprotectant role of topical steroids.

Anti-inflammatory and Immunosuppressive Agents

Tacrolimus (FK-506, Fujimycin, Protopic) is a macrolide immunosuppressant drug that inhibits calcineurin, inhibiting T-lymphocyte signal transduction and interleukin-2 transcription. It has been shown to be as effective as some moderate-strength steroids, and can be used for long periods because it does not have the same side-effect profile of topical steroids that includes skin atrophy. It can also be used in regions of fragile or sensitive skin. Side effects include burning, pruritus, flulike symptoms, and headache.[81,82] Randomized controlled prospective trials have shown that topical 0.03% and 0.1% tacrolimus ointments were more effective than 1% hydrocortisone acetate and similarly effective as 0.1% hydrocortisone butyrate and 0.1% methylprednisolone aceponate ointments in adults and children with moderate to severe atopic dermatitis.[83,84]

Caffier and associates[81] and Harth and coworkers[82] studied the efficacy of tacrolimus ointment for chronic noninfectious OE in a prospective trial of 53 patients whose disease was refractory to standard management. Otowicks infused with tacrolimus ointment were placed every 2 to 3 days for a total of three treatments. In the short-term, 85% of the patients had significant improvement in otalgia, edema, otorrhea, erythema, pruritus, and desquamation. In the 10- to 22-month follow-up, 46% of patients had no relapsing symptoms, and the 54% of patients who did have relapses had longer symptom-free periods.[81,82]

Pimecrolimus cream 1% is also a calcineurin inhibitor and is used in milder cases of dermatitis. Pimecrolimus is more highly skin-selective than tacrolimus (which is also used as a general immunosuppressant for transplant patients). It has fewer side effects than topical steroids, has a better side-effect profile than tacrolimus, is safe in infants, and is safe for intermittent long-term therapy of dermatitis.[85,86] The direct drug cost of pimecrolimus compares favorably with tacrolimus, but it is significantly more expensive than generic topical steroid creams.[86] Djalilian and Memar[87] performed a retrospective chart review of 36 patients with pruritic external ears who were treated with 3 months of topical pimecrolimus ointment. Thirty-four of 36 patients experienced significant improvement in pruritus compared with a group of 19 control patients who received only aural hygiene.[87]

For the treatment of eczematous OE and pruritic ears, some clinicians still depend on an old remedy, coal tar, although no randomized controlled trials exist to prove its efficacy in treating this disorder. Coal tar has been used for more than 100 years, and was the mainstay for treating inflammatory skin conditions before the development of topical steroids.[88] Coal tar has anti-inflammatory, antibacterial, antipruritic, and antimitotic effects; common short-term side effects are folliculitis, irritation, and contact allergy. Hoare and colleagues[89]

Table 138-2

Potencies of Topical Steroids

Group I (*Most Potent*)
Clobetasol propionate 0.05% (Temovate)
Betamethasone dipropionate 0.25% (Diprolene)
Halobetasol propionate 0.05% (Ultravate)
Diflorasone diacetate 0.05% (Psorcon)

Group II
Fluocinonide 0.05% (Lidex)
Halcinonide 0.05% (Halog)
Amcinonide 0.05% (Cyclocort)
Desoximetasone 0.25% (Topicort)

Group III
Triamcinolone acetonide 0.5% (Kenalog, Aristocort cream)
Mometasone furoate 0.1% (Elocon ointment)
Fluticasone propionate 0.005% (Cutivate)
Betamethasone dipropionate 0.05% (Diprosone)

Group IV
Fluocinolone acetonide 0.01-0.2% (Synalar, Synemol, Fluonid)
Hydrocortisone valerate 0.2% (Westcort)
Hydrocortisone butyrate 0.1% (Locoid)
Flurandrenolide 0.05% (Cordran)
Triamcinolone acetonide 0.1% (Kenalog, Aristocort A ointment)
Mometasone furoate 0.1% (Elocon cream, lotion)

Group V
Triamcinolone acetonide 0.1% (Kenalog, Aristocort cream, lotion)
Fluticasone propionate 0.05% (Cutivate cream)
Desonide 0.05% (Tridesilon, DesOwen ointment)
Fluocinolone acetonide 0.025% (Synalar, Synemol cream)
Hydrocortisone valerate 0.2% (Westcort cream)

Group VI
Alclometasone dipropionate 0.05% (Aclovate cream, ointment)
Triamcinolone acetonide 0.025% (Aristocort A cream, Kenalog lotion)
Fluocinolone acetonide 0.01% (Capex shampoo, Derma-Smoothe/FS)
Desonide 0.05% (DesOwen cream, lotion)

Group VII (*Least Potent*)
Hydrocortisone 2.5% (Hytone cream, lotion, ointment)
Hydrocortisone 1% (many over-the-counter brands)

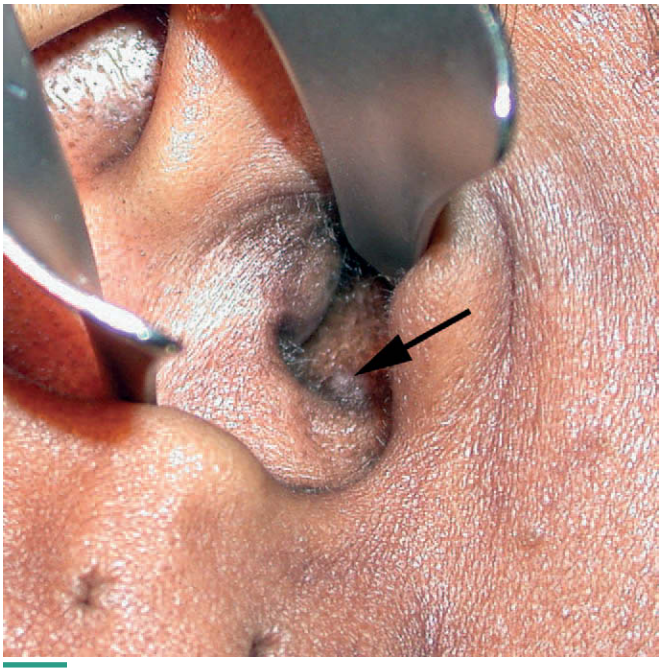

Figure 138-2. Human papillomavirus infection of the right external auditory canal. The previous biopsy site is seen in the posterior-superior quadrant. This otherwise healthy woman presented with chronic pruritus bilaterally and muffled hearing, and no previous history of human papillomavirus infection. Examination revealed numerous, circumferential papillomas of the lateral external auditory canal bilaterally. She was referred to a dermatologist for treatment with topical immune-response modifiers. The *arrow* points to a papilloma.

performed a meta-analysis on the treatments for atopic eczema and determined there is insufficient evidence to make recommendations on the use of coal tar in the treatment of the disease. Potential carcinogenicity of coal tar is still a concern, although there is no clear evidence of an increased risk of skin tumors or internal tumors in randomized clinical trials using coal tar for eczema.[90]

Viral Infections

Viral lesions of the external ear are extremely rare. In aural papillomatosis, papillomas fill the external auditory canal (Fig. 138-2). Human papillomavirus type 6 (HPV-6) has been shown to be the cause of aural papillomatosis.[91] Middle ear inverting papillomas are rarely described in the literature, and may extend through a tympanic membrane perforation into the external canal.

Management Options

Only a few cases of aural papillomatosis have been reported, and successful treatment has involved primary resection.[92] Blair and colleagues[93] managed a patient with aural papillomatosis with CO_2 laser removal. Yadav and associates[94] treated a 3-year-old patient with surgical excision of the external canal aural papillomatosis. No trials exist to document the use of topical therapies for aural papillomatosis; however, the immune-response modulator imiquimod 5% (Aldara) has been used topically with good success in treating HPV-6-associated papillomatosis of the external genitalia.[95] Topical treatment with imiquimod 5% three times weekly for 16 weeks resulted in 50% complete resolution of disease and 74% partial resolution of disease in randomized, controlled trials.[95] Mild localized side effects of imiquimod include erythema, itching, and burning, and are the most commonly reported adverse events, occurring in 67% or less of patients applying imiquimod 5% cream three times a week in a meta-analysis of the literature.[96] Based on these data, topical imiquimod therapy may be a reasonable nonsurgical option for aural papillomatosis. Imiquimod is currently being used by some practitioners to minimize keloid recurrence after excision from the auricle.[97,98] These studies are small and uncontrolled so far, but have shown that there are no significant side effects other than mild localized skin irritation with the use of topical imiquimod 5% on the external ear.[97,98]

Cerumen Impaction

Cerumen impaction is an extremely common problem for which patients seek otolaryngologic advice and treatment because it can cause discomfort, hearing loss, tinnitus, dizziness, and chronic cough.[99] Cerumen impaction is present in approximately 10% of children, 5% of healthy adults, 57% of elderly patients in nursing homes, and 36% of patients with mental retardation.[100] Chronic manipulation with cotton-tip applicators, narrow external canals, hair in the lateral canal, hearing aids, and earplug use have been associated with an increased incidence of cerumen impaction. Cerumen removal is the most common otolaryngologic procedure performed in the primary care setting.[99,101]

Therapy Options

Many approaches for removing cerumen, including manual débridement, irrigation, and ceruminolytics, have been described in the literature. There are, however, no data from large randomized prospective trials comparing the efficacy of the different methods of cerumen removal. Manual removal and irrigation are effective, but may risk trauma to the canal skin, infection, or tympanic membrane perforation. Irrigation should not be done if a tympanic membrane perforation or myringotomy tube is present.

Initial treatment of cerumen impaction with ceruminolytics is reasonable in most cases. There are three types of cerumen-softening preparations: water-based, oil-based, and non–water-based/non–oil-based (Table 138-3). Water-based and non–water-based/non–oil-based agents increase cerumen miscibility, whereas oil-based preparations lubricate the wax. All agents should be avoided in patients with tympanostomy tubes or tympanic membrane perforation; manual removal of cerumen, ideally using a binocular microscope, may be the best option for this population.

Comparing ceruminolytics, Hand and Harvey[102] concluded in their review of the literature that triethanolamine was better than saline, and that longer treatment duration with softening agents was better than a shorter duration in overall efficacy of treating cerumen impaction. These authors also noted that docusate sodium was not statistically better than triethanolamine or saline.[102] Roland and associates[103] found no statistical difference in resolution of cerumen impaction in 74 patients randomly assigned to saline, Cerumenex, or Murine ear wax removal products, and Whatley and coworkers[104] found no difference among saline, Colace, and triethanolamine.

The use of ceruminolytics before irrigation may increase the success of irrigation by 97%.[102] Use of a ceruminolytic agent 15 to 30 minutes before irrigation was found to be as effective as several days of treatment,[105] and a water-based agent (water, saline, or triethanolamine) was found to be superior to carbamide peroxide (a non–water-based/non–oil-based preparation) before irrigation.[102] Overall, no ceruminolytics when used immediately before irrigation seemed to be superior to saline, making saline an inexpensive first-line agent. McCarter and colleagues[99] stated that "based on current evidence, if treatment with a ceruminolytic agent followed by irrigation is chosen, an initial attempt at irrigation with water should be made. If irrigation is unsuccessful, the water should be instilled and left in the external auditory canal for 15 to 30 minutes, after which another attempt at irrigation should be made. If this second attempt is also unsuccessful, it would be reasonable to use a ceruminolytic for two to three days, followed by another trial of irrigation."[106]

Ear Hygiene and Chronic Draining Ear

In patients with chronic otorrhea or moist ears, a thorough history and physical examination is required to rule out hypersensitivity to previous ototopical therapy, autoimmune condition, cholesteatoma, granuloma, or malignancy. Chronic inflammation or low-grade chronic infection with the same bacteria responsible for chronic OE may result in persistent otorrhea. Ear hygiene and dry ear precautions (use of ear plugs or

Table 138-3

Cerumen-Softening Agents for Cerumen Removal

Agent	Use	Dosing
Water-Based		
10% Trolamine polypeptide oleate-condensate (Cerumenex)	Soften cerumen before irrigation	Fill affected ear canal 15-30 min before irrigation
Docusate sodium (Colace)	Soften cerumen before irrigation	Fill affected ear canal with 1 mL 15-30 min before irrigation
3% Hydrogen peroxide	Soften cerumen before irrigation	Fill affected ear canal 15-30 min before irrigation
2.5% Acetic acid	Home treatment of impacted cerumen	Fill affected ear with 2-3 mL twice daily for up to 14 days
10% Sodium bicarbonate	Soften cerumen before irrigation or as an alternative to irrigation	Fill affected ear with 2-3 mL 15-30 min before irrigation, or alternatively for 3-14 days at home with or without irrigation
Water or saline	Soften cerumen before irrigation	If irrigation is attempted without softening and is ineffective with the first irrigation attempt, instill water and wait 15 min before repeating irrigation
Non–Water-Based/Non–Oil-Based		
Carbamide peroxide (Debrox, Murine removal kit)	Soften cerumen before irrigation or as an alternative to irrigation	Put 5-10 drops into affected ear twice daily for up to 7 days
50% Choline salicylate and glycerol (e.g., Earex Plus, Audax); ethylene oxide polyoxypropylene glycol (Addax); propylene glycol; 0.5% chlorbutol	Soften cerumen before irrigation or as an alternative to irrigation	Put 3 drops into affected ear twice daily for 4 days
Oil-Based		
57.3% Arachis oil, 5% chlorbutol, 2% paradichlorobenzene, 10% oil of turpentine (e.g., Cerumol)	Soften cerumen before irrigation or as an alternative to irrigation	Fill affected ear with 5 mL twice daily for 2-3 days
Arachis oil, almond oil, rectified camphor oil (e.g., Otocerol, Earex)	Soften cerumen before irrigation or as an alternative to irrigation	Put 4 drops into affected ear twice daily for up to 4 days
Olive oil, almond oil, or mineral oil	Soften cerumen before irrigation	Put 3 drops into affected ear at bedtime for 3-4 days

From McCarter D, Courtney A, Pollart S. Cerumen impaction. *Am Fam Physician*. 2007;75:1523-1528.

cotton balls with petrolatum jelly) are crucial. The safest way to dry ears is with a hair dryer on the cool setting, or with a specifically designed ear dryer.[107,108]

Acidifying or alcohol drops can be used as a preventive measure during the at-risk period (e.g., swim season, scuba diving trip), and can be used as treatments in patients with chronic draining ears. Acetic acid solutions (i.e., Domeboro, trichloroacetic acid solutions) and alcohol solution[14,17,109] evaporate moisture and help prevent bacterial overgrowth. A review of the literature indicates that acetic acid and alcohol-based drops may be ototoxic, and should be avoided in patients with tympanic membrane perforations or tubes.[42,110,111] Iodine and Burow's solution do not seem to have ototoxic or vestibulotoxic potential.[111,112]

Various powders designed for use in the external ear canal have been developed as treatments for chronically moist canals and mastoid bowls. Most preparations are a mixture of antibacterial antibiotics, antifungal agents, and steroids. Two preparations are used at the University of Texas Southwestern Medical Center. *Gold dust* comprises chloramphenicol, sulfanilamide, and hydrocortisone. The chloramphenicol in gold dust powder has ototoxic potential and should not be used with perforated tympanic membranes.[113-115] *Mastoid powder* comprises ciprofloxacin powder, clotrimazole powder, dexamethasone powder, and boric acid. Compared with gold dust, the mastoid powder seems more effective, is easier to apply, and has no ototoxic potential.[4,7,23-25,76-78] The House Ear Institute developed a mastoid powder that consists of chloromycetin, 50 mg; sulfanilamide, 50 mg; and Fungizone, 5 mg (CSF powder). Hydrocortisone powder may also be added to make CSF-HC. At Johns Hopkins, a preparation consisting of hydrocortisone powder 4% and boric acid 96% is used. These powders are not always readily available because a pharmacy capable of compounding is needed.

A bulb insufflator was developed in 1983 by House and Sheehy at the House Ear Clinic for the topical application of these powders to the external auditory canal or mastoid bowl. This bulb is commonly used today and accepts No. 3 medication capsules (Fig. 138-3).

Finally, in many cases, the underlying cause of chronic otorrhea may be the presence of granulation tissue. Silver nitrite can be applied topically to the granulation tissue.[116,117] In patients who have had a canal wall down mastoidectomy, it is essential to note whether the facial nerve is dehiscent before using silver nitrite to avoid accidentally chemically cauterizing the nerve. Because the silver nitrite sticks are frequently too large and imprecise to place directly on granulation tissue in the external ear, small slivers can be obtained and used with alligator forceps to apply the chemical cautery precisely using a binocular microscope. Care should be taken to use as little as possible because the depth of burn cannot be easily controlled.

Conclusion

Many topical therapies in suspension, solution, lotion, ointment, or powder forms are available to the otolaryngologist to treat external ear disorders (Table 138-4). Although most ototopicals can be used safely for the management of common bacterial and fungal infections of the external ear, the possibility of ototoxicity and hypersensitivity must be kept in mind, especially in refractory cases or in patients with a perforated tympanic membrane. Systemic therapy should be used in

Table 138-4

Summary of Available Ototopical Agents

Generic Names	Brand Names	Indication	Dose Range	Frequency	Duration of Treatment	Contraindications	Pregnancy*	Lactation	Children	Notes	Cost
Acidifying Agents											
Alcohol-vinegar mix: ½ alcohol, ¼ white vinegar, and ¼ distilled water		Prevention of OE, treatment of mild cases of acute bacterial OE	4-5 drops	2-4 times per day		TM perforation, tubes, hypersensitivity reaction	Safe	Safe	Safe	May be used more copiously for irrigation if copious debris present	
Acetic acid in aluminum acetate	Domeboro/ modified Burow's solution	Treatment of mild fungal/ bacterial OE	5 drops	2-4 times daily	10 days	TM perforation, tubes, hypersensitivity reaction	Unknown	Unknown	Safe	May be used more copiously for irrigation if copious debris present	~$70 for 100 packets
Propylene glycol and acetic acid otic solution	VoSol	Treatment of mild fungal/ bacterial OE	2-4 drops	2-4 times daily	10 days	TM perforation, tubes, hypersensitivity reaction	Unknown	Unknown	Safe >3 yr old		~$7 for 10 mL
Hydrocortisone 1%, propylene glycol and acetic acid otic solution	VoSol HC	Treatment of mild fungal/ bacterial OE	2-4 drops	2-4 times daily	10 days	TM perforation, tubes, hypersensitivity reaction	Category C	Unknown	Safe >3 yr old		
Antibiotics											
Ofloxacin	Floxin (0.3% solution)	Treatment of bacterial OE, prevention of otorrhea post ear surgery; treatment of OM with tubes	Adults: 10 drops Children (<13 yr): 5 drops	qd or bid qd or bid	7-10 days 7-10 days	Hypersensitivity	Category C	Unknown	Safe	Safe in middle ear	10 mL: $136.03
Ciprofloxacin + hydrocortisone	Cipro HC (0.2%/1% suspension)	Treatment of bacterial OE	3 drops	bid	7 days	Hypersensitivity, viral external ear infection, TM perforation	Category C	Probably safe	Safe		10 mL: $91.39
Ciprofloxacin + dexamethasone	Ciprodex (0.3%/0.1% suspension)	Treatment of bacterial OE, treatment of OM with tubes	4 drops	bid	7 days	Hypersensitivity, viral external ear infection	Category C	Probably safe	Safe	Safe in middle ear	7 mL: $94.68
Neomycin, polymyxin B, hydrocortisone	Cortisporin (solution, suspension)	Treatment of bacterial OE	Adults: 4-5 drops; children: 3 drops	3-4 times daily	Maximum 10 days	Hypersensitivity, TM perforation, tubes, viral ear infection	Category C	Unknown	Safe	Solution burns—recommend suspension	10 mL: $72.99 (suspension or solution)

Powder insufflator. **A,** Assembled insufflator and No. 3 capsules filled with compounded antibacterial and steroidal components. **B,** An individual capsule is opened, and the open end containing the medicated powder is inserted *(arrow)* and left in the insufflator before reassembly. Care should be taken to avoid overapplication.

immunocompromised patients. Severe or chronic infections that do not respond to aggressive ototopical therapy, systemic therapy, and manual débridement must be carefully re-evaluated to exclude the possibility of a malignancy, cholesteatoma, keratosis obturans, an autoimmune disorder, hypersensitivity, or malignant OE. In most cases, meticulous ear hygiene and avoidance of self-manipulation contribute to better outcomes for patients with infectious and inflammatory conditions of the external ear.

CHAPTER ONE HUNDRED AND THIRTY-NINE

Chronic Otitis Media, Mastoiditis, and Petrositis

Richard A. Chole

Holger H. Sudhoff

Key Points

- Otitis media is one of the most common diseases of childhood, and may result in complications including acute and chronic mastoiditis, petrositis, skull base osteomyelitis, intracranial infection, and the sequelae of early childhood auditory deprivation.
- Acute otitis media may result in persistent otitis media with effusion, which is now recognized as the leading cause of childhood hearing loss.
- Aural cholesteatomas are epidermal inclusion cysts of the middle ear or mastoid, and are classified as congenital and acquired.
- Cholesteatomas can be eradicated from the temporal bone only by surgical resection.
- Osteoclastic bone resorption in chronic otitis media with or without cholesteatoma is stimulated by various factors, including inflammation, local pressure, keratin, specific cytokines, and bacterial toxins.
- The mechanism of bone resorption in chronic otitis media with and without cholesteatoma is an increased number and activity of osteoclasts.
- Tympanosclerosis is tympanic membrane or middle ear hyalinization. It results from chronic inflammation or trauma, but it often leads to conductive hearing loss caused by ossicular fixation.
- Petrous apicitis is an extension of infection from the mastoid air cell tract into a pneumatized anterior or posterior petrous apex.
- The management of petrous apicitis is directed toward control of the infection, such as topical and systemic antibiotic management and surgical approach through many surgical routes.

Otitis media is the most common disease of childhood after viral upper respiratory infections. The acute bacterial infection occurs in 80% of children 1 to 6 years old, and it is the disease most frequently managed with antibiotics in the United States. The infectious and noninfectious complications of otitis media in childhood may result in serious morbidity. Later in life, the infectious complications, including acute and chronic mastoiditis, petrositis, and intracranial infection, still occur despite the widespread use of antibiotics for this disease. The noninfectious sequelae, including chronic perforation of the tympanic membrane, ossicular erosion, labyrinthine erosion, and tympanosclerosis, are major causes of hearing loss throughout the world.

Some cases of acute otitis media (AOM) result in persistent otitis media with effusion (OME), which is recognized as the leading cause of childhood hearing loss. The exact cause of OME is unclear; however, more recent data suggest that reflux of gastric contents may be associated with OME in children.[1-4] Although eustachian tube dysfunction alone may lead to effusion of the middle ear, there is mounting evidence that most cases of OME occur as a sequelae of AOM, or at least share the same etiologic factors. Specific causes can be identified in many cases of adult-onset otitis media, such as paranasal sinus disease, nasopharyngeal carcinomas and tumors, and postradiation sequelae.

In most children, AOM and OME subside spontaneously or after medical intervention. It is unknown how many children with OME eventually have complications. The sequelae of otitis media can be considered in two broad categories: (1) direct destructive effects of the localized process, and (2) the effects of auditory deprivation during early childhood. Otitis media may be complicated by acute or chronic perforation of the tympanic membrane, acute mastoiditis, middle ear atelectasis, adhesive otitis media, tympanosclerosis, ossicular erosion or fixation, petrous apicitis, cholesteatoma, chronic otomastoiditis, labyrinthitis, facial paralysis, and intracranial infection. There is evidence that sensorineural hearing loss may result from chronic otitis media with or without cholesteatoma. There is also evidence that the auditory deprivation associated with childhood otitis media may lead to indirect sequelae, such as language and speech delays.

Effects on Mastoid Pneumatization

It has been observed that patients with a history of chronic OME have more sclerotic mastoids with decreased pneumatization compared with healthy subjects. There are two theories to explain this observation: (1) the hereditary theory, which states that children with hypoaeration of the mastoid are prone to OME, and (2) the environmental theory, which states that chronic OME results in hypopneumatization of the mastoid.[5] Although measurable correlations between mastoid hypocellularity and OME,[6,7] and between the length of the mastoid process or the degree of pneumatization and an abnormal eardrum[8] have been proven, a cause-and-effect relationship is unclear. Available evidence generally supports the concept that chronic inflammation in early

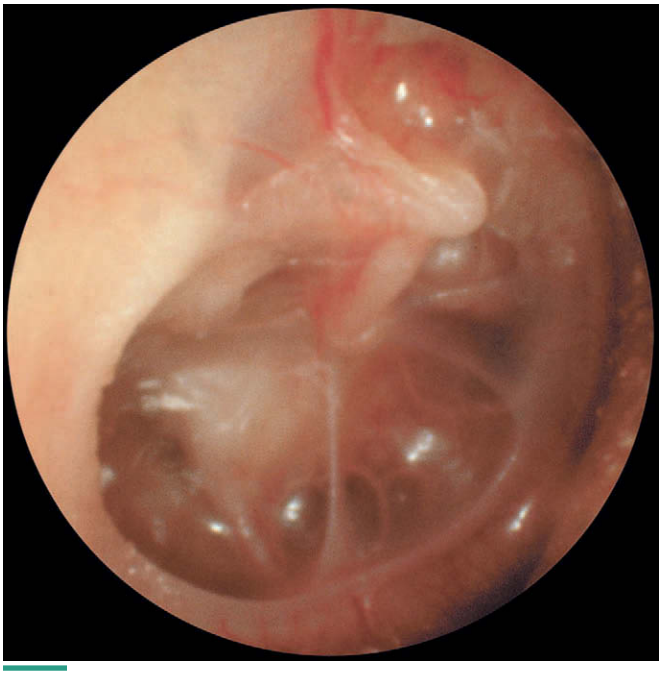

Figure 139-1. Middle ear atelectasis.

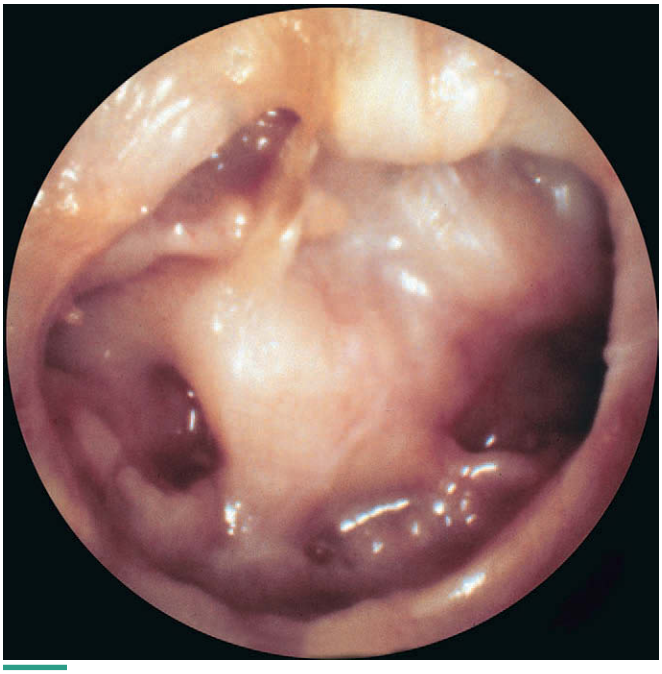

Figure 139-2. Middle ear atelectasis with ossicular erosion.

childhood may lead to new bone formation within the middle ear and mastoid and, subsequently, decreased size of mastoid air cells. Shatz and Sadé[9] measured the distance from the lateral sinus to the external auditory canal and found it to be significantly smaller in patients with sclerotic mastoids; they believed that this finding supported the hereditary theory because it was unlikely that otitis would change the position of the lateral sinus. A chronically inflamed mastoid in a young child may not develop normally, however.

Hasebe and colleagues[10] carried out a study to establish which type of cholesteatoma is controllable by conservative treatment from the viewpoint of mastoid ventilation. Their clinical observations suggest that progressiveness of cholesteatoma is related to the ventilatory conditions in the mastoid, rather than eustachian tube function, and that conservative treatment may be effective if ears with cholesteatoma have aeration in the mastoid.

Middle Ear Atelectasis and Adhesive Otitis Media

Middle ear atelectasis (Fig. 139-1) is thought to result mainly from long-standing eustachian tube dysfunction. One of the main functions of the eustachian tube is ventilation of the middle ear and mastoid. Opening of the eustachian tube allows exchanging of gases and equalization between the environment and middle ear. The middle ear gases also are exchanged with the middle ear mucosa. Bilateral diffusion between the middle ear cavity and the blood may be an important factor in middle ear atelectasis because the gas composition of the middle ear basically resembles that of venous blood.[11]

If the atelectasis develops, the tympanic membrane becomes retracted onto the promontory and the ossicles of the middle ear. In atelectatic ears, the middle ear space is partially or completely obliterated, but the tympanic membrane is not adherent to the medial wall of the middle ear, and the mucosal lining of the middle ear is intact. In contrast, adhesive otitis media exists when the middle ear space is totally obliterated, and the tympanic membrane is adherent to the ossicles and promontory; mucosal surfaces are not present. Retraction of the tympanic membrane may lead to erosion of the long process of the incus and the stapes suprastructure (Fig. 139-2).

Not all patients with chronic OME develop atelectasis; in most patients with OME, retraction of the tympanic membrane is limited. In patients with bilateral OME, 1.5% of untreated ears and 2% of ears treated with tubes developed severe atelectasis.[12] It may be that repeated bouts of AOM lead to weakening and thinning of the membrane, which allows atelectasis. Sadé and Berco[13] showed destruction of the collagen-containing fibrous layer of the tympanic membrane in some ears with recurrent infection. Collagen destruction within the tympanic membrane may lead to another complication of OME—tympanosclerosis. Sadé and Berco[13] and Tos and Poulsen[14] described four stages of tympanic membrane retraction: stage I, retracted tympanic membrane; stage II, retraction with contact onto the incus; stage III, middle ear atelectasis; and stage IV, adhesive otitis media (Fig. 139-3).

Middle ear atelectasis may be reversible with ventilating tubes. Sadé[15] showed that ventilating tubes improved the state of atelectatic ears. Graham and Knight[16] reported three cases in which atelectatic tympanic membranes were restored to their normal position by administration of nitrous oxide during anesthesia and insertion of a ventilating tube.

Atelectasis and adhesive otitis media usually coexist with OME, although OME may resolve in these ears, allowing aeration of the attic and mastoid, but leaving a collapsed middle ear. In extreme cases, when hearing loss or ossicular erosion occurs, a myringoplasty for the reinforcement of atelectatic tympanic membrane may be indicated.[6,17] Cholesteatomas may originate from deep retraction pockets in which desquamated keratin debris would not be cleared into the ear canal.[18,19] These retraction pockets may occur in the pars tensa or pars flaccida of atelectatic ears, and should be considered precursors to cholesteatomas (see discussion of cholesteatoma). Nonpneumatized mastoids may have a limited ability to buffer pressure changes and can manifest as an atelectasis, a retraction pocket, or a cholesteatoma.[20]

Chronic Otitis Media with Cholesteatoma

Aural cholesteatomas are epidermal inclusion cysts of the middle ear or mastoid (in the case of a retraction pocket cholesteatoma, the "cyst" opens into the external auditory canal). They contain the desquamated debris (principally keratin) from their keratinizing, squamous epithelial lining. Cruveilhier[21] first described aural cholesteatoma as a "pearly tumor" of the temporal bone. The term *cholesteatoma,* coined by the German physiologist Müller[22] in 1838, is a misnomer because this entity does not contain cholesterol; the white-yellow keratin flakes found within cholesteatomas grossly resemble cholesterol crystals. Cholesteatomas of the temporal bone may be congenital or acquired.

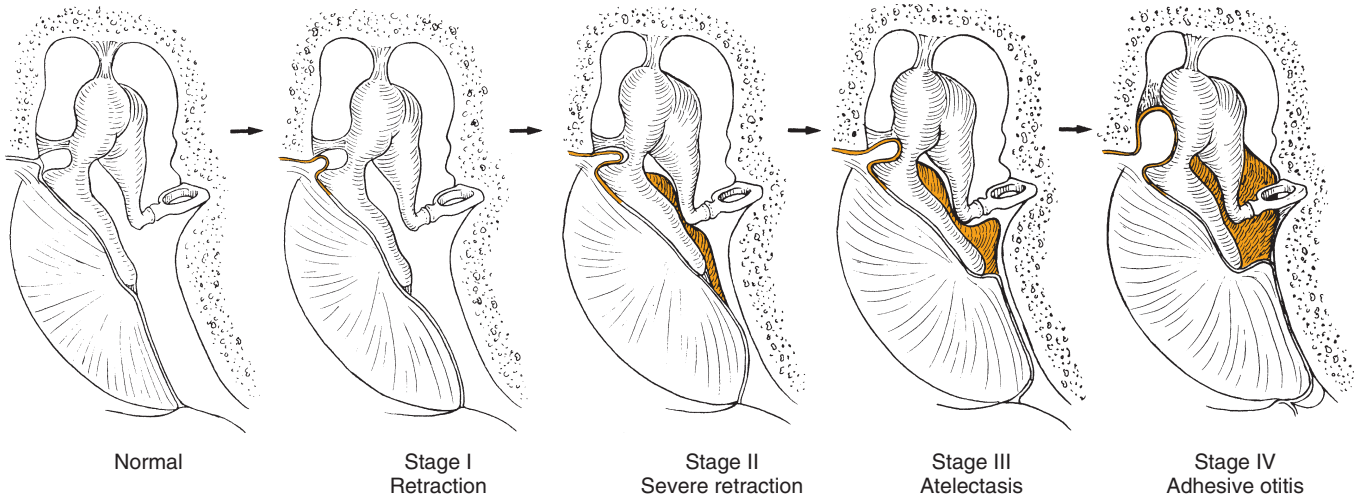

Figure 139-3. Four stages of middle ear atelectasis. *(Adapted from Sadé J, Berco E. Atelectasis and secretory otitis media.* Ann Otol Rhinol Laryngol. *1976;85(Suppl 25):66.)*

Acquired cholesteatomas are the consequence of OME, AOM, or both. An understanding of the pathogenesis and pathophysiology of aural cholesteatoma is particularly important because the destructive nature of this entity is responsible for much of the morbidity associated with chronic otitis media. The propensity of cholesteatomas to erode bone and the lack of effective, nonsurgical management add importance to the understanding of this disease.

Diagnosis

The diagnosis of aural cholesteatoma is made on otoscopic examination, including endoscopic and microscopic evaluation or surgical exploration. Special imaging procedures, such as high-resolution computed tomography (CT) and magnetic resonance imaging (MRI), may suggest the presence of cholesteatomas within the temporal bone, and may be used to complement the clinical examination. High-resolution CT is useful for operative planning and is recommended for all revision mastoid operations. The symptoms of cholesteatoma vary; some cholesteatomas are asymptomatic, whereas others become infected and rapidly cause bone destruction. Some patients seen by the physician show slowly progressive conductive hearing loss, and frequently patients with cholesteatomas consult a physician because of chronic otitis with purulent otorrhea. The otorrhea from an infected cholesteatoma often is malodorous because of the frequent infection with anaerobic bacteria.[23]

Patients with infected cholesteatoma occasionally are misdiagnosed as having external otitis. Careful follow-up evaluation and thorough canal débridement of a patient with otorrhea are mandatory because the cholesteatoma may not be evident during an acute flare-up. Some patients have signs and symptoms of the complications of a cholesteatoma: vertigo and hearing loss caused by a labyrinthine fistula, facial nerve paralysis, or intracranial infection.

The otoscopic appearance of an aural cholesteatoma also varies. A typical attic retraction cholesteatoma (Fig. 139-4) appears as a defect of variable size adjacent to the posterosuperior portion of the tympanic membrane. The center of the defect contains keratin debris (primary acquired cholesteatoma). In other patients, keratinizing epithelium has migrated through a perforation into the middle ear (secondary acquired cholesteatoma) (Fig. 139-5). Cholesteatomas sometimes appear behind or within an intact tympanic membrane—so-called congenital cholesteatoma (Fig. 139-6). These cholesteatomas have been considered to be congenital, but more recent experimental evidence raises the possibility that they may originate during an inflammatory process.[24] An infected cholesteatoma sometimes manifests as an "aural polyp." These "polyps" actually are granulation tissue at the junction between an eroding cholesteatoma and bone. The presence of an aural polyp in a chronically infected ear should be considered to be a cholesteatoma until proved otherwise. Occasionally, a cholesteatoma cannot be seen otoscopically, but is discovered during tympanomastoid surgery.

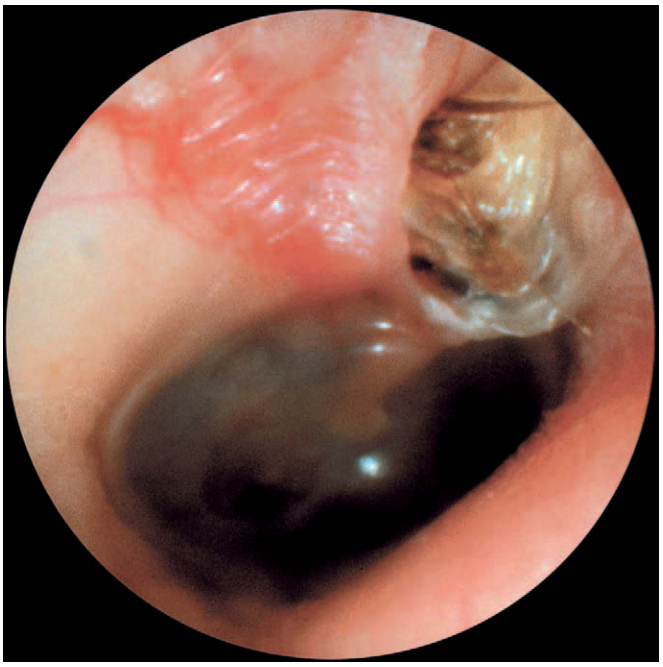

Figure 139-4. Primary acquired cholesteatoma in the region of the pars flaccida with scutum erosion.

The exact prevalence of cholesteatoma is unknown. In 1978, there were 4.2 hospital discharges per 100,000 population with cholesteatoma.[25] In addition, there were 13.8 hospital discharges per 100,000 population with chronic otitis media without cholesteatoma. Studies by Harker[23] documented an annual incidence of 6 cholesteatomas per 100,000 population. Tos[26] found an annual incidence of 3 cholesteatomas in children and 12.6 cholesteatomas in adults per 100,000 population. In the human temporal bones with chronic otitis media, cholesteatoma was observed in 36% of ears with perforations and in 4% of ears without the perforated tympanic membranes.[27]

Pathogenesis

Congenital cholesteatomas, by definition, originate from areas of keratinizing epithelium within the middle ear cleft. Michaels[28] showed that

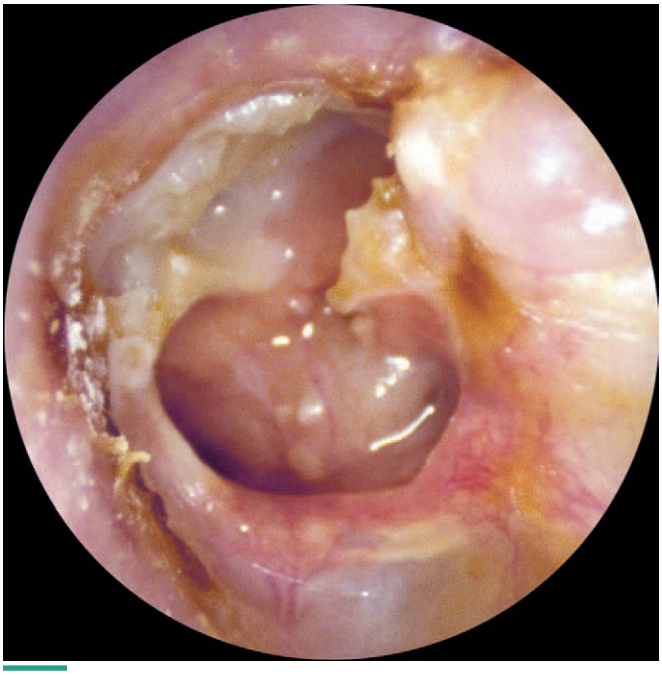

Figure 139-5. Cholesteatoma developing at the margin of perforation (secondary acquired cholesteatoma) with secondary infection.

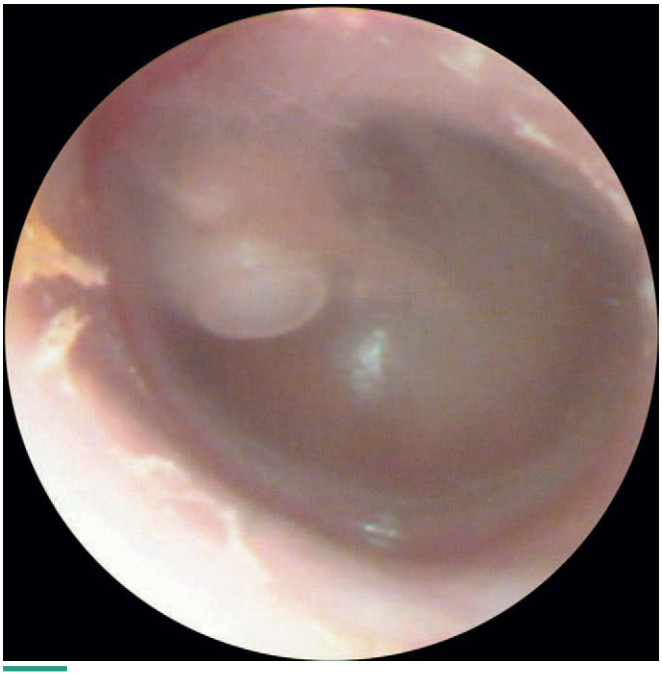

Figure 139-6. Cholesteatoma behind intact tympanic membrane.

a small area in the anterior tympanum in the developing fetus often contains a small area of keratinizing epithelium. He found epidermoid formation in 37 of 68 temporal bones of fetuses at 10 to 33 weeks' gestation. Congenital cholesteatomas may originate in this region. Although congenital cholesteatomas generally are seen as pearl-like masses behind an intact membrane, Koltai and coworkers[29] presented a convincing case that some congenital cholesteatomas advance to perforate and become chronically infected, taking on the appearance of an acquired cholesteatoma. Potsic and colleagues,[30] in a review of 172 series of congenital cholesteatomas, developed a useful staging system: stage I, limited to one quadrant; stage II, involving multiple quadrants without ossicular involvement; stage III, ossicular involvement without mastoid extension; and stage IV, mastoid involvement. They showed a correlation between stage and risk of residual disease; stage IV carries a 67% risk of residual cholesteatoma.

The pathogenesis of *acquired* cholesteatoma has been debated for more than a century. There are four basic theories of the pathogenesis of acquired aural cholesteatoma: (1) invagination of the tympanic membrane (retraction pocket cholesteatoma), (2) basal cell hyperplasia, (3) epithelial ingrowth through a perforation (the migration theory), and (4) squamous metaplasia of middle ear epithelium (Fig. 139-7). Additionally, Sudhoff and Tos[19] proposed a combination of the invagination and basal cell theories as an explanation for retraction pocket cholesteatoma formation.

Invagination Theory

The invagination theory[5] of the genesis of cholesteatoma generally is regarded as one of the primary mechanisms of the formation of attic cholesteatomas. Retraction pockets of the pars flaccida deepen because of negative middle ear pressure and possibly repeated inflammation (see Fig. 139-2). As the retraction pocket deepens, desquamated keratin cannot be cleared from the recess, and a cholesteatoma results. The origin of such retraction pocket cholesteatomas is thought to be eustachian tube dysfunction (or OME) with resultant negative middle ear pressure (*ex vacuo* theory). Usually, the pars flaccida, being less fibrous and less resistant to displacement, is the source of the cholesteatoma.

The result of this type of cholesteatoma (so-called primary acquired cholesteatoma) is an apparent defect in the posterosuperior quadrant of the tympanic membrane and erosion of the adjacent canal wall.[31] Although these defects have the appearance of a marginal perforation, it is not a perforation, but rather an invagination. Sadé[20] showed that epithelial migration patterns within attic retraction pockets are altered. This failure of epithelial migration may allow the accumulation of keratin within a retraction pocket, with subsequent enlargement merely from the accumulation of keratin within a relatively closed space. This theory has been supported by the experimental creation of retraction pockets by use of the eustachian tube obstruction,[32] and external auditory canal ligation.[33]

Ruah and colleagues[31] suggested that inflammation of middle ear and persistent mesenchyme lead to a greater inflammatory reaction in pars flaccida and posterosuperior quadrant of the tympanic membrane of the human temporal bones with serous and purulent otitis media in children. These findings support this theory of primary acquired cholesteatoma in children. Retraction pockets are considered as precursors to cholesteatoma. Bacteria can infect the keratin matrix, forming biofilms leading to chronic persistent infection. The presence of bacterial biofilms in the cholesteatoma matrix may lead to epithelial proliferation and invasion of the cholesteatoma.[34,35]

Basal Cell Hyperplasia Theory

Another possible mechanism for the histogenesis of cholesteatoma was suggested by Lange in the 1920s.[49] In this theory, he proposed that epithelial cells (prickle cells) of the pars flaccida could invade the subepithelial tissue by means of proliferating columns of epithelial cells. Nearly 40 years later, Ruedi[50] supported this hypothesis with clinical and experimental evidence. For epithelium to invade into the lamina propria, the basal lamina (basement membrane) should be altered. Basal lamina disruptions now have been documented in human[51,52] and animal[53] cholesteatomas.

Huang and colleagues[54] and Masaki and coworkers[55] provided experimental support of this theory by showing that epithelial ingrowth from the tympanic membrane can be induced by instillation of propylene glycol into the middle ear of chinchillas. These basal lamina breaks allow the invasion of epithelial cones into the subepithelial connective tissue and the formation of microcholesteatomas. This mechanism may explain some types of human cholesteatomas, even those occurring behind an intact tympanic membrane.[56] According to this theory, microcholesteatomas may enlarge and then perforate secondarily through the tympanic membrane, leaving the typical appearance of an attic cholesteatoma. This sequence of events has not been documented, although the alternations in the differentiation of keratinocytes and basal cell layer of cholesteatoma matrix have been observed in several studies.

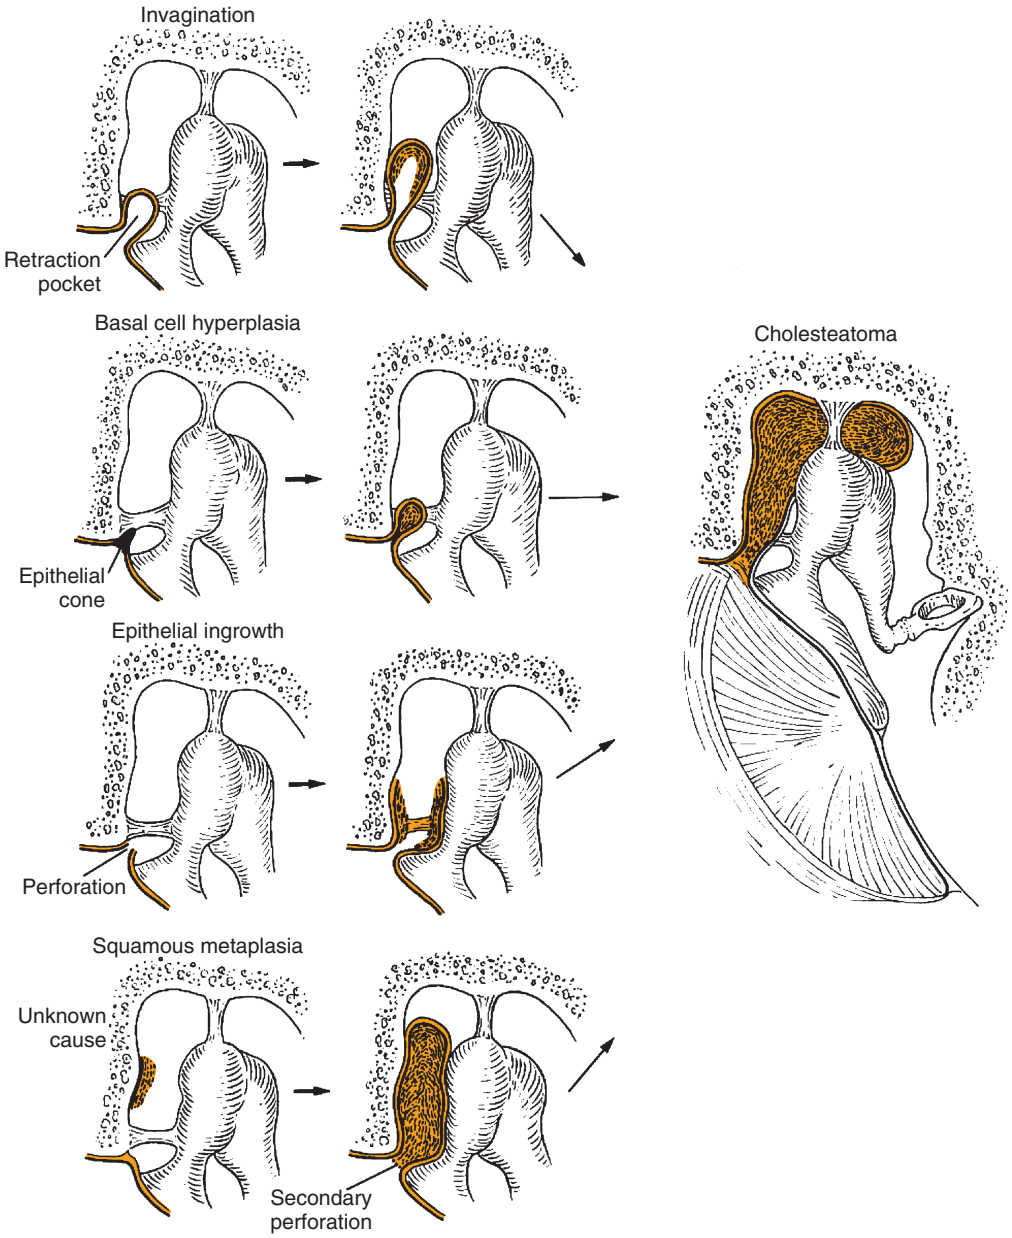

Figure 139-7. Theories of pathogenesis of aural cholesteatoma.

Abnormal distribution of epidermal differentiation markers, such as filaggrin and involucrin,[57] c-jun and p53 proteins,[58] and increased epidermal growth factor receptor,[59,60] has been shown in middle ear cholesteatoma matrix. Increased levels of proteins cytokeratin 13 and cytokeratin 16, which are markers for differentiation and hyperproliferation, were also found.[61] Kim and Chole[39] showed the increased expression of cytokeratin 13 and cytokeratin 16 in the area of the peripheral area of the pars tensa of induced cholesteatoma by ear canal ligation and in the peripheral and central area of pars tensa of induced cholesteatoma by eustachian tube obstruction. Sakamoto and associates[62] found ErbB-2 protein to be overexpressed, and cell proliferation and apoptosis of keratinocytes accelerated. Caspases play a key role in apoptosis; Miyao and coworkers[63] suggested that caspase-8, which is activated by the induction of tumor necrosis factor-α, leads to activation of caspase-3, which activates apoptotic nucleases in cholesteatoma tissue.

Human toll-like receptors are crucial in the induction and activation of innate immunity in the course of an infection. Expression of toll-like receptor–3 on the epithelium and some cells within the perimatrix and the presence of T cells may suggest that apart from innate immune responses, mechanisms of adaptive immunity also operate in cholesteatoma.[64] Data from Parisier and colleagues[65] suggested that fibroblasts in the subepithelium of cholesteatomas showed an invasive phenotype, whereas fibroblasts from postauricular and ear canal skin appeared either weakly invasive or not invasive. In a similar study, Chole and colleagues[66] found that normal fibroblasts and fibroblasts from induced cholesteatomas did not exhibit the invasive phenotype characteristics of true neoplastic cells.

Other lines of evidence support the basal cell hyperplasia/migration theory. Increased expression of human intercellular adhesion molecule-1 and intercellular adhesion molecule-2 has been shown, suggesting a role in cell migration into tissue.[40] The presence of heat shock proteins 60 and 70 suggested proliferation and active differentiation of basal keratinocytes in cholesteatomas.[58] There are some reports that immune response is involved in the hyperproliferative state of cholesteatoma epithelium.[52,67,68] Langerhans cells may initiate immune reaction and promote proliferation of keratinizing epithelium via an interleukin (IL)-1α and transforming growth factor (TGF)-β mechanism.[42,67,69]

Epithelial Invasion Theory

The epithelial invasion theory[36] states that keratinizing squamous epithelium from the surface of the tympanic membrane invades or migrates into the middle ear from a perforation in the tympanic membrane. This theory is supported by clinical observation and experimental evidence. Weiss[37] showed that epithelial cells could migrate along a surface by a process that he called *contact guidance,* and that, when they encounter another epithelial surface, they stop migrating, for which he used the term *contact inhibition*. van Blitterswijk and Grote[38] reported that cytokeratin 10, which was seen in the meatal epidermis and migrating epithelium, was preferentially expressed in the cholesteatoma matrix, rather than in the middle ear mucosa. This finding suggests an epidermal origin of cholesteatoma. Kim and Chole[39] showed increased cytokeratin 10 expression in the peripheral area of the pars tensa of induced cholesteatoma by ear canal ligation and in the peripheral and the central area of the pars tensa of induced cholesteatoma by eustachian tube obstruction. The findings of this study also support the basal cell hyperplasia hypotheses for the pathogenesis of aural cholesteatoma, with regard to hyperproliferation, migration, and an altered differentiation of keratinocytes.[39] High levels of fibronectin and tenascin and focal disruptions of the basement membrane, were reported in the middle ear cholesteatoma, supporting the concept of the invasion theory.[40-43]

This theory also is supported by investigations in animal cholesteatoma models and human temporal bones. Jackson and Lim[44] gave histologic and ultrastructural evidence that keratinizing epithelium can migrate into the cat bulla by contact guidance. It is likely that in some tympanic membrane perforations, inflammation damages the inner mucosal lining of the tympanic membrane, allowing the outer keratinizing epithelium to migrate inward and generate a cholesteatoma. Hueb and associates[45] showed similar evidence in chinchillas. Palva and colleagues[46] showed histologic evidence for this theory in human temporal bones. Cholesteatomas originating after temporal bone fractures may result from this mechanism; fractures within the ear canal may allow ingrowth of keratinizing epithelium by contact guidance.[47] 7,12-Dimethylbenz[a]anthracene, a chemical carcinogen, could induce the advancing of the keratinizing squamous epithelium into or under the mucosal layer, and ingrowth and spreading over the middle ear cavity and eustachian tube in the rat ear.[48]

Squamous Metaplasia Theory

Wendt[70] theorized that the simple squamous or cuboidal epithelium of the middle ear cleft could undergo a metaplastic transformation into keratinizing epithelium. Sadé[15,71] supported this theory, noting that epithelial cells are pluripotent and can be stimulated by inflammation to become keratinizing. According to this theory, an area of keratinizing epithelium within the middle ear would enlarge because of accumulated debris and contact with the tympanic membrane. With intercurrent infection and inflammation, the cholesteatoma would lead to lysis of the tympanic membrane and perforation, resulting in the typical appearance of an attic cholesteatoma. This theory is supported by the demonstration that biopsy specimens from the middle ear of children with OME sometimes contain islands of keratinizing epithelium.[15]

Some experimental evidence supports the contention that middle ear mucosa can become metaplastic and keratinize. Chole and Frush[72] showed that extreme vitamin A deficiency leads to the formation of keratinizing epithelium within the middle ear and eustachian tube of rats. None of their experimental animals had developed cholesteatomas. Consequently, there is no direct evidence that cholesteatomas arise by squamous metaplasia of the middle ear mucosa.

From a clinical perspective, it seems that each of these pathogenic mechanisms accounts for a proportion of acquired cholesteatomas. Regardless of the pathogenesis of aural cholesteatomas, they all share certain properties. Cholesteatomas are prone to recurrent infection, and they characteristically erode the bone of the ossicles and the otic capsule. Aural cholesteatomas originating from the vicinity of the tympanic membrane exhibit typical growth patterns into the temporal bone. Because most acquired cholesteatomas originate by invagination of the pars flaccida, their growth is limited by the mucosal folds and suspensory ligaments of the ossicles. The pars flaccida may invaginate into the lateralmost portion of the epitympanum (Prussak's space) and then into the recesses of the epitympanum posteriorly, lateral to the body of the incus, inferiorly into the middle ear by way of the pouch of von Tröltsch (Fig. 139-8), or anteriorly into the protympanum (Fig. 139-9).[73-75]

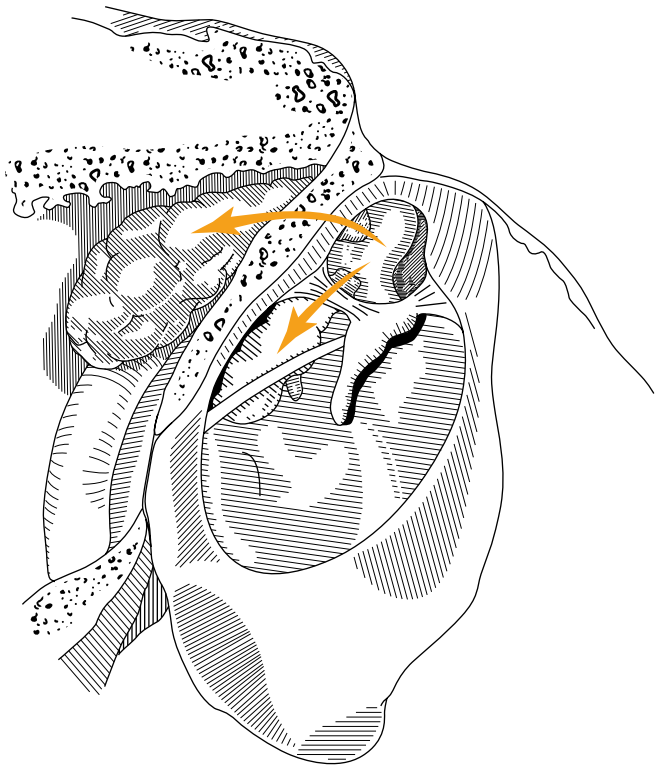

Figure 139-8. Posterior mesotympanic cholesteatoma. This sac forms because of retraction of the posterior portion of the pars tensa, and frequently invades the sinus tympani and facial recess. Extension to the mastoid occurs medial to ossicle heads *(arrows)*. *(From Jackler RK. The surgical anatomy of cholesteatoma.* Otolaryngol Clin North Am. *1989;22:883.)*

Complications

The expansion of cholesteatoma may result in bone erosion of the ossicles, otic capsule, fallopian canal, tegmen tympani, and tegmen mastoideum. These complications may cause intracranial complications (Box 139-1). The erosion of ossicles, most commonly in the incus, may result in conductive hearing loss. The severity of hearing loss is related to the status of the ossicles and the position of the cholesteatoma sac. Erosion of the otic capsule occurs most commonly in the lateral semicircular canal and rarely in the cochlea. A labyrinthine fistula has been reported in 10% of cholesteatomas in adults and children,[76] which may result in sensorineural hearing loss and vertigo. Sensorineural hearing loss may result from the secondary suppurative labyrinthitis or from the cochlear hair cell loss adjacent to cholesteatoma.[66] Facial nerve paralysis may occur acutely as a result of infection or slowly as a result of expansion of the cholesteatoma. Erosion of the tegmen tympani or the tegmen mastoideum may lead to development of a brain hernia or cerebrospinal fluid leakage.[77]

Because cholesteatomas contain keratin debris enclosed in a tissue space, they are subject to recurrent infection. The bacteria found in infected cholesteatomas differ from bacteria found in AOM or OME. Significant anaerobic bacteria are present. The most common aerobic bacterium is *Pseudomonas aeruginosa,* and the most common anaerobic microorganism is *Bacteroides* sp (Table 139-1).[78]

Management

Congenital and acquired cholesteatomas can be eradicated from the temporal bone only by surgical resection. The goals of surgery are to

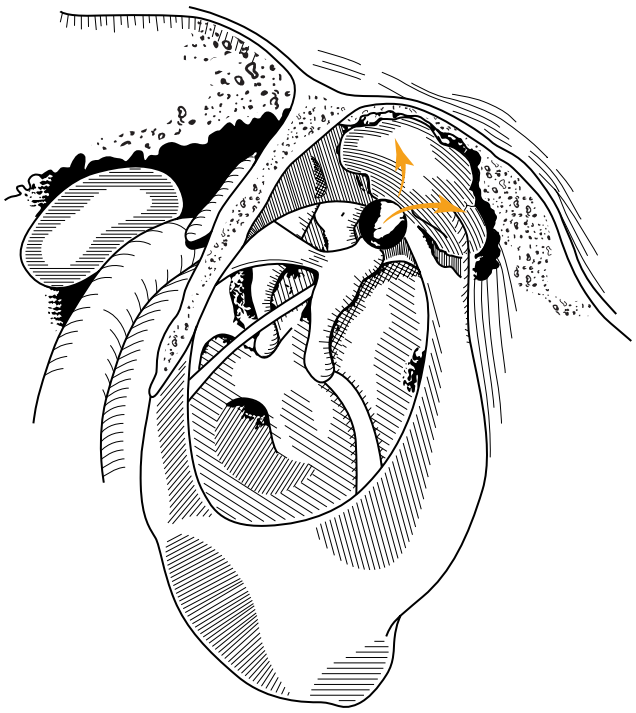

Figure 139-9. Anterior epitympanic cholesteatoma. Invagination of the epitympanum anterior to the malleus head and neck creates a cholesteatoma sac that threatens the horizontal facial nerve and geniculate ganglion. Forward extension into the supratubal recess is common (*arrows*). *(From Jackler RK. The surgical anatomy of cholesteatoma.* Otolaryngol Clin North Am. *1989;22:883.)*

Complications and Emergency States of Chronic Otitis Media with Cholesteatoma

Hearing loss—conductive, sensorineural, mixed type
Labyrinthine fistula—mainly horizontal semicircular canal, rarely cochlea
Facial nerve paralysis—acute or chronic
Intracranial infections
Brain hernia or cerebrospinal fluid leakage

eradicate disease and manage complications and, secondarily, to reconstruct the middle ear. The decision whether to perform surgery depends on the nature and extent of disease, the existence of complications, mastoid pneumatization, eustachian tube function, hearing status of both ears, the reliability of the patient, and the experience and skill of the surgeon.[77,79] Surgical approaches include atticotomy, simple mastoidectomy, canal wall-up or canal wall-down procedures, radical mastoidectomy, modified radical mastoidectomy, and Bondy procedure.

The open (canal wall-down) and the closed (intact canal with facial recess) procedures have advantages and disadvantages (Table 139-2). The reported results of both procedures vary. Residual disease and recurrent disease occur in 11% to 27% and 5% to 13% of patients undergoing the closed procedure, whereas residual or recurrent disease occurs in 2% to 10% of patients undergoing the open procedure.[80] In the cases of labyrinthine fistula, facial nerve paralysis, and intracranial complications, surgery should be performed as soon as possible.

In some patients, a cholesteatoma can be débrided of entrapped keratin by direct removal or by irrigation. In some cases, surgical intervention is impossible or not advisable; the patient may not be medically able to withstand surgery, or the risks of surgery may not outweigh the benefits in some patients with only-hearing ears. Irrigation with 1:1:1 distilled white vinegar, distilled water, and 70% isopropyl alcohol may keep some cholesteatomas stable if their opening into the ear canal is sufficiently large (Box 139-2). If surgery is required for a cholesteatoma in an only-hearing ear, careful preoperative evaluation and operative planning, perioperative use of antibiotics and steroids, ossicular reconstruction, and postoperative care should be considered.[81]

Chronic Otitis Media without Cholesteatoma

Acute or recurrent infection of the middle ear may result in a permanent perforation of the tympanic membrane. Ears with chronic perforations without cholesteatoma may be chronically or intermittently infected. Three times as many operations were performed in the United States for this disease as were performed for cholesteatomas.[25] Paparella and Kim[81a] reported that of 375 primary tympanomastoid operations for chronic mastoiditis, two thirds were performed in ears with granulation tissue and without cholesteatoma.

Diagnosis

Tympanic membrane perforation (Fig. 139-10) may result from AOM, chronic otitis media, or trauma (injury or surgery). In some instances, a dry, simple perforation results from a single episode of AOM (i.e., necrotizing otitis media). Perforation of the tympanic membrane, especially involving the tympanic anulus, may allow ingrowth of the keratinizing epithelium of the ear canal or tympanic membrane, leading to cholesteatoma. An ear with a simple perforation may become infected because of contamination from the ear canal or because of a smoldering infection in the mastoid. A simple perforation commonly is seen as a low-frequency conductive hearing loss clinically. This finding is supported by experimental perforation in rats.[82] The tympanic membrane velocity was found to be decreased in the low frequency in a small perforation and in the high and low frequencies in a large perforation.[83]

Table 139-2

Advantages and Disadvantages of Canal Wall-Up and Canal Wall-Down Procedures in Chronic Otitis Media with Cholesteatoma

Advantages	Disadvantages
Canal Wall-Up	
Physiologic position of tympanic membrane	Residual and recurrent cholesteatoma may occur
Enough middle ear space	Incomplete exteriorization of facial recess
No mastoid cavity problem	Second-stage operation often required
Canal Wall-Down	
Residual cholesteatoma easily found on follow-up evaluation	Mastoid cavity problem often
Recurrent cholesteatoma rare	Middle ear shallow and difficult to reconstruct
Total exteriorization of facial recess	Position of pinna may be altered; second-stage operation sometimes required

Box 139-2

Management of Chronic Otitis Media with Cholesteatoma

Factors for Determination of Treatment

Extent of disease
Presence of complications
Hearing states of both ears
Eustachian tube function
Mastoid pneumatization
Patient factors: general medical condition, age, occupation, reliability
Surgeon's skill

Conservative Treatment

Removal of entrapped keratin: direct
Irrigation with 1:1:1 distilled white vinegar, distilled water, and 70% isopropyl alcohol for stabilization

Surgical Approach

Atticotomy: transcanal
Simple mastoidectomy
Canal wall-up procedure (intact wall) with or without facial recess approach
Canal wall-down procedure (canal down): radical or modified radical mastoidectomy, Bondy procedure

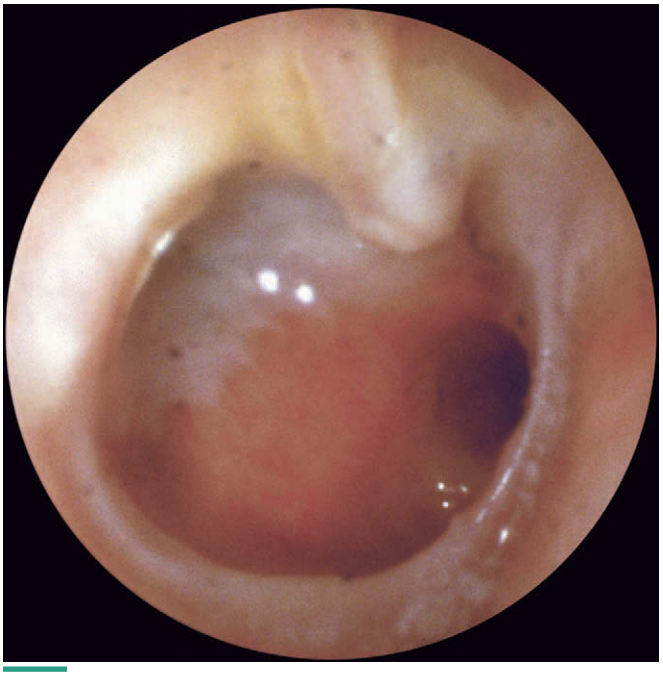

Figure 139-10. Tympanic membrane perforation.

Pathogenesis

Chronic otomastoiditis without cholesteatoma is marked by the presence of irreversible inflammatory changes within the middle ear and mastoid. The factors that allow acute infections within the middle ear and mastoid to develop into chronic infections are unclear. da Costa and colleagues[27] found granulation tissue in 96%, ossicular changes in 96%, tympanosclerosis in 43%, cholesteatoma in 36%, and cholesterol granuloma in 21% of the human temporal bones of patients with chronic otitis media with a perforated tympanic membrane (Table 139-3). Aeration of the middle ear, antrum, and mastoid depends on the free movement of gases from the eustachian tube into the mastoid air cells. In the human temporal bone, gases must travel around the ossicles in the epitympanic space to get into the antrum (Fig. 139-11).

Proctor[74] showed that the middle ear is separated from the antrum not only by the ossicles, but also by mucosal folds. He found that there were only two constant openings: (1) between the tendon of the tensor tympani muscle and the stapes, and (2) between the short process of the incus and the stapedial tendon. Edema and inflammation with granulation tissue may block these communicating openings, preventing drainage of the antrum and mastoid. Chronic obstruction of the attic and antrum with infection leads to "irreversible" changes in the mucosa and bone of the antrum and mastoid. Granulation tissue within the temporal bone can lead to bone erosion; 4 of 123 temporal bones in this series had active bone erosion. Thomsen and colleagues[84] found that bone erosion in patients with chronic otitis media was more prevalent when cholesteatoma was present, but it still occurred in the absence of cholesteatoma. Moriyama and associates[85] found osteoclastic bone resorption in rats with chronic otitis media.

Chronic otitis media may occur in patients who have indwelling tympanostomy tubes. Otorrhea may be a complication of tympanostomy tube insertion; it has been reported to occur in 9% to 34% of children undergoing this procedure.[86] Chronic otorrhea that is resistant to therapy has been reported to occur in 5.5% of children with tubes.[87]

Table 139-3

Pathologic Findings in the Temporal Bones with Chronic Otitis Media

Pathologic Finding	Perforated Tympanic Membrane (n = 116) (%)	Nonperforated Tympanic Membrane (n = 28) (%)
Granulation tissue	113 (97.4)	27 (96.4)
Ossicular changes	105 (90.5)	27 (96.4)
Tympanosclerosis	23 (19.8)	12 (42.9)
Cholesterol granuloma	14 (12.1)	6 (21.4)
Cholesteatoma	5 (4.3)	10 (35.7)

Modified from da Costa SS, Paparella MM, Schachern PA, et al. Temporal bone histopathology in chronically infected ears with intact and perforated tympanic membranes. *Laryngoscope*. 1992;102:1229.

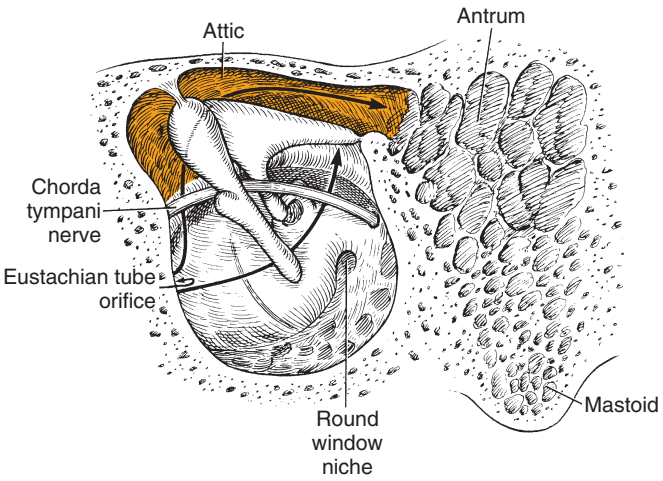

Figure 139-11. Aeration of the antrum and mastoid depends on communication around the ossicle within the attic. Obstruction of these narrow openings may result in chronic infection.

It is unclear whether such chronic infection is a result of the indwelling tube or of the drainage of an already smoldering infection. Giebink and coworkers[88] found the risk of otorrhea on the second postoperative day was significantly increased by the presence of a bacterial pathogen in the ear canal or in the middle ear effusion, and by the presence of inflamed middle ear mucosa at tympanostomy tube insertion. The bacteria that are found in such cases are bacteria found in chronic otitis media generally: *P. aeruginosa* and *Staphylococcus aureus*. Erkan and colleagues[89] reported the culture results of aspiration of exudate in 183 patients with chronic otitis media. Aerobes were found in 39% of the samples, anaerobes were found in 11%, and aerobes and anaerobes were found in 50%. *P. aeruginosa, S. aureus,* and *Klebsiella pneumoniae* were commonly found in aerobes, and *Bacteroides* sp were most commonly isolated in anaerobes. The colonization of tympanostomy tubes in the form of microbial biofilms may lead to persistence and recurrence of infection.[90]

Management

Most infected perforations can be managed conservatively with topical antibiotics. Antibiotic otic suspensions with or without steroids usually are effective. The antibiotics should be chosen to eradicate the most common pathogens, *P. aeruginosa* and *S. aureus*. In cases with recurrent or chronic infections, cultures should be used to adjust antibiotics. Many topical otic antibiotic preparations contain potentially ototoxic substances, including aminoglycoside antibiotics and propylene glycol. Studies of these substances applied to the middle ear have shown ototoxicity in rodents[91] and primates.[92] Although there are reports suggesting that sensorineural hearing loss may occur after topical use of these preparations,[93,94] no conclusive evidence is available proving ototoxicity of commercially available otic preparations in the human middle ear.

Potentially ototoxic topical preparations should be applied to the middle ear only when potential benefits outweigh the potential risks. Topical antibiotics also can be applied in powder form by insufflation. Various agents have been used individually or in combination, including boric acid, sulfamethoxazole, chloramphenicol, and hydrocortisone. This technique is particularly useful in the presence of epithelialitis and in a moist mastoid cavity, although patients may become sensitized to sulfamethoxazole or amphotericin. Systemic antibiotics should be used in refractory cases when specific pathogens are found on culture. Several quinolones such as ciprofloxacin, ofloxacin, and norfloxacin may be useful in these patients. In ears that become repeatedly infected but clear between episodes, tympanoplasty should be considered. Ideally, an ear with a tympanic membrane perforation should be free from infection for 3 months before tympanoplasty.

In some patients, chronic infection with otorrhea, but without cholesteatoma, persists despite aggressive medical therapy. In these cases, two options should be considered: long-term (6 to 8 weeks) intravenous antibiotics or tympanomastoid surgery. Antibiotic therapy can be administered at home or in the hospital. Aggressive local débridement is required. The goals of tympanomastoidectomy include aeration of the middle ear and mastoid, removal of irreversibly diseased tissue, closure of the middle ear, and reconstruction of the sound-conducting mechanism. These goals are not always achieved in a single stage.

Otorrhea occurs after insertion of tympanostomy tubes in approximately 10% of ears. The incidence of immediate postoperative otorrhea usually can be decreased by the use of topical antibiotics at the time of tube insertion.[95,96] The use of Silastic tympanostomy tubes impregnated with silver oxide was shown to decrease the incidence of otorrhea significantly in a randomized clinical trial.[86] If infection persists, intravenous antibiotic therapy directed at specifically identified organisms should be considered. Because chronically infected tympanostomy tubes may have persistent bacterial biofilms, removal of the tympanostomy tube may be necessary in some refractory cases.[90,97]

Bone Erosion in Cholesteatoma and Chronic Otitis Media

In Virchow's description of the pathology of aural cholesteatoma in 1854, he noted that "the cholesteatoma extended through the bone to the external auditory canal, sometimes, also, in the cranial cavity."[98] Since that time, clinicians and investigators have studied the pathophysiology of bone resorption from this disease. Although much progress has been made in the understanding of the resorptive process, the actual sequence of events and their relative importance are not completely understood.

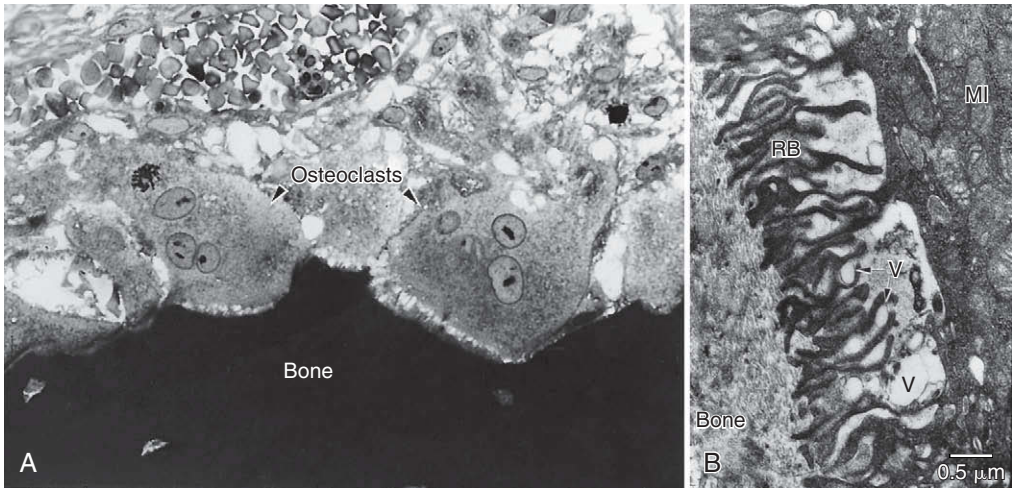

Figure 139-12. **A,** Multinucleated osteoclasts actively absorbing bone beneath human cholesteatoma in a surgical biopsy specimen. **B,** Transmission electron micrograph of the ruffled border (RB) of an osteoclast showing mitochondria (MI) in the cytoplasm and vacuoles (V) containing acid proteases in the eroding zone.

In the first half of the 20th century, it was believed that the bone resorption seen adjacent to cholesteatomas was a result of pressure necrosis,[99] although clinical observations led to the abandonment of the pressure necrosis theory. It was thought to be highly unlikely that cholesteatomas could exert pressure exceeding capillary perfusion pressure (approximately 25 mm Hg), and this was later confirmed by Orisek and Chole[100] using direct measurements of the pressure exerted by experimental cholesteatomas (1.3 to 11.9 mm Hg). Lautenschlager[101] first suggested that cholesteatomas may elaborate enzymes that directly erode bone, and some investigators showed that cultured human cholesteatoma could degrade guinea pig collagen.[63,102] Direct extracellular dissolution of bone was never shown, however.

It is now clear that inflammatory processes in the temporal bone induce the development and activation of osteoclasts, the only cell capable of resorbing bone. Several early human temporal bone studies revealed osteoclastic bone resorption adjacent to cholesteatoma matrix.[103,104] Because of the relative scarcity of osteoclasts seen in surgical specimens, however, numerous investigators hypothesized that mononuclear histiocytes were the predominant cell associated with erosive cholesteatomas.[105-107] Bernstein and colleagues[108,109] noted that early studies were based on biopsy material taken during tympanomastoid surgery, and surgery often is preceded by attempts to control active inflammation; biopsy material may represent the reparative phase instead of the resorptive phase. Chole[110] showed ultrastructural evidence in human and experimental cholesteatomas that bone resorption is primarily a result of the action of multinucleated osteoclasts on bone (Figs. 139-12 and 139-13). Although many mononuclear cells (histiocytes and fibroblasts) were present in the vicinity of active bone resorption, only multinucleated osteoclasts were seen to disrupt the lamina limitans of bone and cause resorption lacunae. It is established that multinucleated osteoclasts caused bone resorption in patients with cholesteatoma and chronic otitis media.[110-114]

For bone resorption to occur, enzymatic removal of the organic and inorganic components must occur. These enzymes likely are elaborated or activated by the resorbing cells (osteoclasts) in their immediate microenvironment. These enzymes include acid phosphatase,[54,110,115,116] collagenase,[54,116] and acid proteases.[117] In studies by Blair and colleagues,[117] a cathepsin-like proteolytic enzyme with maximal activity at pH 4.0 was shown to be active in the microenvironment of the ruffled border of the osteoclast.

Numerous factors may lead to localized osteoclast recruitment and activation in regions of inflammatory osteolysis. It has been shown that bone remodeling and bone loss are controlled by a balance between the receptor activator of NF-κB (RANK) and its ligand, RANKL.[113] The RANKL receptor, or RANK, has been identified on dendritic cells, chondrocytes, osteoclast precursors, and mature osteoclasts.[113] Hamzei and coworkers[118] indicated an increased number of osteoclast precursor cells in the perimatrix of cholesteatoma tissue concomitant with an enhanced expression of RANKL, osteoprotegerin, and macrophage colony-stimulating factor. The cholesteatoma-induced inflammatory process is associated with the release of RANKL from stromal cells and activated T cells, which triggers osteoclastogenesis.[113,118]

The localized control of osteoclastogenesis is complex, and signaling pathways may vary during the natural course of an inflammatory process. The type of bone undergoing resorption may also modify the process. The endochondral bone of the otic capsule seems to be more resistant to erosion than the intramembranous bone of the middle ear and mastoid.[119]

Some investigators have noted that the keratin debris within a cholesteatoma sometimes extrudes into the subepithelium adjacent to bone eliciting an inflammatory and osteoclastic response. Yuasa and colleagues[120] showed that the pH of keratin debris within cholesteatomas was acidic, which they believed led to demineralization of the hydroxyapatite of bone. Some investigators have shown that the keratin itself may induce an inflammatory reaction (foreign body granuloma), which leads to cellular bone resorption.[85,121,122]

The extracellular matrix exhibits alterations in cholesteatoma, and many studies have evaluated the role of enzymes in cholesteatoma-induced bone resorption. By immunocytochemistry and zymography, the expression of matrix metalloproteinases (MMP-1, MMP-2, MMP-3, and MMP-9) was found to be strictly confined to the basal and suprabasal cell layers of the cholesteatoma epithelium.[123-126] The neutrophil collagenase showed a more disseminated expression in the epithelium and the granulation tissue. The tissue inhibitor of metalloproteinases, TIMP-1, could be detected only in very limited areas of the granulation tissue in a quite randomized manner.[126] Because of their destructive capacity, matrix metalloproteinases are normally tightly controlled. A derailment of these regulatory mechanisms in favor of proteolysis was postulated to play a role in the invasion of cholesteatomas into the temporal bone.[125,126]

Collagenase plays an important role in the mechanism of local invasion by aural cholesteatoma.[116,127] Neutral collagenase may stimulate osteoclastic resorption by degrading the osteoid surface of bone, allowing osteoclastic activity.[128] Neutral collagenase has not been found within osteoclasts,[129] but has been localized in the vicinity of resorbing bone.[116] In the collagenase cascade, procollagenase is activated to collagenase by plasmin. Plasminogen is activated to plasmin by plasminogen activator. Plasminogen activator is thought to play a role in keratinocyte proliferation, migration, and differentiation.[130] Plasminogen activator can be divided into two types: tissue-type plasminogen activator and urokinase-type plasminogen activator. Tissue-type plasminogen activator is known to activate osteoclasts in vitro.[131] Naka-

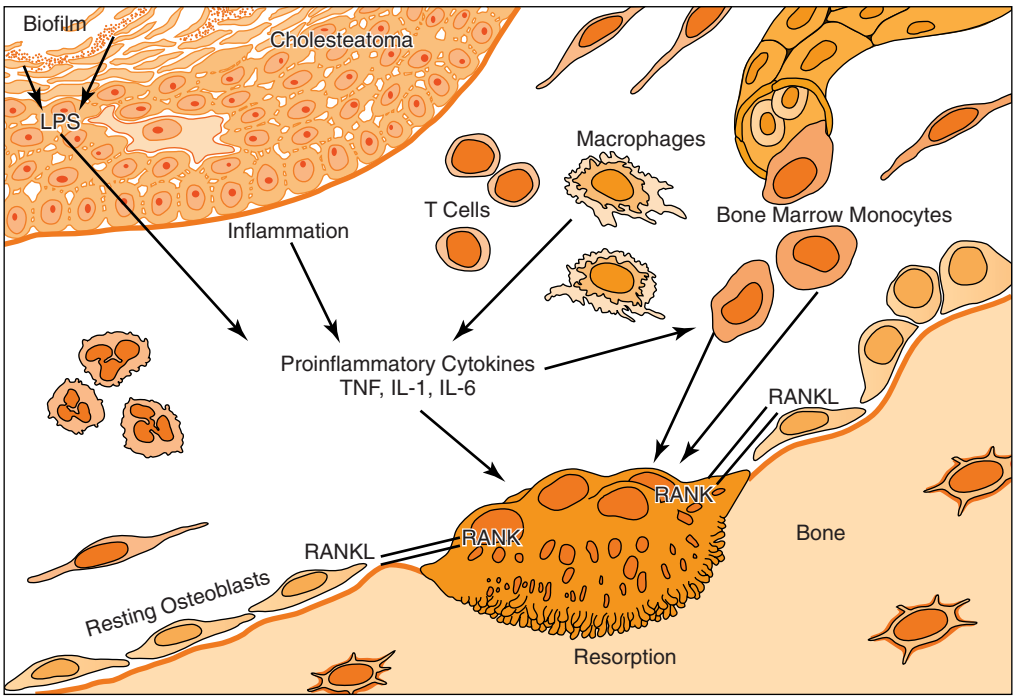

Figure 139-13. The bone resorption associated with cholesteatomas occurs as a result of the recruitment of osteoclasts. Osteoclasts are derived from bone marrow mononuclear cells. The receptor activator of NF-κB ligand (RANKL) on osteoblasts or T cells binds to receptor activator of NF-κB (RANK) on monocytes forming osteoblasts. Osteoclast activation is potentiated further by numerous proinflammatory cytokines (tumor necrosis factor [TNF], IL [interleukin]-1, IL-6) that are produced in response to factors produced by the cholesteatoma or bacterial products such as lipopolysaccharide (LPS).

mura and associates[132] showed both types of plasminogen activator in two of six tissue extracts of human cholesteatoma.

Ohsaki and colleagues[133] showed that bone adjacent to cholesteatomas is demineralized. Although their study suggested that demineralization by acidic cholesteatomas may explain bony destruction, intimate contact of the cholesteatoma matrix with bone does not seem to be necessary for bone resorption. Bone resorption has been shown to occur in patients with chronic otitis media with or without cholesteatoma.[84] Macri and Chole[134] showed that an implanted silicone barrier between a cholesteatoma and underlying bone did not prevent osteoclastic bone resorption in experimental cholesteatoma. It is likely that indirect effects (e.g., pressure or inflammation) may activate the cellular events of bone resorption.[135] More recent studies have shown that pressure with[85,136] or without[32,137] inflammation is sufficient to induce bone resorption in experimental animals. The histologic appearance of pressure-induced bone resorption is similar to that seen in cholesteatoma, showing osteoclasts and granulation tissue.[111] It has been postulated that the physical effects (pressure) of cholesteatomas may lead to transient electrical potentials[138] and the recruitment of monocytes into the subepithelial space. These monocytes may activate the downstream cellular events leading to bone resorption.

Activated monocytes can produce arachidonic acid metabolites such as prostaglandins and leukotrienes, which are potent inflammatory mediators. Prostaglandin E_2 (PGE_2)[139] has been shown to stimulate bone remodeling similar to the kallikrein-kinin system.[51] Prostaglandins, produced from the cyclooxygenase pathway of arachidonic acid metabolism, can be inhibited by aspirin, indomethacin, and ibuprofen. Indomethacin has been shown to impede bone resorption by inhibiting the production of PGE_2 in vitro.[140] This study also showed that in vivo indomethacin can inhibit pressure-induced bone resorption in an animal model. Ibuprofen, another prostaglandin inhibitor, has also been shown to inhibit bone resorption in a dose-dependent manner.[141] Leukotrienes are 5-lipoxygenase metabolites of arachidonic acid. Although the role of leukotrienes in cholesteatoma is unclear, the peptidoleukotrienes (LTC_4, LTD_4, and LTE_4) stimulate isolated osteoclasts to accumulate tartrate-resistant acid phosphatase and resorb bone.[142]

Although the mechanism is unknown, osteoclast activity can be inhibited by bisphosphonates, also known as antiosteolytic agents such as 1-hydroxyethylidene-1,1-bisphosphonate (HEBP), risedronate, and zoledronate. These drugs inhibit the localized recruitment and activation of osteoclasts in vivo and in vitro.[143,144]

Proinflammatory cytokines play an important role in middle ear infections and cholesteatoma. They are released by macrophages, T lymphocytes, monocytes, and many other cells at the site of infection. IL-1 was identified in cholesteatoma matrix,[8] and was shown to stimulate fibroblasts and macrophages to produce PGE_2 and collagenase.[105] Cultured cholesteatoma specimens produced IL-1α and IL-1β, and both isoforms have been detected within cholesteatoma tissue.[41,145,146] IL-1α and IL-1β are potent inducers of bone resorption and may act by increasing PGE_2. Human recombinant IL-1 receptor antagonist blocked bone resorption in mouse calvaria as a result of IL-1β, but not IL-1α.[147]

Concomitantly, a parallel process of osteoblastic bone deposition invariably accompanies osteoclastic bone resorption. Factors known to induce new bone formation such as transforming growth factor (TGF)-β and bone morphogenetic protein-2 have been identified in cholesteatomas.[105,148,149] Cytokines such as TGF-β1 and TGF-β2 may potentially slow the proliferation and tissue destruction associated with human cholesteatoma.[150] TGF-β is involved in matrix formation and stimulates numerous matrix proteins, such as collagen, laminin, and fibronectin. TGF-β may also initiate bone formation by recruitment and proliferation of osteoblast precursor, whereas bone morphogenetic protein-2 seems to be important in inducing differentiation of pluripotent progenitor cells.

Fujioka and Huang[151] identified platelet-derived growth factor in human cholesteatoma tissue, which stimulates monocytes to form multinucleated osteoclast-like cells. Additionally, Bujia and coworkers[60] and Sudhoff and colleagues[59] showed abnormal expression of epidermal growth factor in human cholesteatoma, which is a potent stimulator of cell proliferation and differentiation. Production of parathyroid hormone–related protein was detected in cholesteatoma cell cultures and may increase incidence of bone resorption.[152]

Vascularization within the perimatrix of cholesteatoma showed a fivefold increase compared with middle ear mucosa and a twofold increase compared with skin.[152] Sudhoff and colleagues[153] found a close relationship between the density of capillaries, degree of inflammation, and expression of different angiogenic factors. Because proliferating tissues such as middle ear cholesteatoma require an enhanced blood supply, angiogenesis seems to be necessary for the expansion of cholesteatoma matrix within the middle ear cavity.

The role of other cells in the pathophysiology of bone erosion in patients with chronic otitis media is unclear. Gantz[154] suggested that Langerhans cells within the matrix of cholesteatomas might initiate an immunologic response to the presence of antigens (keratin and bacterial debris); these cells may induce the cellular events outlined previously. These cells may also promote proliferation of keratinized epithelial cells by means of IL-1α in vitro.[92] Aberg and associates[155] found no increase in Langerhans cells compared with ear canal epithelium, however, suggesting that these cells may not have a primary role in the development of cholesteatoma. Mast cells are seen in cholesteatoma matrix, but their role is unknown.[156]

The important role of infection in the pathogenesis of cholesteatoma is highlighted by the more recent identification of bacterial biofilms in otitis media[157] and cholesteatoma.[35,158] Biofilms are bacterial communities enclosed in a self-produced matrix adherent to a surface.[147] Many bacterial species relevant to otologic infections are known to form biofilms, including *P. aeruginosa, H. influenzae, Streptococcus pneumoniae,* and *S. aureus*.[34] Bacteria within biofilms are more resistant to antibiotics and are likely responsible for the chronicity and recurrence of these infections. The presence of antibiotic-resistant bacterial biofilms in cholesteatomas may also explain their aggressiveness.[35] Bacterial biofilms within cholesteatomas may elaborate lipopolysaccharide and other bacterial products that stimulate osteoclastogenesis. Zhuang and colleagues[159] showed that lipopolysaccharide derived from *P. aeruginosa* can induce osteoclast development in vitro and potently stimulates in vivo bone resorption through a toll-like receptor–4–dependent mechanism.[159]

Sensorineural Hearing Loss

The destructive effects of an expanding cholesteatoma within the middle ear or mastoid and concomitant chronic infection are not limited to the bony structures of the temporal bone. Paparella and coworkers[160] observed sensorineural hearing loss in patients with chronic otitis media, and Chole and Chiu[161] observed loss of cochlear hair cell stereocilia in animals with experimental cholesteatomas with or without infection. In a study of age-matched, staged cholesteatomas, McGinn and Chole[162] showed loss of cochlear hair cells in areas subjacent to areas of bone erosion, suggesting that ototoxic substances may traverse the bony wall of the cochlea directly. Meyerhoff and associates[163] found that 17.9% of temporal bones with chronic otitis media had histologic evidence of labyrinthitis.

Vartiainen and Karjalainen[164] compared 874 chronically infected ears with and without cholesteatoma with 609 control ears, and found significantly worse bone conduction in the infected group; ears with cholesteatomas were generally worse than ears without cholesteatomas. Fria and coworkers[165] found that there was a tendency for bone conduction thresholds to be elevated at 2 kHz and 4 kHz in the ears with chronic OME compared with bone conduction thresholds in children with or without OME. In animal experiments, the inner ear is particularly sensitive to injury by middle ear infection. Morizono and associates[166] found that otitis media in chinchillas resulted in significant increase in tone-burst elicited compound action potentials after the otitis had cleared, indicating a sensory hearing loss.

In contrast, after correcting for the artificial elevation of bone conduction thresholds from conductive hearing loss, also known as the Carhart effect, Browning and Gatehouse[167] found no difference in the bone conduction thresholds between 395 ears with chronic otitis media and 920 control ears. These results were supported by MacAndie and O'Reilly,[168] who pointed out that the presence of cholesteatoma or ossicular erosion, or both, was not associated with a significantly increased risk of sensorineural hearing loss. Rahko and colleagues[169] studied bone conduction thresholds in 359 children with a history of recurrent AOM and found no correlation between the number of bouts of infection and permanent sensorineural hearing loss.

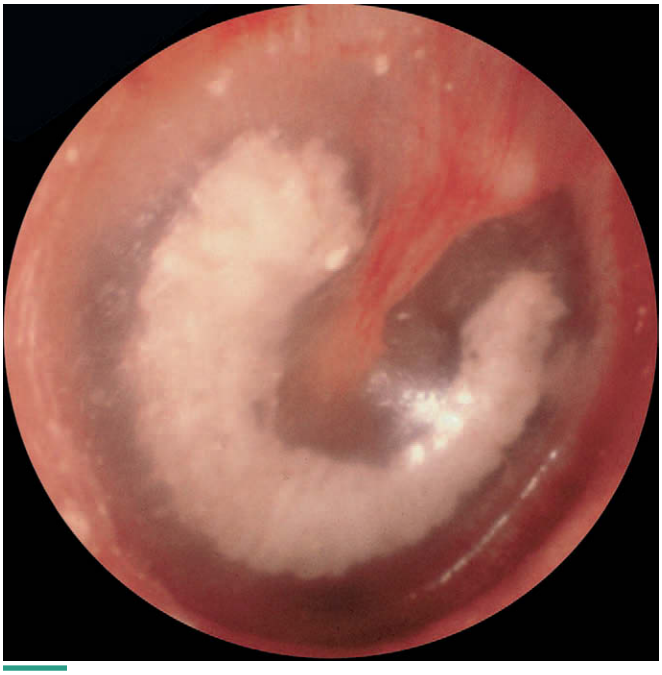

Figure 139-14. Tympanic membrane tympanosclerosis (myringosclerosis).

Tympanosclerosis

Diagnosis

Tympanosclerosis is thought to be a complication of otitis media in which acellular hyalin and calcified deposits accumulate within the tympanic membrane and the submucosa of the middle ear. In most patients, these plaques are clinically insignificant and cause little or no hearing impairment. Tympanosclerotic plaques within the tympanic membrane appear as a semicircular crescent or horseshoe-shaped white plaque within the tympanic membrane (Fig. 139-14).

Pathogenesis

Tympanosclerosis is a consequence of resolved otitis media or trauma. Hussl and Mueller[170] found tympanosclerosis to be a frequent sequela of chronic OME; they found tympanosclerosis in 19.7% of drumheads 6 to 8 years after the insertion of ventilating tubes for OME. They also noted that middle ear tympanosclerosis often was seen after recurrent bouts of AOM. Tos and Stangerup[171] found a significant increase in tympanosclerosis in ears in which grommets were placed (59%) compared with the contralateral ears, in which only myringotomy was performed (13%). Daly[172] reported the weighted average incidence of tympanosclerosis is 10% in children 4 to 15 years old, with an average follow-up period of 4 years. The incidence of tympanosclerosis in chronic otitis media has been reported to range from 9% to 38%. Kinney[173] found that 20% of 1495 patients undergoing surgery for chronic otitis media or its sequelae had tympanosclerosis. Mangat and coworkers[174] found that 23.6% of 1274 patients treated with tympanostomy tubes had tympanosclerosis.

Tympanosclerosis appears histologically as an acellular hyalinization of the subepithelial connective tissue of the tympanic membrane and middle ear. In most instances, calcification is present. Osteoneogenesis also can occur within these lesions. The bone deposition and ossicular fixation occur most frequently in the attic associated with the heads of the malleus and incus. When plaques occur within the tympanic membrane, they are limited to the lamina propria. Hussl and Lim[175] found these plaques to be a degenerative process resulting in calcification in connective tissue of the middle ear. They hypothesized

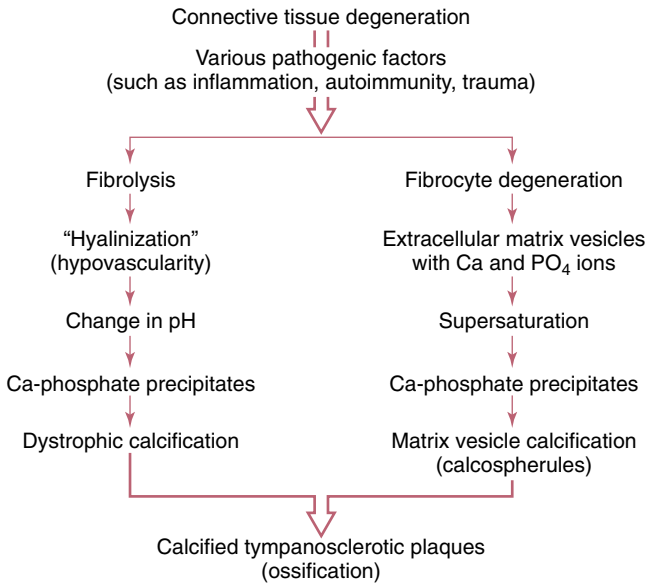

Figure 139-15. Two possible mechanisms for formation of tympanosclerotic plaques. *(Adapted from Hussl B, Lim DJ. In: Lim DJ, Bluestone CD, Klein JO, eds.* Recent Advances in Otitis Media with Effusion. *St. Louis: Mosby; 1984.)*

that OME or AOM led to a destructive process within connective tissue, which led to degeneration of collagen and subsequently dystrophic calcification and tympanosclerosis.

The degeneration of collagen may be a direct result of inflammation or infection within the middle ear (e.g., by bacterial proteinases and collagenases). Wielinga and colleagues[176] showed that eustachian tube obstruction alone, without infection, caused tympanosclerosis in rats; they hypothesized that deformation alone was sufficient to cause the plaques to form. Another possible cause of tympanosclerosis is an autoimmune process occurring within the tympanic membrane. Schiff and associates[61] prepared antisera to guinea pig lamina propria and passively immunized guinea pigs. When the tympanic membranes of these animals were traumatized, tympanosclerotic plaques developed. Chole and Henry[177] found that LP/J inbred mice spontaneously developed middle ear lesions that resembled tympanosclerosis and may be immunologically mediated.[178] Hussl and Lim[175] proposed two possible mechanisms for the formation of tympanosclerotic plaques, beginning with collagen degeneration (Fig. 139-15). Russell and Giles[179] found that the process of tympanosclerosis started in the submucosal connective tissue layer and progressed to involve all connective tissue sublayers in an animal model. The extent of calcium deposition and fibrosis across the membrane was related to the duration of OME.

Management

Tympanosclerosis within the middle ear (Fig. 139-16) is histologically similar to tympanosclerosis occurring within the tympanic membrane, but it often leads to conductive hearing loss caused by ossicular fixation. Although some authors have stated that tympanosclerosis tends to recur after surgical removal, others have reported stable hearing results in these patients. Smyth and colleagues[180] reported excellent hearing results in 79% of tympanosclerotic ears in which ossicular reconstruction (stapedectomy and total ossicular reconstruction) was performed in two stages, although Gormley[181] found that only 7% of his cases had an air-bone gap of less than 21 dB on long-term follow-up evaluation, questioning the advisability of stapedectomy in ears with tympanosclerosis. In the earlier series[182] in which one-stage procedures were performed, 21% of 57 cases resulted in cochlear losses. Tympanoplasty and ossicular reconstruction can be performed in ears with tympanosclerosis, but the risks of cochlear damage seem to be greater than in other middle ear diseases because of the extensive dissection that is required in tympanosclerotic ears and the coexistence of labyrinthine erosion.

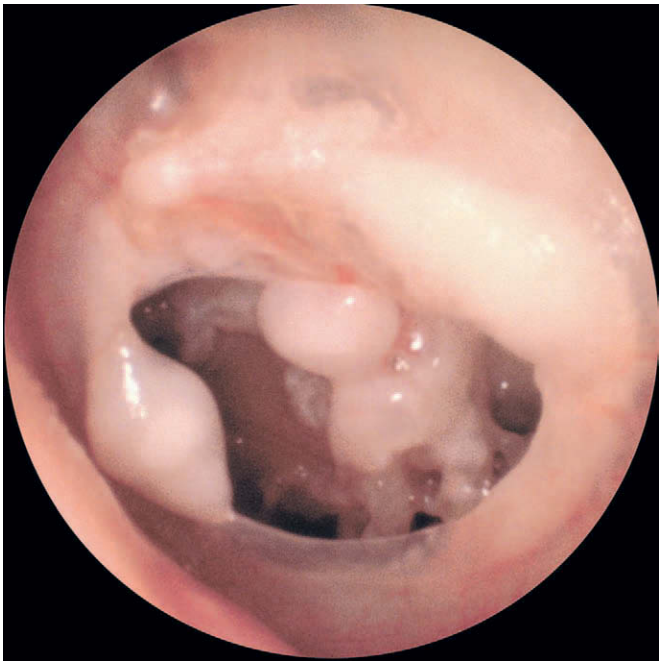

Figure 139-16. Advanced tympanosclerosis of the tympanic membrane and the middle ear.

Petrositis

Infection of the mastoid and middle ear may be complicated by the spread of infection within the temporal bone into the petrous apex. Petrous apicitis is an extension of infection from the mastoid air cell tract into a pneumatized anterior or posterior petrous apex. In the preantibiotic era, otitis media often was complicated by a spread into the petrous apex and further intracranial complications. The classic symptoms of petrous apicitis include deep facial pain, otitis media, and ipsilateral abducens nerve paralysis. This triad, called Gradenigo's syndrome,[183] is rare, although suppurative processes in the petrous apex occur in patients with AOM and chronic otitis media, but most often manifest as chronic infection with otorrhea and sometimes deep pain after adequate surgery. More recently, otologic diseases have been observed as complications in patients with acquired immunodeficiency syndrome (AIDS). Chandrasekhar and colleagues[184] reported six of seven specimens had petromastoiditis in the temporal bones of AIDS patients.

Historical Note

The history of petrous apicitis and its management has been reviewed more recently.[185] A patient with petrous apicitis and Gradenigo's triad was first described by Goris.[186] In Gradenigo's review of previously published cases of 57 patients with petrositis, 24 actually had the pure triad; others had multiple complications. In the early part of the 20th century, there was a controversy as to whether petrous apicitis can develop in diploic (marrow-filled) or pneumatic (air-filled) petrous apices.[187] It is generally believed that petrous apicitis occurs in patients who have pneumatized petrous apices. In the 1930s, Almour[188] and Kopetzky and Almour[189] described surgical approaches for petrous apicitis in which fistulous tracts were followed into the petrous apex. Ramandier in 1933,[190] and soon thereafter Lempert[191] described the now classic operation for exenteration of the anterior petrous apex. The histopathology of petrous apicitis was described by Lindsay.[192] An additional surgical approach for suppuration of the petrous apex was described in a case report by Hendershot and Wood,[193] in which they drained an osteomyelitis of the petrous apex through the middle cranial fossa.

Anatomy

The petrous apex is a truncated pyramid, which is the portion of the temporal bone medial to the inner ear labyrinth (Fig. 139-17). The

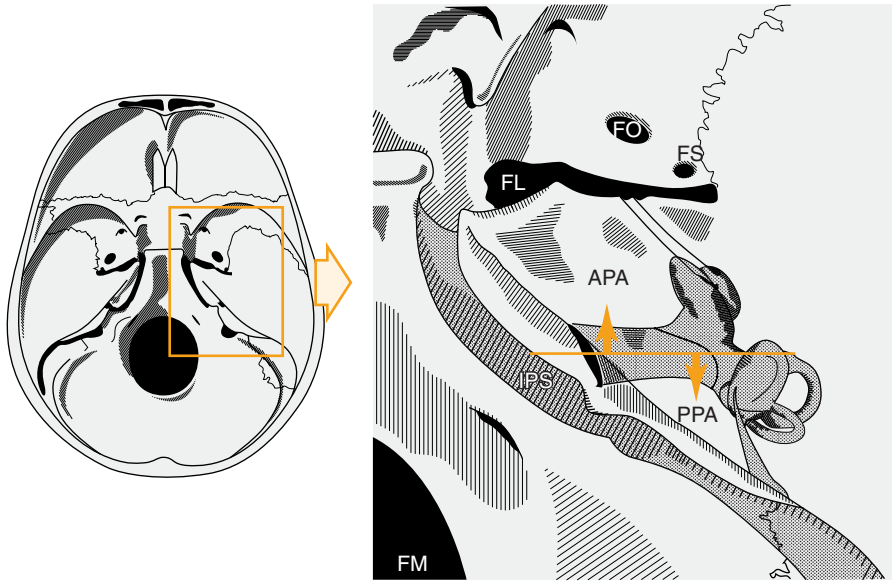

Figure 139-17. Base of skull viewed from above, revealing the relationship of the petrous apex to the foramen magnum (FM) and the rest of the temporal bone (*box*,enlarged on right). The anterior petrous apex (APA) is a truncated pyramid based on labyrinth *(shaded)* and bound by foramen lacerum (FL) anteriorly and inferiorly and inferior petrosal sinus (IPS) posteriorly. If the petrous apex is viewed from above, it can be divided into anterior and posterior sections by a line drawn through the internal auditory canal. APA is located medial to the cochlea and internal auditory canal, and posterior petrous apex (PPA) is medial to the semicircular canals. FO, foramen ovale; FS, foramen spinosum. *(Modified from Chole RA. Petrous apicitis: surgical anatomy.* Ann Otol Rhinol Laryngol. *1985;94:251.)*

petrous apex is the most surgically inaccessible portion of the temporal bone.[194] The apex may be arbitrarily bisected by a coronal plane through the internal auditory canal (see Fig. 139-17). This plane divides the apex into an anterior portion, the peritubal area, and a posterior portion, the perilabyrinthine area. The posterior petrous apex, which is pneumatized in 33% of patients, is just medial to the semicircular canals. The anterior apex, which is pneumatized in 10% of patients, is anterior and medial to the cochlea. The carotid artery traverses the anterior petrous apex.

The petrous apex may be pneumatic (air cell filled), diploic (marrow filled), or sclerotic (solid bone). Direct extension of infection from the mastoid and middle ear through pneumatized air cell tracts into the petrous apex is thought to be the etiology of petrous apicitis. It has been estimated that 30% of posterior petrous apices are pneumatized, and in a study of 84 normal human temporal bones, 9% of anterior petrous apices were found to be pneumatized (Fig. 139-18).[195]

The anatomic relationship at the petrous tip may explain some of the symptoms of petrous apicitis. An undetected and poorly drained infected air cell of the petrous apex must trail through small air cell tracts into the middle ear and mastoid. These cell tracts consist of the infralabyrinthine air cell tract, the retrofacial tract, and the peritubal air cells superior to the eustachian tube. If the bony cortex of the anterior petrous apex is involved by the extension of infection, the infection may cause an epidural abscess in the region or damage nearby cranial nerves. On the superior aspect of the petrous tip lies the trigeminal or gasserian ganglion. Damage or irritation to the ganglion may explain the deep facial pain that some patients with apicitis experience. Extending from the tip of the petrous apex to the clinoid is the petroclinoid ligament. The abducens nerve travels below the petroclinoid ligament in a small canal called Dorello's canal.[196] Entrapment or inflammation in the ear of Dorello's canal is thought to account for the presence of abducens paralysis in some patients with petrous apicitis.

Diagnosis

Symptoms of petrositis usually are subtle. Typically, a patient who has had previous mastoid surgery complains of persistent infection and deep facial pain. In a series of 22 patients during 20 years, 16 patients (72.7%) had otalgia, and 13 patients (59.1%) had deep facial pain and headache; trigeminal nerve paralysis (68.2%) most frequently involved the cranial nerve; 6 (27.3%) had facial nerve paralysis, 4 (18.2%) had abducens nerve paralysis, and 2 had coma (Table 139-4).[197] Patients with suppuration may manifest various symptoms, none of which are pathognomonic for the syndrome. In patients with long-standing chronic otomastoiditis, deep pain, and persistent infection, the diagnosis of petrositis should be considered. In a more recent series of patients with petrous apicitis, the predominant organism was *P. aeruginosa*. The physical findings of petrositis usually include those of chronic otitis media with chronic otorrhea. In some patients, the infection can be

limited to the anterior petrous apex, and the middle ear is normal.[197] Many patients have involvement of cranial nerves V, VI, and VII.

Diagnostic Tests

When the diagnosis of petrous apicitis is suspected on clinical grounds, the most appropriate diagnostic procedure is CT. High-resolution CT usually shows details of the petrous apex and provides important details about potential surgical routes. A pneumatized petrous apex on the uninvolved side can sometimes be contrasted with a fluid-filled or sclerotic petrous apex on the involved side, although Roland and colleagues[198] have shown that asymmetry of the petrous apex is not diagnostic for apicitis because asymmetric pneumatization of the apex can occur in healthy subjects. If CT scan indicates a potential apicitis, MRI may add information about the nature of the fluid or tissue within the apex (Fig. 139-19). A gallium bone scan may provide additional information, showing increased uptake on the side of the apicitis. A combination of MRI and CT is necessary to evaluate normal anatomic variations and to be capable of differentiating diagnosis.[199]

Management

The management of petrous apicitis is directed toward control of the infection. If topical and systemic antibiotic management is inadequate to control the suppuration, various surgical approaches are available. Surgical therapy aims to achieve drainage of the petrous apex through the mastoid and middle ear into the petrous apex. These air cells have been well defined anatomically[194]; they include the subarcuate and sinodural angle cells toward the posterior petrous apex and the peritubal, retrofacial, infralabyrinthine, and infracochlear tracts toward the anterior petrous apex. The anterior apex may be widely exposed through the glenoid fossa with the approach of Ramandier[190] and Lempert.[191] If adequate air cells cannot be identified through the middle ear and mastoid, the middle cranial fossa approach can be used to enter the roof of the anterior petrous apex.[193] Brackmann and Toh[138] found the translabyrinthine approach useful in nonhearing ears. In hearing individuals, anatomy permitting, the transcanal infracochlear approach with stenting was the preferred approach for drainage of the petrous apex.

Summary

Otitis media is one of the most common diseases of childhood, and the most frequent disease managed with antibiotics in children. The infectious and noninfectious complications of otitis media may result in significant morbidity and complications, including acute and chronic mastoiditis, petrositis, and intracranial infection. The noninfectious sequelae, including chronic perforation of the tympanic membrane, ossicular erosion, labyrinthine erosion, and tympanosclerosis, are major causes of hearing loss.

Acute or recurrent infection of the middle ear may result in a permanent perforation of the tympanic membrane and irreversible inflammatory changes within the middle ear and mastoid known as chronic otomastoiditis. Chronic otitis media may occur in patients who have indwelling tympanostomy tubes. Most cases of chronic otitis media can be managed with topical antibiotics.

Aural cholesteatomas are epidermal inclusion cysts of the middle ear or mastoid, and are classified as congenital and acquired. Acquired cholesteatomas possibly result from OME or AOM or both. There are four basic theories of the pathogenesis of acquired aural cholesteatomas, which are supported by clinical and experimental evidence. The diagnosis of aural cholesteatoma is made on otoscopic examination and special imaging procedures, such as high-resolution CT and MRI. The expansion of cholesteatomas may result in erosion of surrounding structures, which may result in local and intracranial complications. Cholesteatomas can be eradicated from the temporal bone only by surgical resection; various surgical approaches are available.

The main mechanism of bone resorption in chronic otitis media with and without cholesteatoma is thought to be the increased number and activity of osteoclasts. Many metabolites and cytokines are known to activate osteoclasts locally. PGE_2, osteoprotegerin, and macrophage

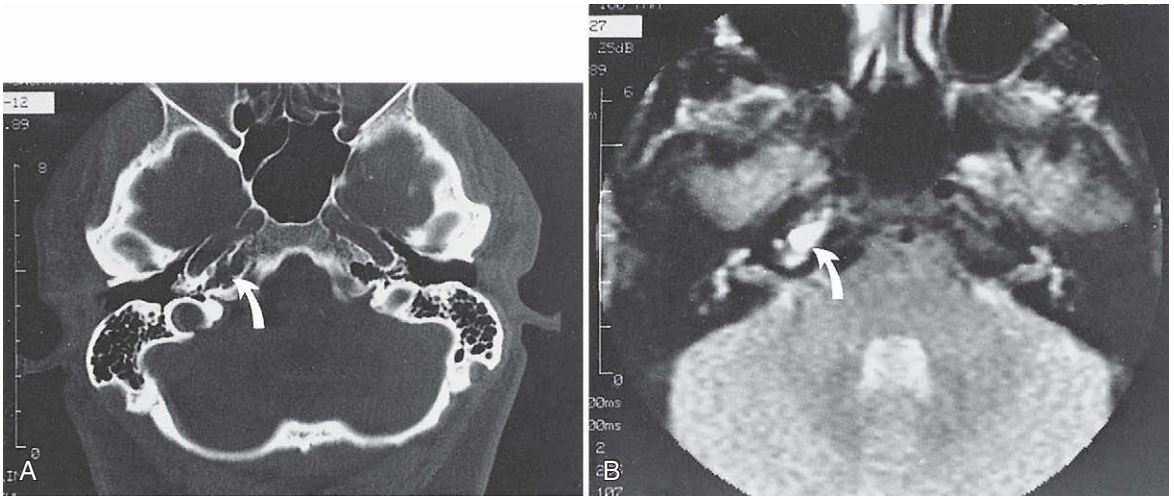

Figure 139-19. CT **(A)** and MRI **(B)** are helpful adjuncts in the diagnosis of petrous apicitis. **A,** In the CT scan, the fluid-filled petrous apex *(arrow)* can be compared with the opposite air-filled apex. **B,** In the MRI scan, the area of increased signal is present in involved apex *(arrow)*. An amber-colored, fluid-filled cyst was found at surgery.

colony-stimulating factor are some of the most potent osteoclast-activating metabolites. Cytokines and growth factors such as IL-1, IL-6, tumor necrosis factor-α, epidermal growth factor, parathyroid hormone–related protein, and TGF-β seem to play an important role in middle ear infections and cholesteatoma. Tissue-type plasminogen activator and collagenase also may play a role in local invasion of cholesteatoma. More recent evidence suggests that bacterial biofilms within chronically infected cholesteatomas may contribute to their aggressiveness by local elaboration of lipopolysaccharide.

Sensorineural hearing loss and tympanosclerosis are thought to be complications of otitis media. Tympanosclerosis in the middle ear often leads to conductive hearing loss caused by ossicular fixation. Petrous apicitis may be complicated by the spread of infection within the temporal bone into the petrous apex. The appropriate diagnostic procedure is high-resolution CT scanning. MRI and gallium bone scan may provide additional information. The management of petrous apicitis is directed toward control of the infection and includes topical and systemic antibiotic management and surgical approach through many surgical routes.

Key Points

- Although declining in incidence, the complications of temporal bone infections continue to carry the potential for extensive morbidity and mortality.
- Because of the complexity of their pathogenesis, complications related to otitis require a thoughtful diagnostic approach. Although the management of such complications is invariably urgent, a stepwise approach should be taken, and time efficiency is gained by fully considering the patient history and physical examination.
- The management of intratemporal complications of infection that are suppurative in nature, or related to cholesteatoma, can be facilitated by recognizing patterns of extension within the temporal bone and neurovascular involvement.
- The management of intracranial complications of temporal bone infection should be guided by a similarly thoughtful diagnostic approach. The evaluation should be supported by history, findings, awareness of cerebrospinal fluid and cerebrovascular dynamics, and neurosurgical collaboration when an intradural process is identified.
- Microbiologic testing and imaging modalities are essential tools in the contemporary management of complications of temporal bone infections.
- Imaging with CT and MRI offers precise assessment of disease extension and characteristics of the offending lesion itself.

General Considerations

Although the incidence and prevalence of complications related to otitis are now diminished, their clinical impact requires a thorough understanding of related pathophysiology and management. This chapter reviews the complications of acute otitis media (AOM) and chronic otitis media (COM), including their etiology, pathophysiology, diagnosis, and treatment.

Epidemiology

Table 140-1 presents the age distribution of extracranial, intracranial, and combined complications in a large series of patients. Nearly 80% of extracranial complications and 70% of intracranial complications occurred in children in the first 2 decades of life. Extracranial complications, led by postauricular abscess, most commonly occurred in children younger than 6 years.[1] In a series of 93 intracranial and extracranial complications of otitis media, 58% were present in patients younger than 20 years.[2] Low socioeconomic status and overcrowding confer either greater risk of or diminished resistance to an infection with an extended course and complications. Associations with inadequate health education and limited access to medical care likely contribute to heightened risk of complication. For this reason, most of the current reports of otogenic brain abscesses come from underdeveloped countries. Although the number of cases with immunodeficiency has increased, large series of patients with complications of otitis media have not been reported in patients with human immunodeficiency virus infection or acquired immunodeficiency syndrome, or in patients receiving immunosuppressive therapy after organ transplantation, even though such individuals do have heightened risks of suppurative ear disease.

Table 140-2 shows the classification of extracranial and intracranial complications, and Table 140-3 summarizes the relative frequencies of those complications. The dominant extracranial complication is postauricular abscess, and the dominant intracranial complication is meningitis. Complications tend to occur multiply, especially intracranial complications, as shown in Tables 140-4 and 140-5. Although all of the complications originate from infection in the pneumatized spaces of the middle ear and mastoid, the mechanisms by which complications occur in AOM differ from the mechanisms associated with COM. We discuss these two entities separately.

Acute Otitis Media

An estimated 85% of all children experience at least one episode of AOM, making it the most common bacterial infection of

childhood.[3] Predisposing factors include young age; male sex; receiving bottle feedings; and being exposed to a daycare environment, crowded living conditions, or smoking within the home. Medical conditions such as cleft palate; Down syndrome; and mucous membrane abnormalities such as cystic fibrosis, ciliary dyskinesia, and immunodeficiency states also predispose individuals to otitis media.

AOM is a bacterial infection of the middle ear space characterized by vascular dilation and proliferation (manifested externally by tympanic membrane edema and erythema), mucosal edema, exudation, bacterial proliferation, white blood cell infiltration, and pus formation. AOM here refers only to an acute infection that arises de novo, in a previously normal middle ear, rather than an acute clinical infection arising in long-standing otitis media with effusion. This distinction underscores that patterns of complications are different in AOM versus COM.

After the first few weeks of life, acute suppurative otitis media is caused primarily by three organisms: *Streptococcus pneumoniae,*

Haemophilus influenzae, and *Branhamella catarrhalis,* composing roughly 30%, 20%, and 10% of isolates.[3] Optimal treatment for acute suppurative otitis media with complications includes appropriate antibiotics in addition to myringotomy and placement of a ventilating tube. Tympanocentesis is used primarily to obtain material for culture and sensitivity to identify the offending organism, but it can also reduce the bacterial population. Myringotomy and tube placement also provide material to identify the involved organism. After treatment, the physician should document that the AOM has completely resolved by tympanometry and otoscopy if the tympanic membrane is intact, and by otoscopy if a ventilating tube is in place. If the complication was intracranial, a computed tomography (CT) scan or magnetic resonance imaging (MRI) study should be obtained.

Chronic Otitis Media

AOM is primarily a middle ear infection that extends into the contiguous mastoid, whereas COM reflects persistent mastoid infection with concurrent otitis media. COM is present when an infectious process persists for longer than the 1 to 3 weeks usually necessary for resolving AOM in a previously healthy ear. COM can occur with or without cholesteatoma. Without cholesteatoma, there is typically a tympanic membrane perforation. A third type of COM is evident in young children with persistent otorrhea with a patent middle ear ventilating tube.

If infection in the middle ear and mastoid does not resolve, mucosal edema and exudation increase, and mucous glands and secretory elements proliferate. Mucosal edema in the spaces between the middle ear and the epitympanum and in the aditus between the epitympanum and mastoid antrum block the normal pathways for aeration and decrease oxygenation and vascularity. At the same time, the blockage prevents pharmacologic agents from reaching the attic and mastoid. Radiographically, the mastoid air cell system is partly or completely opaque, reflecting the loss of aeration.

COM changes are accompanied by a characteristic bacteriology compared with acute conditions. Harker and Koontz[4] cultured 30 cholesteatomas at surgery and isolated at least one anaerobic organism in 67% of the cases, at least one aerobic organism in 70%, and both organisms in 50%. In 57% of the cholesteatomas, multiple organisms were cultured; in 30%, five or more bacteria were identified. Even without clinical infection, anaerobes, such as *Propionibacterium acnes,* were frequently isolated. An ear with COM is highly likely to harbor multiple bacteria of anaerobic and aerobic types.

COM that develops in patients with indwelling middle ear ventilating tubes has a different bacterial flora. In most instances, these cases begin with an upper respiratory infection or with water contamination. A series of events, including treatment with antibiotic drops, treatment with oral antibiotics, repeated contamination, repeated culture and sensitivity tests, increasing patient and physician frustration, decreasing patient compliance, and fungal overgrowth, frequently results in resistant organisms developing. The resistant bacteria most often found are *Pseudomonas aeruginosa, Achromobacter xylosoxidans,* and methicillin-resistant *Staphylococcus aureus,* although the etiologic importance of individual organisms identified on swab culture is unclear. A fungal component of the external auditory canal and the middle ear and mastoid should be considered.

Pathophysiology

Complications associated with AOM may occur during the first few days of the infection as a result of associated bacteremia. Alternatively, bacteria can extend infection to a new location. A patient may develop partial or complete facial paralysis because of dehiscence of the bony fallopian canal in the tympanic segment. If there are preformed pathways leading to the meninges or the labyrinth, patients with AOM are at risk to develop meningitis, subdural effusion, or suppurative labyrinthitis. Developmental anomalies, such as an enlarged vestibular aqueduct or Mondini's deformity, present such a risk. Bacteria can propagate along preformed pathways left from previous surgery or temporal bone fractures. With AOM, there is no granulation tissue formation or bone destruction; complications develop by hematogenous dissemination or by direct extension along preformed pathways. The usual medical treatment of the AOM resolves the otitis, and mastoidectomy is unnecessary. It is crucial to know whether the middle ear was normal before the current AOM began.

In COM and mastoiditis, complications occur with bone destruction, granulation tissue formation, or the presence of cholesteatoma. Bacteria gain access to the involved structures most commonly by direct extension from mastoid infection, and by infecting and propagating along veins leading from the mastoid to adjacent structures. Direct extension can come about as a result of bone resorption from cholesteatoma or osteitis, or it can occur without bone erosion if the patient has preformed pathways from previous mastoid surgery, temporal bone fracture, congenital dehiscences, or other conditions that removed the intervening bone. The mechanisms by which bone is actively resorbed, although incompletely understood, probably include enzymatic degradation, suppuration, and decreased blood supply.

Diagnosis

History

The clinician must establish when the patient's ear was last free of disease and perfectly normal to differentiate AOM from COM because the bacteriology, medical treatment, and most probable complications are different for each. Key questions relate to the following: (1) prior evaluation of the involved ear, (2) past history and treatment of the otitis media, (3) the order of appearance and magnitude of symptoms, and (4) objective evidence that the ear was normal recently (e.g., tympanogram, radiographic study that included the ears).

Intracranial complications, most notably meningitis, intraparenchymal brain abscess, and subdural empyema, can alter the patient's level of consciousness. Of patients in the study by Singh and Maharaj,[1] 15% were drowsy on admission, 18% were stuporous, and 2% presented in a comatose state. Establishing the chronology of this alteration

of sensorium helps the physician differentiate among diagnoses of brain abscess, meningitis, and subdural empyema. A brain abscess takes weeks to develop, whereas it takes only a few hours to several days for meningitis and subdural empyema to become fulminant and progress to coma.

Physical Examination

The vital signs, especially the temperature, provide a pretreatment baseline and one parameter for following the course of the disease and the treatment; however, if the patient has previously received oral or parenteral antibiotics, he or she may present without a fever. Although some patients with extracranial or intracranial complications remain afebrile during the entire course of their illnesses, the temperature curve can provide useful information in other patients.

Patients with intracranial or multiple complications often appear more systemically ill than patients with otitis alone. They can present with toxicity or with obtundation, manifesting depressed levels of consciousness that can vary from lethargy to total unresponsiveness. Focal neurologic signs may be absent, subtle, or florid. The physical examination of the ear itself usually does little to pinpoint a specific complication, unless there is an obvious postauricular, cervical, or temporal abscess.

A complete neurologic examination is essential. The clinician should evaluate the mental status and evaluate the station and gait along with the Romberg and sharpened Romberg tests. The motor and sensory function of the extremities should be evaluated, and a complete cranial nerve evaluation should be performed, including an assessment of vision, extraocular muscle function, facial nerve function, and facial sensation. The presence of nystagmus should be assessed. The clinician should evaluate cerebellar function by checking the alternate motion rate of the extremities, determining whether past pointing is present or absent, and performing the finger-to-nose test. Ocular saccades and smooth pursuit should be assessed.

It is crucial to determine whether nuchal rigidity is present, and if so, Kernig's and Brudzinski's signs must be sought. The optic discs should be observed with an ophthalmoscope to determine whether papilledema is present.

The otologic examination should begin with an assessment of the color, size, shape, and position of the pinna compared with the opposite side. The clinician should make note of any erythema, tenderness, or drainage, and any evidence of trauma, excoriation, or protrusion outward or downward. Next, the clinician should observe the regions adjacent to the auricle and note any swelling, erythema, tenderness, purulent drainage, or fluctuation.

The external auditory canal and tympanic membrane should be examined using a microscope and fine suction. If purulent secretions are present, a culture test should be performed. The clinician should document the presence of any edema, and whether it primarily affects the posterosuperior bony canal wall or the entire canal circumference. A drawing of the tympanic membrane should be made, illustrating any perforation, granulation tissue, or epithelial debris, and any erosion of the scutum. Pneumatic otoscopy should determine if there is conjugate deviation of the eyes suggesting a labyrinthine fistula.

The tympanic membrane can appear normal or near-normal even when an otologic complication is suspected because it reflects only the status of the middle ear. Although mastoid infection always begins with a middle ear infection, suppuration in these two locations can proceed differently, in that the middle ear may revert to normal or near-normal under treatment, whereas the mastoid may not.

We make special notation of the problem of an aditus block. The middle ear can appear normal after several courses of antibiotics while symptoms from the mastoid persist (see section on masked mastoiditis). When evaluating a patient with any infectious condition that could be caused by AOM or COM, a CT scan can evaluate the possibility of an aditus block as the cause, even if the tympanic membrane appears normal.

Imaging Techniques

CT scanning is essential for all patients suspected to have complications of otitis media. CT is a fast and reliable method for assessing the status of the middle ear and the mastoid air cell system and diagnosing intracranial complications of otitis media.[5,6] CT reveals bony details of the middle ear, epitympanic, and mastoid structures, and documents pneumatization versus opacification by inflammatory process. CT can show progressive demineralization and loss of the bony septa of air cells in coalescent mastoiditis, and reveal erosion of the bony plates covering the sigmoid sinus, cerebellum, or tegmen of the middle ear, mastoid, and bony labyrinth itself.

CT scans can help to establish the specific primary otologic diagnosis (e.g., AOM, COM, cholesteatoma), and several of the specific cranial and intracranial complications of otitis media. In addition to their diagnostic value, CT scans are useful in assessing the results of therapy, and provide a baseline post-treatment study of the mastoid for comparison in case of further complications.

When the patient is somnolent or unstable, and when intracranial complications are suspected, CT may be the study of choice because it is fast and gives the health care team better access to the patient during the study than MRI does. Even without enhancement, CT scanning can be an adequate diagnostic tool for a febrile, stuporous patient with meningeal irritation when ruling out the presence of an intraparenchymal brain abscess or communicating hydrocephalus before performing lumbar puncture to establish the diagnosis of meningitis. Intravenous injection of an iodinated contrast agent is essential, however, when using CT to diagnose cerebritis, cerebral abscess, subdural empyema, and ventriculitis.

MRI provides sensitive imaging for diagnosing intracranial complications because paramagnetic contrast agents such as gadolinium-DTPA (pentetic acid) cross the blood-brain barrier in areas of cerebritis or abscess. Meningeal enhancement is easily seen with MRI (and not on CT scanning, in which the adjacent bony skull often obscures the meninges). T2-weighted MR images can show intraparenchymal edema from subtle brain infection much earlier than a CT scan can. When otitic complications are suspected, CT scans and MRI provide valuable complementary information.

Fibrous tissue in the mastoid that is a result of previous (nonactive) COM or prior surgery enhances on MRI and may be misinterpreted by the radiologist as "mastoiditis." In such cases, the enhancement reflects the increased vascularity of this fibrous tissue and is analogous to the routine observation of enhancement of the highly vascular nasal turbinates with gadolinium.

Lumbar Puncture

To detect meningitis, the physician must perform a lumbar puncture, measuring the cerebrospinal fluid (CSF) pressure when starting and ending the procedure. The CSF is examined for bacteria on direct smear and measured for glucose, chloride, and protein to compare with their concentrations in serum. Lumbar puncture should be undertaken only after clinical assessment, ophthalmoscopic examination (noting that papilledema sometimes requires hours to develop), and CT scan have ruled out significantly increased intracranial pressure that can result in herniation of the cerebellar tonsils during or after the procedure. Lumbar puncture is contraindicated in the presence of elevated intracranial pressure with brain abscess and subdural empyema.

Treatment

Although each complication has its own separate treatment, there are certain general management principles for treating the underlying otitis. For each patient, the treatment of the underlying acute or chronic otitis and the treatment of any complications can be medical or surgical, and can be administered sequentially or concurrently. In nearly all instances of complications resulting from AOM, appropriate antibiotic therapy is sufficient to resolve the otitis without any need for surgery. This usually includes aspiration by tympanocentesis or myringotomy, as previously discussed.

When complications have resulted from COM and mastoiditis, initial antibiotic therapy should involve broad-spectrum antibiotics effective against anaerobic and aerobic organisms. In all of these cases, some form of mastoidectomy is required. When surgery is necessary for intracranial complications, the neurosurgeon operates first. Temporal bone management is considered separately. A mastoidectomy may be

performed at the same sitting if the patient's condition permits. In most instances (except for brain abscess and subdural empyema), the COM and its complications are treated entirely through the mastoid. When intracranial and otologic surgical procedures are necessary, the surgeons must plan the order of procedures, preparation, draping, and incisions to limit duration of anesthesia and optimize surgery.

A mastoidectomy under these circumstances is hampered by inflammation, and landmarks can be obscured. When no cholesteatoma is associated with the mastoiditis, the external auditory canal wall can be left intact unless visibility is inadequate. An open cavity, canal wall down procedure is preferred in the presence of cholesteatoma.[1]

Alternatively, these cases can be operated as canal wall up procedures, wherein the cholesteatoma is debulked and infection is cleared. Several months later, after the inflammation has resolved, the residual cholesteatoma is removed at definitive surgery. Allowing the inflammation to resolve may improve the effectiveness of cholesteatoma removal. With this approach, a second-stage operation (third procedure) is often required.

Postoperative follow-up is an essential part of the general treatment of patients who experienced life-threatening complications of AOM or COM. Even when the patient responded perfectly, the surgeon should consider follow-up CT scan to confirm objectively the status of the mastoid at the termination of treatment because there is a risk of recurrence or emergence of new intracranial complications. In patients who have experienced lateral sinus thrombosis, epidural abscess, subdural empyema, or brain abscess, follow-up evaluation with enhanced MRI 2 to 4 weeks after treatment is recommended.

Extracranial (Intratemporal) Complications

Acute Mastoiditis

Acute mastoiditis can develop when AOM fails to resolve. According to Luntz and colleagues,[7] acute mastoiditis exists when there are signs of AOM on otoscopy and local inflammatory findings over the mastoid process (e.g., pain, erythema, tenderness, auricular protrusion), or when the mastoid inflammatory changes coexist with radiographic or surgical findings of mastoiditis with or without evidence of AOM. Other authors insist on the concomitant presence of AOM, mastoid physical findings, and radiologic findings.[8]

Luntz and colleagues[7] reported results of a multicenter retrospective study of 223 such patients that provided valuable insight into the process. Of patients, 28% were younger than 1 year at diagnosis, 38% were 1 to 4 years old, and 21% were 4 to 8 years old. Although one third of patients experienced signs and symptoms of AOM immediately preceding the mastoiditis, two thirds did not. Thirty percent of the patients had a history of recurrent AOM, and 5% (all of whom had recurrent AOM) had a prior episode of acute mastoiditis.

One third of the patients exhibited symptoms for 48 hours or less before diagnosis, and another third had symptoms for 2 to 6 days before presenting with acute mastoiditis. Spontaneous tympanic membrane perforation occurred in less than one fourth of patients; the tympanic membrane was bulging or erythematous in two thirds. Twenty-two percent of the patients presented with complications on admission, the most common of which was subperiosteal abscess (Fig. 140-1), followed by meningoencephalitis and occasional cases of other complications.

Despite parenteral antibiotics, 8% of the patients who had been free of complications on admission developed complications of acute mastoiditis during hospitalization. The most common was subperiosteal abscess, but three patients developed intracranial complications, and two developed facial paralysis while receiving parenteral antibiotics. One third of patients required surgery because they had extracranial or intracranial complications on admission, failed to exhibit satisfactory clinical improvement, or developed complications despite adequate antibiotic treatment during hospitalization.

Bak-Pedersen and Ostri[9] reviewed the records of 79 patients who underwent acute cortical mastoidectomy for acute mastoiditis. All patients had erythema and swelling and pain over the mastoid associated with a current or recent episode of AOM that did not improve after 24 to 48 hours of intravenous antibiotics. The average age in the series was 16 months, and the average duration from the onset of disease (AOM) until admission for acute mastoiditis was 9 days. Only one third of the patients exhibited an asymptomatic interval between AOM symptoms and the mastoiditis.

Both of the aforementioned studies established that acute mastoiditis is a disease of the very young. Also, they dispelled the classic notion that acute mastoiditis develops only after an asymptomatic period of 3 to 4 weeks.

Van Zuijlen and colleagues[10] pointed out that in countries such as the Netherlands, where it is unusual to prescribe antibiotics as first-line treatment for AOM, the incidence of acute mastoiditis is considerably higher than in countries where antibiotics are routinely prescribed for AOM. Lower overall costs and reduced incidence of allergic reactions resulting from withholding antibiotics in routine AOM must be weighed against heightened risks of mastoiditis and other complications.

Coalescent Mastoiditis

Etiology

Sometimes when a patient has AOM and mastoiditis that persist unabated for 2 to 4 weeks, coalescent mastoiditis develops. This mastoiditis is an acute progressive clinical infection with corresponding changes in the bone and mucoperiosteum of the mastoid air cell system. Coalescent mastoiditis is a disease affecting especially boys. Most patients are 4 years old or younger when they contract this disease. Bacterial virulence and decreased host resistance are important in its etiology, but mastoid development also plays a role. The condition rarely develops in children who have had chronic ear disease or in children with poorly pneumatized mastoids containing few air cells. Rather, coalescent mastoiditis tends to occur in children with well-developed air cell systems that contain numerous small pneumatic spaces, and in children who have had little or no previous otologic disease.

Pathology

Initially, hyperemia and edema of the mucoperiosteal lining of the mastoid air cells block the narrow aditus and disrupt aeration. The mucous membrane thickens, and impaired ciliary function prevents normal middle ear drainage through the eustachian tube. The serous

exudate becomes purulent as inflammatory cells accumulate. Continued inflammation, hyperemia, and accumulation of purulent debris result in venous stasis, localized acidosis, and decalcification of the bony septa. The osteoclastic activity in the inflamed periosteum softens and decalcifies the bony partitions, causing the small air cells to coalesce into a larger cavity.[11]

Pathophysiology

As the infection grows, elevated pressure within the mastoid may extend the infection beyond the confines of the mastoid. In the presence of intense inflammation and infection, phlebitis and periphlebitis are common and spread the infection to the adjacent meninges, sigmoid sinus, cerebellum, and temporal lobe.[12] Infection may extend to the meninges, sigmoid sinus, labyrinth, or facial nerve. The most common pathway for infection to extend beyond the mastoid is through the lateral cortex behind the ear. Less commonly, it can extend to the soft tissues in the upper portion of the neck (see section on Bezold's abscess) and, rarely, to the soft tissue anterior and superior to the auricle either by direct extension through eroded bone or by phlebitis and periphlebitis. Go and coworkers[13] found only 8 of 118 patients in whom the mastoiditis had caused an intracranial complication.

Diagnosis

Symptoms of coalescent mastoiditis (purulent otorrhea, fever, toxicity, and ear pain) are the same as symptoms seen in patients with uncomplicated AOM. The strongest historic suggestion of coalescent mastoiditis is the chronology of the infection in which purulent drainage or significant otalgia persists for 2 or more weeks, recurs after 10 to 14 days, or significantly worsens after that time interval. As a group, children with coalescent mastoiditis look sicker and have more toxicity with higher temperature and more persistent fevers than children with AOM. Older children may be able to localize the pain to the postauricular area rather than the ear canal. Physical findings that are most helpful include mastoid tenderness to percussion, mastoid erythema, and sagging of the posterosuperior external auditory canal wall.

The clinician should order a complete blood count and hematologic studies followed by CT scanning, which can establish the diagnosis by documenting the breakdown of the bony cell walls and opacification of the pneumatized spaces (Figs. 140-2 and 140-3). If any suggestion of an intracranial complication exists, the clinician should obtain an enhanced MRI scan.

Treatment

Treatment for coalescent mastoiditis can be either medical or surgical. Without question, complete mastoidectomy with ventilating tube placement in conjunction with appropriate antibiotic therapy provides prompt, precise eradication of all infected tissue in an expeditious and cost-effective manner. This approach is the most conservative management of this potentially serious complication. Because the increased vascularity and granulation tissue greatly increase the difficulty of the operation, however, it should not be undertaken lightly. Another consideration is that pneumatization has not progressed to incorporate the mastoid tip in children younger than 2 years, so there is risk of surgical injury to the facial nerve. The primary author's experience with cochlear implant surgery in children 12 to 24 months old suggests, however, that the facial nerve does not exit through the lateral surface of the mastoid in this age group as is commonly taught, and the risk of facial nerve injury in this age group is not substantial.

Appropriate intravenous antibiotics for a minimum of 3 to 6 weeks also eradicate the disease process in most infected infants who have no additional complications. The therapeutic choice for a specific patient depends on the clinical factors present and regional preferences. At the end of medical therapy, it is essential to document that the disease process has been completely eradicated. The patient should continue receiving antibiotic therapy until a CT scan documents that the mastoid air cell system is no longer opacified, and the middle ear is normally aerated.

Chronic Mastoiditis

Etiology

Chronic mastoiditis can occur in association with a long-standing tympanic membrane perforation, with cholesteatoma, or as a complication from an infection after placement of a middle ear ventilating tube. As noted previously, ventilating tube mastoiditis tends to occur in young children who have experienced water contamination and have undergone cultures and treatment with multiple antibiotic drops and oral antibiotics. Mastoiditis with tympanic membrane perforation occurs when an episode of AOM with perforation pursues a course of chronic infection, rather than resolving or developing into coalescent mastoidi-

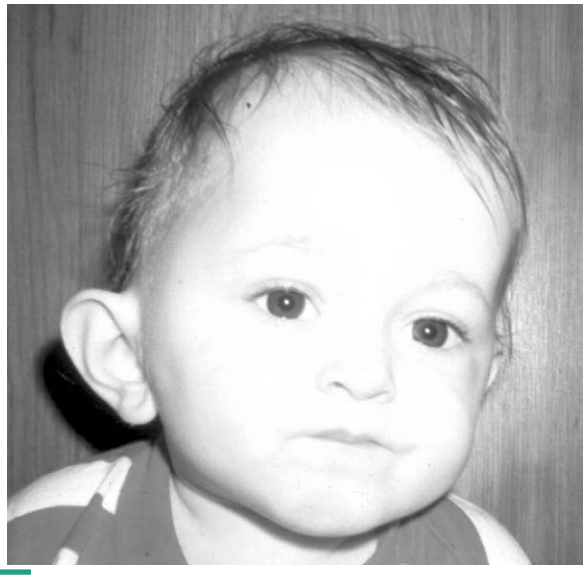

Figure 140-5. Postauricular abscess associated with coalescent mastoiditis. Auricle is displaced laterally and inferiorly. *(From Harker LA. Cranial and intracranial complications of acute and chronic otitis media. In: Snow JB, Ballenger JJ, eds.* Ballenger's Otorhinolaryngology Head and Neck Surgery. *16th ed. Hamilton, Ontario: Decker; 2003.)*

tis. Chronic mastoiditis of this type can also begin when a long-established uninfected central perforation becomes infected and extends to the mastoid (Fig. 140-4).

Although cholesteatoma frequently remains uninfected for long periods, it tends to suppurate, form granulation tissue, and erode bone. When any type of mastoiditis causes continuous purulent drainage, there is little likelihood of complete resolution with antibiotics. Chronic mastoiditis requires surgical intervention to heal, and an infected cholesteatoma requires surgical ablation, regardless of duration. Complications in patients with chronic mastoiditis with tympanic membrane perforation can develop at any time, but often occur only after weeks or months of otorrhea. In contrast, cholesteatoma typically requires months or years to produce complications.

Masked Mastoiditis

Chronic otitis with granulation tissue formation and bone erosion can occur without otorrhea. It can persist despite a normal or near-normal tympanic membrane. This condition has been referred to as *masked mastoiditis* and usually occurs in patients who have received numerous courses of antibiotics. In this complication, the middle ear and much of the mastoid respond to the antibiotics, but a focal area of persistent infection somewhere in the mastoid does not. Patients experience chronic but not severe auricular and postauricular pain, slight but definite tenderness to percussion of the mastoid cortex, and CT scan evidence of a localized area of opacification in an otherwise normal mastoid. Surgical excision eliminates the symptoms.

Samuel and Fernandez[14] described 21 cases of mastoiditis with retroauricular swelling and an intact tympanic membrane in a South African population (19 patients were <13 years old) in whom the duration of symptoms was shorter than that usually seen with coalescent mastoiditis. The predominant finding at mastoidectomy was granulation tissue filling the mastoid cavity and the antrum. The tympanic membrane was described as hyperemic, dull, bluish, bulging, or retracted. In addition to their mastoiditis, 10 patients had postauricular abscesses, 3 had Bezold's abscesses, and 2 had facial nerve palsy. Four patients had cellulitis or abscess in the posterior fossa. Although these cases do not represent masked mastoiditis, they show the important fact that medically significant mastoiditis can exist without purulent otorrhea. There are two keys to the successful diagnosis and management of masked mastoiditis: (1) mastoid disease is not always reflected by the appearance of the tympanic membrane, and (2) chronic mastoiditis is a surgical condition, regardless of the appearance of the tympanic membrane. In this regard, the diagnosis and management of masked mastoiditis are no different from the diagnosis and management of mastoiditis with otorrhea emanating from other causes.

Postauricular Abscess

Postauricular abscess is the most common complication of mastoiditis. It is most often seen accompanying acute or coalescent mastoiditis in young children. The infection extends from the mastoid to the subperiosteal space; this usually occurs by direct extension subsequent to bone destruction or by phlebitis and periphlebitis of mastoid veins. The tiny pits in adult temporal bones that make up the cribriform area of the mastoid near the spine of Henle exist in newborns as a series of open channels between the interior of the mastoid and the cortex. Until these channels have closed, infection can pass directly from the mastoid to the subperiosteal space in these very young children. Regardless of how it starts, soft tissue infection leads to tissue necrosis and abscess formation. The surrounding soft tissue exhibits thickening, inflammation, erythema, tenderness, and fluctuation.

The diagnosis is usually obvious. Because only the upper part of the mastoid is pneumatized, the process develops in that upper portion, and the tissue edema and the abscess drive the auricle downward and laterally (Fig. 140-5). In the early stages, if fluctuation is not obvious, the clinician should use imaging studies or ultrasonography to document the presence of air within the soft tissue or an abscess cavity with its capsule (Figs. 140-6 and 140-7). When mastoiditis has produced an abscess, excision and drainage in conjunction with mastoidectomy is indicated. Only in the most unusual of circumstances would treatment by prolonged antibiotics and drainage of the abscess without mastoidectomy be appropriate.

Bezold's Abscess

In his 1913 text, *Diseases of the Ear,* Kerrison[15] described a Bezold abscess as a condition:

> ... caused by a perforation in the bony plate forming the inner surface of the tip of the mastoid. It occurs presumably in cases in which the tip cells are especially large and in which the bony plate forming the inner or medial wall of the tip is very thin, and the outer cortex thick. Pus escaping through such a perforation burrows down-

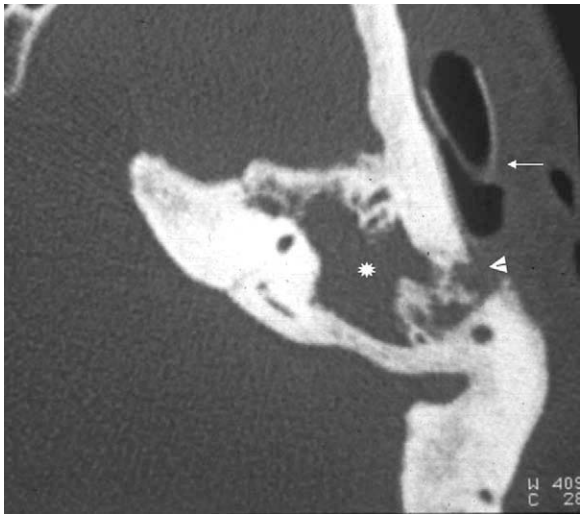

Figure 140-6. Axial temporal bone CT scan (soft tissue) showing abscess cavity with gas *(arrow)*. Note cortical defect *(arrowhead)* and mastoid opacification and loss of bony septa *(star)*.

Figure 140-7. Axial temporal bone CT scan (soft tissue) with contrast enhancement. Note postauricular abscess with enhancing capsule *(arrow)*.

ward in the neck beneath the sternomastoid, or may be confined between layers of the deep cervical fascia.

The cervical infection develops into an abscess in the upper neck deep to the sternocleidomastoid muscle. Bezold's abscess can also develop without any erosion or penetration of the inner and outer cortex of the mastoid if phlebitis and periphlebitis propagate the infection to the same area. Because infants have limited mastoid pneumatization, Bezold's abscess occurs more commonly in older children in whom pneumatization has extended into the mastoid tip and in adults who have either chronic mastoiditis or cholesteatoma.

Often, the diagnosis of Bezold's abscess is not considered initially in young patients with deep, tender, upper cervical masses because inflamed lymph nodes from many causes are so common. If the history and physical examination do not reveal a specific etiology, the clinician should obtain a CT scan to identify or rule out a mastoid source (Figs. 140-8 through 140-11).

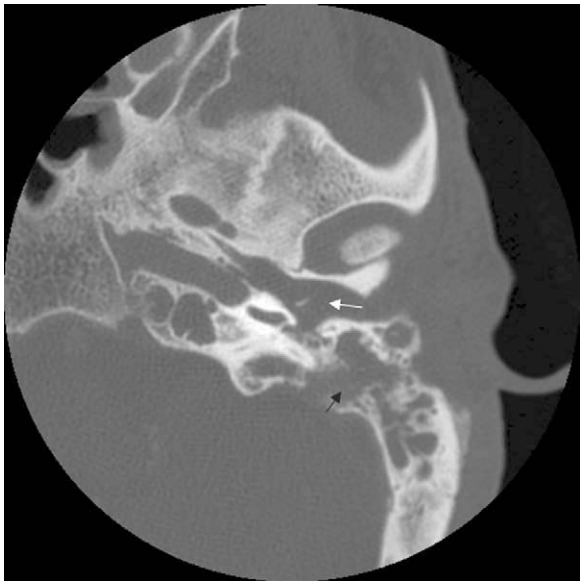

Figure 140-8. Axial temporal bone CT scan showing opacification of external auditory canal and middle ear *(white arrow)*. Also note the destruction of bony septa in the inferior part of the mastoid process *(black arrow)*.

The recommended treatment is complete surgical excision of the mastoid pathology, drainage of the abscess, and removal of any associated granulation tissue. The surgeon should use bipolar electrocautery, copious suction irrigation, and coarse diamond burs to allow him or her to visualize the pathology adequately and exenterate all of the diseased cells thoroughly. The surgeon should drain the mastoid and the abscess cavity.

Temporal Root Abscess

The soft tissues above and even anterior to the auricle can become infected and form an abscess from suppuration that involves the cells of the zygomatic root of the mastoid (temporal root of the zygoma). Similar to Bezold's abscesses, temporal root abscesses can form by direct extension via bone erosion through epitympanic temporal root cells or via phlebitis. The clinical picture may be confusing because abscesses in this location are rare. CT scanning is always recommended to rule out mastoiditis as the source. Surgical drainage is recommended.

Petrous Apicitis

Each petrous apex is undeveloped (sclerotic), contains marrow, or exhibits a variable degree of pneumatization. Pneumatization develops in only approximately 30% of temporal bones.[12] Much has been written about the different cell tracts that extend into and pneumatize the petrous apex. Basically, the cells extend into the apex above (supralabyrinthine) (Fig. 140-12), behind (retrolabyrinthine) (Fig. 140-13), beneath (infralabyrinthine) (Fig. 140-14), or in front of the labyrinth (anterior labyrinthine). Petrous apicitis is essentially mastoiditis that occurs in the petrous apex. It is rare because infection in sclerotic apices or petrous apices containing marrow is uncommon, and because the prevalence of pneumatization is low. Petrositis develops by direct extension of a mastoid infection, but the mastoid may respond to medical or surgical treatment without apical resolution. Just as there can be disjunction between the state of infection in the middle ear and the mastoid, the same holds true between the mastoid and the petrous apex.

The pathology of the infection can mirror that seen in coalescent mastoiditis, with dissolution of thin cellular septa and coalescence, or it can resemble the formation of granulation tissue with chronic bone erosion seen with chronic mastoiditis. Rarely, there is extension of

cholesteatoma to the apex. Imaging studies usually include CT and MRI. CT scan shows the bony details of the septa of the air cells and the size and contour of the entire apex (Figs. 140-15 through 140-20). MRI differentiates marrow from mucus or CSF. CT and MRI studies are essential to establish when there is opacification of the air cells in the petrous apex under suspicion, as opposed to asymmetric pneumatization. When one petrous apex is well pneumatized, a small sclerotic or marrow-containing apex on the opposite side can be misinterpreted as a pneumatized apex opacified by fluid or infection.

The symptoms of infection in the petrous apex reflect the innervation of the air cells and the structures adjacent to the apex itself. Although increased pressure within the mastoid air cell system causes pain in the region of the mastoid and the ear itself, pressure within the petrous apex usually results in pain referred to the retro-orbital area or deep within the skull. Patients with petrous apicitis can have symptoms that reflect infection in the middle ear and mastoid, and symptoms emanating from the apex. The most common symptoms are deep or retro-orbital pain (from irritation of the contiguous trigeminal ganglion in Meckel's cave), paralysis of cranial nerve VI as it passes through Dorello's canal abutting the petrous apex, dysfunction of cranial nerves VII and VIII, or labyrinthitis. In 1904, Gradenigo described the triad of retro-orbital pain, sixth cranial nerve paralysis, and otorrhea, since known as Gradenigo's syndrome.[12] Only a few patients with petrous apicitis exhibit the full triad today.

The treatment of the apicitis depends on the duration, severity, and presence or absence of associated complications. Because of the anatomic complexities and the necessity to work around the labyrinth and the carotid artery, petrous apex air cell disease cannot be excised. Established drainage and prolonged antibiotics are an integral part of treatment, with or without surgery. When there is obvious necrotic

bone, surgical drainage is a necessary adjunct to intravenous antibiotic therapy. When there is adequate access and widespread disease, even partial apicectomy can reduce the bacterial load so that antibiotics and host defenses can control the disease.

The surgical approach to the apex depends on available air cell pathways and the portion of the apex involved. In some temporal bones, access can be gained by a route posterior to the posterior semicircular canal; in others, the best route is subcochlear, infralabyrinthine. In a small percentage of temporal bones, there is an opportunity to provide drainage via cells extending over the superior semicircular canal and through the "hole in the doughnut," working through the center of the superior semicircular canal. Air cell tracts containing granulation tissue can usually be followed into the apex. The original anterior petrous apex drainage procedure described by Lempert necessitated a radical mastoidectomy and is rarely used today. Occasionally, with evidence of osteitis or abscess formation in the apex, and limited or inadequate access via the existing air cells pathways, the middle cranial fossa approach can provide access for exposure, culture, and irrigation.

Labyrinthine Fistula

Labyrinthine fistula represents an erosive loss of the endochondral bone overlying the semicircular canals without loss of perilymph (distinguished from perilymphatic fistula, discussed elsewhere in this text). This loss of the overlying protective bone allows pressure or mass-induced motion of the underlying endosteum, perilymph, and, by contiguity, endolymphatic compartment, evoking vestibular and sometimes auditory symptoms. Most labyrinthine fistulas involve only the lateral semicircular canal. In a few instances, these erosions expose the superior or posterior semicircular canal, the vestibule, or the cochlea.

This bone resorption is almost exclusively secondary to cholesteatoma, and it occurred in 7% of the cholesteatomas in the large series by Gersdorff and Nouwen.[16] Higher percentages have been reported, but the actual incidence is hard to determine. Most reports of labyrinthine fistulas caused by cholesteatoma are from tertiary care referral centers that include many large or previously operated cases, perhaps biasing the prevalence. Studies reviewing suppurative complications of otitis media usually do not include all cases of labyrinthine fistulas because many are not infected, or do not cause significant symptoms and are detected only at surgery. The mechanisms by which cholesteatoma causes this bony erosion are not fully understood, and are the subject of other chapters. Suffice it to say, first there is demineralization of the dense endochondral bone, and then loss of bone substance, so that the perilymph and its surrounding endosteal membrane have less and less bone between them and the overlying cholesteatoma matrix. As the bone becomes thin, it can be observed at surgery as a "blue line" parallel to the underlying semicircular canal lumen because the illuminating light along the blue line is no longer reflected off the dense bone, but absorbed into the underlying fluid.

Manolidis[17] reviewed the records of 111 inner-city patients in Texas with labyrinthine fistulas, and assessed their coexisting complications. Two associations were prominent. The facial nerve was involved with cholesteatoma or functionally damaged by a cholesteatoma in 60% of the patients, and dehiscences of the tegmen occurred in 39%. Most of these cases were reoperations, with an average of 2.6 operations per patient. Although the data are biased by the number of revision operations, surgeons should always assume that the bony fallopian canal is eroded and the facial nerve is in direct contact with cholesteatoma whenever a lateral semicircular canal fistula is suspected, and they should consider the possibility of defects in the tegmen in such patients, especially patients with previous mastoid surgery.

Most patients present with signs and symptoms of the underlying cholesteatoma. Symptoms attributable to labyrinthine fistulas are primarily vestibular. Patients recount brief periods of imbalance, dysequilibrium, or vertigo, but have normal equilibrium most of the time. Some may be able to recall causing momentary imbalance by pushing on their external ear canal, such as with a washcloth, or have noticed that loud sounds provoke brief imbalance (Tullio's phenomenon).

After a suspicious history, the principal diagnostic maneuver is the fistula test. The clinician occludes the external auditory canal of the ear with the pneumatic otoscope, and then gently increases and decreases the external auditory canal pressure so that the changes are transmitted from the external auditory canal to the middle layer and mastoid air cells system via an intact or perforated tympanic membrane. During the procedures, the patient is asked to fix the eyes in the cardinal position, and the physician observes the patient's eyes for any deviation from that cardinal position. In the case of a normal ear, no eye motion or symptoms are provoked. With a lateral canal fistula, positive external auditory canal pressure causes compression of the lateral semicircular canal endosteum, and utriculopetal endolymph flow resulting in conjugate deviation of the eyes away from the side of compression, a positive fistula sign. Negative external auditory canal pressure results in conjugate deviation toward the ear under the test. The patient may subjectively note motion of the environment or slight nausea during the pressure alterations.

The fistula test results are reported as positive in only 55% to 70% of patients with lateral canal erosion, but if positive, they are highly reliable and facilitate surgical planning and execution.[18] CT scanning (Figs. 140-21, 140-22, and 140-23) also provides preoperative evidence suggesting a labyrinthine fistula, and images in the bone algorithm usually document the bone erosion of the lateral semicircular canal and show other signs suggestive of cholesteatoma.

The treatment of labyrinthine fistulas addresses the underlying cholesteatoma. When there are other, more grave complications, their management supersedes that of the fistula. The decision whether to remove the external auditory canal and perform an open cavity mastoidectomy or to retain the canal wall in a canal wall up technique is made on the basis of the surgeon's ability to eradicate the cholesteatoma completely, the degree of pneumatization of the temporal bone (adequate access), and the surgeon's confidence that he or she can completely remove the cholesteatoma matrix from the fistula site. Whether the canal wall up or canal wall down technique is used, the operation is completed, leaving the fistula site for last.

The surgeon identifies the blue line of the actual fistula and the adjacent thinned layer of bone on either side of it. The plane separating the matrix and the endosteum is developed, and under high magnification with good hemostasis a flat dissector wider than the semicircular canal itself is used to peel the matrix gently from the underlying endosteum. A fine microsuction elevates the cholesteatoma and facilitates visualization and removal. If the endosteum is torn, it is best to replace

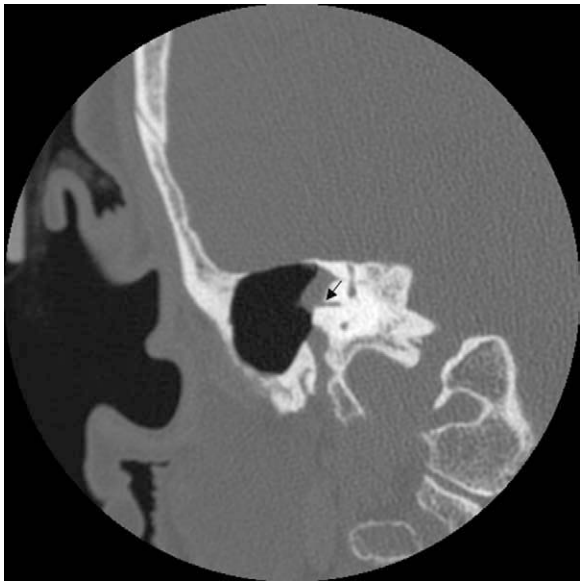

Figure 140-23. Coronal temporal bone CT scan of the patient in Figure 140-21 showing erosion of horizontal semicircular canal *(arrow)*.

the adjacent matrix and terminate the procedure. If it is successfully removed, a small piece of tissue or a shaped cap of bone is placed over the site and secured in place with fibrin glue or packing. In some cases, especially with large fistulas, it may be best to perform a canal wall down procedure and leave the fistula covered by matrix, which later forms the mastoid cavity lining.

Removal of the fistula generally improves the vestibular symptoms, although symptoms related to pressure transmitted from the external auditory canal can persist for some time. Because there is no protective bone to prevent compression of the endolymphatic compartment by pressure changes in the external auditory canal, a positive fistula sign persists until there is a regrowth of bone. Loss of hearing in the involved ear and worsening of existing hearing are the risks that always accompany the procedure, but these have been reported to occur in less than 20% of carefully managed fistula cases.[9]

Facial Nerve Paralysis

Facial nerve paralysis can result from AOM, COM without cholesteatoma, or cholesteatoma. Bacteria reach the nerve because of congenital dehiscences of the bony fallopian canal or via erosion with granulation tissue or cholesteatoma. Facial nerve function is lost with inflammatory pressure or suppurative neurapraxia. If the edema persists, axonotmesis can ensue.

In young children, facial paralysis that is caused by AOM is frequently incomplete and probably occurs only in infants with congenital dehiscence of the fallopian canal in the middle ear adjacent to the stapes. Facial weakness in these cases rarely lasts longer than 3 weeks even when complete paralysis is present.

Facial nerve paralysis caused by COM without cholesteatoma also usually affects the horizontal portion of the facial nerve near the stapes.[19] In these cases, the clinical course of the paralysis is more likely to be prolonged, with a gradual progression from slight weakness to full paralysis; sometimes the progression to complete paralysis is rapid (Figs. 140-24 and 140-25). Facial nerve paralysis caused by cholesteatoma can produce extensive erosion of the horizontal segment of the fallopian canal—especially common in large, uninfected, primary acquired cholesteatomas. An erosive cholesteatoma can expose the facial nerve anywhere in the temporal bone and cause paralysis. In these cases, the onset of the paralysis is usually gradual, and sometimes the progression is so slow that patients do not seek medical attention for months. When the onset of facial paralysis is this slow, the paralysis is more likely to persist after surgical treatment.

When facial paralysis is caused by AOM, appropriate antibiotic therapy for AOM may be adequate treatment, although myringotomy with evacuation of the purulent material and reduction of the numbers of bacteria is recommended. When facial nerve paralysis follows chronic suppurative otitis media (with or without cholesteatoma), the surgeon should remove the infection surrounding the nerve as part of the mastoidectomy. The surgeon gradually approaches the granulation tissue or cholesteatoma overlying the nerve from the proximal and distal portions of the nerve, which are uninvolved by the chronic infection. Diamond burs should be used to remove carefully the bone of the fallopian canal on both sides of the diseased portion. The surgeon uses a flat blunt instrument to dissect the chronic inflammatory tissue from the nerve while elevating the diseased tissue with a small suction tip. It may be necessary to use sharp dissection to separate the inflammatory tissue from the epineurium. The outcome for surgical decompression of the facial nerve caused by chronic suppurative otitis media primarily depends on whether the nerve has undergone complete degeneration before surgery.

Acute Suppurative Labyrinthitis

Bacterial invasion of the labyrinth is always promptly followed by total loss of auditory and vestibular function (Figs. 140-26 through 140-29). Usually, AOM extends into the labyrinth through a weakened or dehiscent oval window membrane, as occurs in congenital labyrinthine deformities such as Mondini's deformity and enlarged vestibular aqueducts, and in individuals who have undergone stapes surgery. Although it is not proven, suppurative labyrinthitis may be a common mechanism for unilateral anacusis in children with Mondini's deformity. These children are at additional risk. The foramina of the internal auditory canal opening into the medial aspects of the labyrinth may also be weak or dehiscent, and those foramina and the cochlear aqueduct can permit bacterial infection to progress from the labyrinth to the meninges or vice versa. It is unknown how frequently suppurative labyrinthitis causes meningitis, or how often meningitis subsequently causes bacterial labyrinthitis, but both probably occur, especially in the special population of children with congenital labyrinthine abnormalities.

Direct bacterial invasion of the labyrinth through a cholesteatomatous lateral semicircular canal fistula is another cause for acute suppurative labyrinthitis. In this situation, infected granulation tissue beneath the cholesteatoma matrix lies directly on the endosteal membrane and its underlying perilymph. The bacteria causing the labyrinthitis are those of the underlying AOM or the cholesteatoma.

The diagnosis of acute suppurative labyrinthitis is clinical. Tinnitus and dizziness rapidly progress to whirling vertigo, pallor, dia-

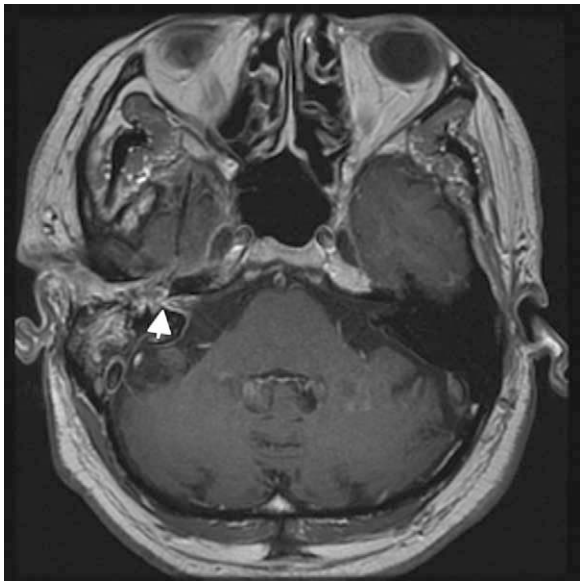

Figure 140-28. Axial contrast-enhanced T1-weighted MRI of the patient in Figure 140-26 showing enhancement of middle ear, vestibule, and internal auditory canal *(arrowhead)*.

phoresis, nausea, and vomiting. Brisk labyrinthine nystagmus directed toward the opposite ear accompanies the vertigo. After the first several hours, the spontaneous vertigo and nystagmus gradually begin to abate. Symptomatic improvement continues during the next few days. Over the next 2 to 3 weeks, central nervous system compensation occurs, and normal or near-normal balance is restored. Tinnitus often abates, but all hearing is lost.

No specific diagnostic studies are necessary when the typical clinical picture develops in a patient with AOM or COM and a predisposing condition. Although there is no possibility of reversing the clinical course, appropriate antibiotic treatment for 10 days is recommended to eradicate the labyrinthine infection and to prevent propagation to the meninges. Other therapeutic measures are dictated by the underlying otitis, but labyrinthectomy is unnecessary in labyrinthitis secondary to AOM.

Encephalocele and Cerebrospinal Fluid Leakage

Encephalocele (brain hernia, brain fungus, meningoencephalocele) and CSF leakage are associated with cranial or intracranial complications when they coexist with AOM or COM. Three different clinical patterns can occur.

Spontaneous CSF leakage sometimes develops in conjunction with defects in the tegmen tympani or, less commonly, the tegmen mastoideum. May and colleagues,[20] Lundy and associates,[21] and others have reported this in more than 50 patients who have not undergone previous otologic surgery. Of such patients, 70% to 80% are older than 45 years. The defects range in diameter from 2 mm to 2 cm, and sometimes are multiple. Usually, an encephalocele protrudes through the defect (Figs. 140-30 and 140-31). There is no agreement as to why the dura breaks down and allows protrusion of cerebral contents and escape of CSF in these older patients, although Jackson and colleagues[22] have suggested that aging, increased intracranial pressure, low-grade inflammation, arachnoid granulation, and irradiation can play a part. Patients frequently visit their physicians because of hearing loss secondary to reduced ossicular motion from the middle ear fluid or the encephalocele. Myringotomy and placement of a ventilating tube manifest profuse watery otorrhea that tests positive for CSF. Other patients present with signs and symptoms of meningitis, and many of these patients have experienced one or more previous bouts of that disease.

Encephalocele and CSF leakage secondary to COM occur when a cholesteatoma and granulation tissue erode through the bony plates separating the mastoid from the temporal lobe, the cerebellum, and the dura adjacent to the bone. The mastoid and epitympanic tegmen are involved more frequently than the cerebellar plate. A cholesteatoma needs to be present for many months to years to cause this degree of bone erosion, cerebral prolapse, and dural erosion.

Traumatic encephalocele and CSF leakage is the most common pattern. Although a few of these cases occur because of temporal bone fracture, most are a consequence of surgical trauma, such as when portions of the tegmen or cerebellar plates have been surgically removed, and the dura is exposed and sometimes traumatized. In these situations, the disease process and the surgery can contribute to the bony and dural trauma that facilitates the development of an encephalocele, CSF leakage, and intracranial complications. Manolidis[23] reported a series of 29 such patients from an inner-city population. More than 80% of the patients had cholesteatoma, and half had undergone one or two previous operations. All had dural herniations and encephaloceles, but

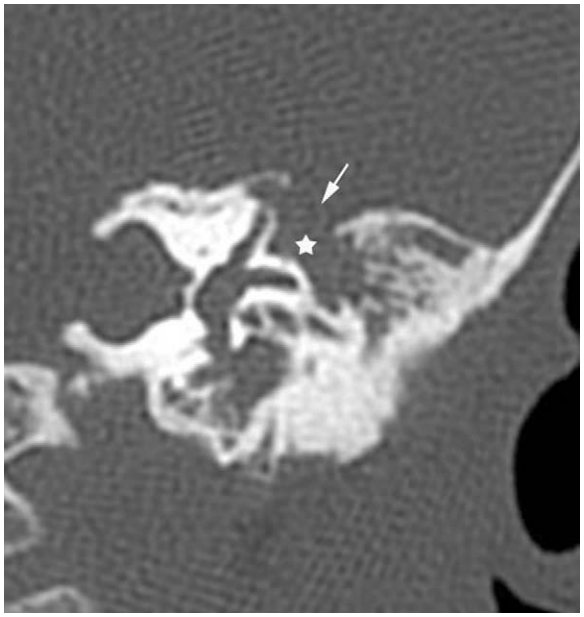

Figure 140-30. Coronal temporal bone CT scan showing encephalocele *(star)* going through a tegmen defect *(arrow)*.

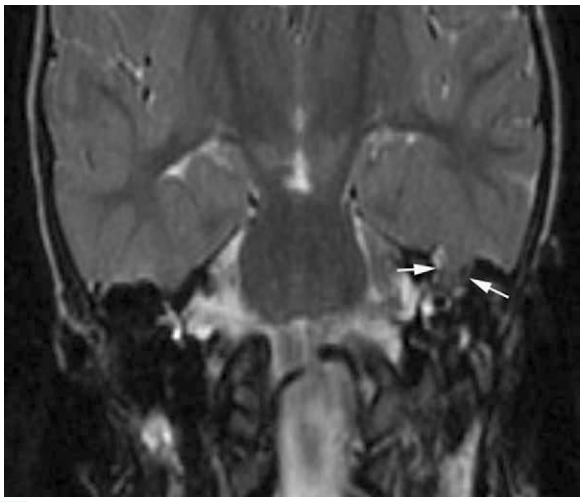

Figure 140-31. Coronal T2-weighted MRI of the patient in Figure 140-30 showing encephalocele *(arrows)*.

only one had CSF leakage. Labyrinthine fistulas, suppurative intracranial complications, and associated facial paralysis were noted.

Jackson and colleagues[22] have written an excellent review of this subject. The size of the bony defect and the volume of herniated brain are two of the important factors in choosing a surgical approach. Small defects are managed adequately through the mastoid; multiple and larger defects are repaired by the middle cranial fossa approach in combination with mastoid exposure.

The middle fossa approach provides excellent exposure of the tegmen defect and access to repair the dural defect. A temporalis fascia graft is used to repair the dura, which is often quite attenuated. The bony defect can be repaired with a split calvarial bone graft taken from the inner table of the craniotomy flap. It is fashioned larger than the bony defect, and is placed on the intracranial surface so that it can support the brain. Another technique to repair the tegmen defect is the use of hydroxyapatite cement. The floor of the middle fossa can be reconstituted, and a watertight seal can be obtained. Care must be taken to avoid cement contact with the ossicles, or a conductive hearing loss results.

Intracranial Complications

Meningitis

A dramatic reduction in the incidence of meningitis caused by AOM and COM has occurred because of immunizations against the common causative organisms. Two decades ago, *H. influenzae* and *S. pneumoniae* caused nearly all cases of otogenic meningitis. After *H. influenzae* type B vaccination became part of routine pediatric immunizations in the United States in the early 1980s, *H. influenzae* meningitis dramatically decreased and has now almost disappeared. Today, pneumococcal conjugate vaccine PCU-7 (Prevnar), the multivalent pneumococcal vaccine effective in young children, is also a routine pediatric immunization in the United States, and similar reductions in otogenic streptococcal meningitis are occurring in the most susceptible age group—younger than 2 years old. In any given country, the incidence of meningitis as a complication of suppurative otitis is inversely proportional to the prevalence of immunizations against these two bacteria.

In the past, meningitis was the most common complication of AOM and COM. In the series by Gower and McGuirt[24] of 100 consecutive patients with intracranial complications of AOM and COM, 76 had meningitis, and 53 of those patients were younger than 2 years. In that age group, most cases occurred by hematogenous dissemination of infection during AOM. Sometimes, these patients are not tabulated in reports documenting the complications of otitis,[1,25] and in those reports the frequency of otitis-induced meningitis is low.

Conditions that allow CSF to gain access to the middle ear cavity predispose to the development or recurrence of bacterial meningitis. CSF otorrhea is common after lacerations of the dura by longitudinal temporal bone fractures. Congenital defects of the tegmen, with or without encephalocele, can also be accompanied by CSF leakage into the epitympanum and middle ear, as can unrecognized injury to the dura of the posterior or middle cranial fossae during mastoid surgery. Patients with syndromic or nonsyndromic congenital stapes fixation, Mondini's dysplasia, and enlarged vestibular aqueducts also are at risk for a bacterial middle ear infection to spread to the CSF. The pathway can be obvious, such as when a "perilymph gusher" is discovered during stapes surgery, or it can be more subtle, when there are microscopic disruptions of the continuity of the oval or round windows, the internal auditory canal, and the cochlear aqueduct. Meningitis can occur even in individuals with normal middle ear and labyrinthine anatomy if AOM complicates conditions such as traumatic stapes dislocation or perilymphatic fistula and then progresses on to acute suppurative labyrinthitis.

The predominant symptoms of meningitis are a generalized severe headache, nausea, and social withdrawal. The patient tends to lie quietly, with photophobia and general hyperesthesia. The patient's level of consciousness may vary from normal to unresponsive. Fever is universal, high, and sustained. Nuchal rigidity and pain with attempted flexion of the neck are ominous cardinal signs, and abnormal abdominal reflexes strengthen the clinical impression. In Brudzinski's sign, passive flexion of the head on the chest is followed by involuntary flexion of both thighs and both legs. In Kernig's sign, the patient is in the supine position, and the thigh is flexed to a right angle, and attempts at passive extension at the knee produce pain and resistance owing to spasm of the hamstring muscles. Funduscopic examination may reveal papilledema.

Whenever meningitis is suspected, a CT scan can rule out the presence of brain abscess, cerebritis, or subdural empyema, and determine that it is safe to perform lumbar puncture (i.e., intracranial pressure is not inordinately increased). CSF from the lumbar puncture is examined for intrathecal pressure, cells, bacteria, glucose, protein, chloride, and other factors. CSF pressure is increased early in the course of the disease, and protein and glucose concentrations increase compared with serum values as it progresses, but bacteria are not present until late in the disease.

When meningitis is caused by AOM or suppurative labyrinthitis, myringotomy and appropriate antibiotics are adequate, and no surgery is indicated. When meningitis develops from COM and mastoiditis, however, the mastoid must be exenterated. When otogenic meningitis is associated with a profound ipsilateral sensorineural hearing loss, a

route of infection to the meninges through the labyrinth is apparent. If the sensorineural function in the affected ear remains at the patient's premeningitis baseline, the route was extralabyrinthine. Some patients with severe AOM experience a partial sensorineural hearing loss because of associated serous labyrinthitis. This partial loss may be reversible. Although the patient has already had a CT scan before the lumbar puncture, an enhanced MRI study should be obtained to rule out the presence of any additional intracranial complications (Fig. 140-32). The neurologic condition of the patient determines the timing of the surgery, and the mastoidectomy should be performed as soon as the patient is stable. Meningitis is one of the gravest complications of acute or chronic otitis, and it seems that it is more lethal when caused by COM and mastoiditis than when it is a hematogenous complication of AOM in the first 2 years of life.

Brain Abscess

The incidence and mortality of intraparenchymal brain abscesses have decreased considerably, and almost all reports in the past 2 decades are from centers outside North America and Western Europe. Excellent reports from Africa and Asia using new imaging techniques have documented improvements in diagnosis and therapy, however, and have clarified some aspects of surgical treatment. The series by Yen and colleagues[26] of 122 consecutive patients seen in a Taiwan hospital between 1981 to 1994 revealed that otogenic causes were the third most common cause of intraparenchymal brain abscess, exceeded only by causes associated with cyanotic congenital heart disease and abscesses resulting from head injury or neurosurgery. Seventy-five percent of abscesses occurred in male patients—principally individuals in the lower socioeconomic classes. In the 1990s, four reports from India, Turkey, and South Africa discussed 149 patients with otogenic brain abscesses.[1,2,27,28] Abscesses from AOM and COM were almost always found on the same side as the otitis and occurred nearly equally in the temporal lobe and cerebellum. Almost three fourths were secondary to cholesteatoma, 50% occurred in the second decade of life, and two thirds affected male patients.

A brain abscess begins when bacteria propagate in and around venous channels leading from the mastoid into the adjacent brain parenchyma. The first event after the arrival of bacteria into the cortex or white matter is the migration of polymorphs into local capillaries with endothelial swelling and focal cerebritis. At this stage, the disease can be successfully managed by intravenous antibiotics alone. With more time, the tissue becomes edematous, hemorrhagic, and necrotic, and the abscess is formed. Brain abscesses may vary greatly in size, often have an irregular shape, and frequently are multilocular. At first, the capsule is poorly defined, but over time it becomes firmer and can easily be stripped from the underlying edematous brain.[29]

In addition to symptoms and signs reflecting general intracranial sepsis, cerebellar abscess is often accompanied by coarse horizontal nystagmus, dysmetria, dysdiadochokinesia, or action tremor. Temporal lobe abscess (Figs. 140-33 through 140-36) can cause homonymous visual field defects, contralateral hemiparesis, and other focal signs listed later for subdural empyema. The physician should examine the patient and the imaging studies looking for other intracranial complications because two thirds of patients with intraparenchymal abscesses have more than one intracranial complication.[27]

The physician should immediately begin the administration of broad-spectrum intravenous antibiotics directed at aerobic and anaerobic organisms. If imaging studies suggest no other complications, and the patient's condition is stable, neurosurgical drainage or abscess excision is performed within the first 24 hours of admission and is followed immediately by mastoidectomy, performed through a separate surgical field. If this course is followed, mortality has decreased to approximately 10%.

Subdural Empyema

Subdural empyema is a fulminating purulent infection that develops between the dura and the pia arachnoid membranes, and represents one of the most immediate of neurosurgical emergencies. It constitutes only about 20% of all cases of localized intracranial bacterial infection, and an otologic etiology is uncommon compared with bacterial contamination (from trauma or a neurosurgical operation), suppurative sinus disease, and meningitis. At least two thirds of the cases occur in men, and most occur in the second decade of life. The abscess usually begins by direct spread from adjacent infected bone or by retrograde venous propagation. When infection enters the subdural space, pus forms rapidly and spreads widely, and thrombophlebitis of cortical veins is virtually guaranteed. Swelling, necrosis, and infarction of the cortex accounts for many of the clinical features and explains how a barely detectable thin layer of subdural pus can cause such devastating

consequences as increased intracranial pressure, focal signs, and seizures.[30]

Clinically, a patient with subdural empyema exhibits a cascade of symptoms including a severe headache, the earliest and the most persistent symptom. The patient's temperature increases dramatically as the disease progresses. General malaise, chills, and nuchal rigidity indicate that the patient is becoming seriously ill. After an unpredictable period, the patient's level of consciousness may abruptly decline, and focal signs

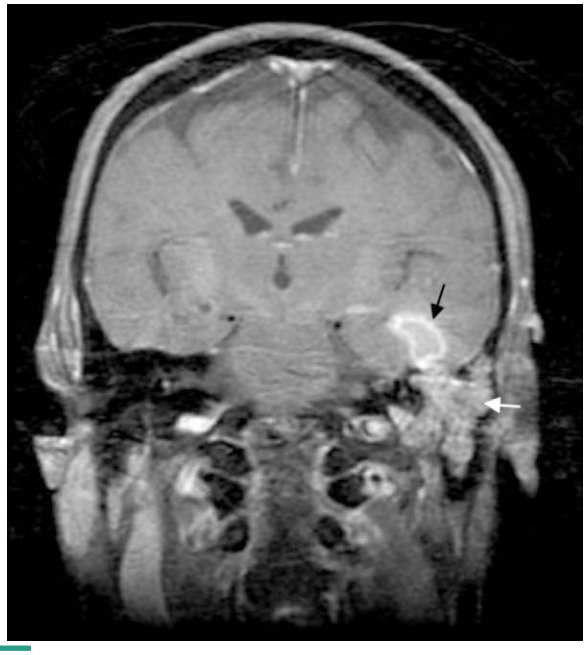

Figure 140-36. Coronal enhanced T1-weighted MRI of the patient in Figure 140-33 showing enhancing tissue in left mastoid *(white arrow)* and temporal lobe abscess with enhancing capsule *(black arrow)*.

and symptoms may develop. Most patients with left-sided collections develop aphasia and a progressive contralateral hemiparesis. Paralysis of conjugate gaze to the contralateral side and deviation of the eyes toward the side of the lesion are also common. Jacksonian seizures are common at this stage, and papilledema may be evident. In patients with posterior fossa collections, localizing signs are often absent, but marked neck stiffness and papilledema are always present. The entire clinical picture of subdural empyema can evolve in a few hours or can take 10 days to develop.

In a well-developed subdural empyema, a contrast-enhanced CT scan shows a crescent-shaped, low-density collection of pus displacing the brain away from the inner table of the skull, with enhancement of the adjacent edge of the cortex. The scan may appear normal early in the course of the disease. When this happens, the clinician should obtain a contrast-enhanced MRI study or repeat the CT scan after a suitable interval. Lumbar puncture is dangerous and is contraindicated because it can precipitate transtentorial coning with elevated intracranial pressure. If the CT scan fails to detect the lesion, and focal signs are absent, lumbar puncture may be unavoidable to rule out meningitis.

Emergency neurosurgical drainage and appropriate antibiotic therapy are necessary. Survival is related to the level of consciousness at the time of surgery. The presence of localizing signs in any patient with COM whose level of consciousness is declining requires immediate and decisive action.

Subdural empyema can also develop in neonates as a complication of meningitis. In 30% of cases of *H. influenzae* meningitis, a collection of fluid develops in the subdural space (usually bilaterally) that varies from 5 to 100 mL.[31] This problem is less common after meningitis from other organisms and is decreasing in frequency because universal immunization against *H. influenzae* has dramatically reduced the incidence of meningitis. Uninfected subdural collections after meningitis are called *subdural effusions*. If bacteria are evident on direct examination of the fluid, the collections are called *infected subdural effusions,* and if the fluid is grossly purulent, they are classified as *subdural empyemas*. Subdural collections from meningitis secondary to COM that require otologic attention are rare in the neonatal age group.

Epidural Abscess

Epidural abscess results from bone erosion caused by cholesteatoma, granulation tissue, or coalescence. In addition to the bone erosion,

an intense inflammatory response to the infection results in granulation tissue formation and forms an abscess between the temporal bone and the underlying dura mater. The involved dura thickens in response to its contact with granulation tissue on its surface (pachymeningitis). Although it can occur as the only complication of chronic mastoiditis, epidural abscess is frequently associated with lateral sinus thrombophlebitis, meningitis, and cerebritis or brain abscess. Rarely, epidural abscess can result from acute otitis and mastoiditis in the same way as was described for lateral sinus thrombosis.

Most patients experience deep mastoid pain, but there are no signs or symptoms specifically attributable to epidural abscess, and many of the cases without associated complications are discovered only at surgery. If it is large enough, the abscess can be detected on contrast-enhanced CT or MRI scans as a fluid-filled cavity between the temporal bone and the enhanced dura. Surgery is the only recommended treatment. The surgeon performs the type of mastoidectomy that is appropriate for the underlying otitis and mastoiditis.

After removal of the cortex, the surgeon should progressively exenterate the air cells, proceeding from lateral to medial, and from regions with less disease to regions with more disease. When the locus of pathology is the cerebellar plate, the surgeon should smooth the tegmen mastoideum and the tegmen tympani first, and then the thin posterior aspect of the bony external auditory canal; the tip cells should be removed. This removal maximizes exposure and hemostasis. Then the surgeon approaches the diseased area along the cerebellar plate from the superior, the inferior, the lateral, and finally the medial direction, removing the overlying bone down to a thin plate. Because the dura is thickened by the infection, blunt flat instruments such as a Freer elevator or large curets can safely scrape the granulation tissue from the abscess cavity and identify the most centripetal extent of the abscess. The surgeon should remove all of the bone overlying the abscess using diamond burs, rongeurs, or curets until healthy dura without granulation tissue is evident on all margins of the abscess. When the abscess involves the tegmen, the order is changed, and the surgeon should complete the surgery in the other areas first, addressing the tegmental abscess last.

Lateral Sinus Thrombosis

Thrombosis of the lateral sinus usually forms as an extension of a perisinus abscess that develops after mastoid bone erosion from cholesteatoma, granulation tissue, or coalescence (Figs. 140-37 and 140-38).[32] The perisinus abscess exerts pressure on the dural outer wall of the sinus leading to necrosis. The necrosis extends to the intima and attracts fibrin, blood cells, and platelets. A mural thrombus forms, then becomes infected, enlarges, and occludes blood flow through the sinus. Fresh thrombus can propagate and extend in a retrograde direction to the transverse sinus (Fig. 140-39), to the torcular Herophili, and even to the superior sagittal sinus. In the opposite direction, the clot can extend via the jugular bulb into the internal jugular vein in the neck, and can extend to the cavernous sinus via the inferior or superior petrosal sinus. The infected clot frequently showers the bloodstream with bacteria, giving rise to the signs and symptoms of septicemia and the possibility of metastatic abscesses (most commonly to the lungs).

Because of the relative frequencies of the various types of mastoiditis and the ages of the patients affected, presently lateral sinus thrombosis is most common in adults or older children with cholesteatoma, and less common from the other types of chronic mastoiditis. In addition to cases arising by direct extension from bone erosion, lateral sinus thrombosis can also be caused by osteothrombophlebitis during AOM and mastoiditis. In this situation (and in occasional cases of chronic mastoiditis), the bony sinus plate is intact at the time of surgical exploration.

Because the sinus is a continuation of the cerebellar dura mater, extension of an infection by only a few millimeters can result in meningitis, epidural abscess, subdural empyema, cerebritis, or cerebellar abscess, all equally grave complications. In two series,[32,33] 14 of 19 patients with lateral sinus thrombosis had one or more of these additional complications.

Figure 140-37. Axial enhanced temporal bone CT scan showing absent enhancement of left sigmoid *(white arrow)* next to an opacified mastoid. Note the normal enhancement of the right sigmoid *(black*

Figure 140-38. Coronal contrast-enhanced CT scan of the patient in Figure 140-37 showing absent flow in left internal jugular vein at the skull base *(white arrow)* and normal flow in right internal jugular vein *(black arrow)*.

Although the frequent association with other complications tends to obscure the clinical picture, the diagnosis of lateral sinus thrombosis can be strongly suspected when there are signs and symptoms of septicemia or blockage of blood flow through the sinus. The picket-fence fever pattern with diurnal temperature spikes exceeding 103° F has been described with this condition for decades. Although some more recent articles have pointed out that this pattern is not seen as frequently, in part because many patients present with previous or current antibiotic therapy, most of the 36 patients reported by Singh[25] were receiving intravenous antibiotics and still exhibited that fever pattern. Unless the patient has been transferred from another hospital, on admission there is only one temperature measurement to observe. Nonetheless, a single high fever reading should alert the clinician to the possibility of sigmoid

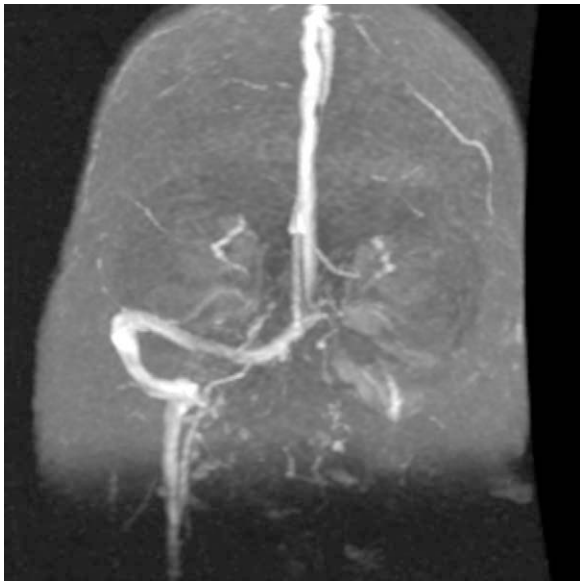

Figure 140-39. MR venogram showing occlusion of left transverse–sigmoid sinus system. *(From Head and Neck Archive, Advanced Medical Imaging Reference Systems [AMIRSYS], Salt Lake City, UT. Accessed January 2003.)*

sinus thrombophlebitis. Singh[25] also pointed out that the neck pain in lateral sinus thrombosis may be mistakenly attributed to the neck stiffness of meningitis, when it actually represents pain and tenderness along the anterior border of the sternocleidomastoid muscle, and he suggested that percussion tenderness of the mastoid tip is another important sign.

More ominous are the signs of sudden intracranial hypertension resulting from decreased venous drainage from the skull (see section on otitic hydrocephalus). Most prominent is the occurrence or sudden worsening of a severe headache. This headache is more likely to occur with the obstruction of the dominant venous drainage system (the right side in 60% of patients). More grave is progressive obtundation; this may herald the development of cerebral edema from the increased intracranial pressure caused by involvement of the superior sagittal sinus or the cavernous sinus, and it carries a very high mortality.

Imaging studies and lumbar puncture are essential to sort out the possible types of complications in obtunded patients. If the patient's condition permits, contrast-enhanced CT scan and contrast-enhanced MRI should be performed (see Fig. 140-32). The delta sign seen on the CT scan, enhancement of the wall of the sigmoid sinus, allows preoperative diagnosis. Wall enhancement is more sensitively evaluated by MRI, which can also document abscess formation within the sinus and exclude adjacent subdural empyema, cerebritis, or cerebellar abscess.

All patients with sigmoid sinus thrombosis require mastoidectomy to treat the underlying mastoid disease adequately. When a brain abscess is also present, surgical drainage of that abscess takes precedence over a mastoid procedure (see section on brain abscess), but if the patient's condition permits, neurosurgical drainage of the brain abscess should be followed in the same anesthetic by expeditious mastoidectomy.

Management of the clot can involve anticoagulation, ligation of the jugular vein in the neck, and opening the sinus and evacuating the infected clot. Use of anticoagulants is rarely indicated, but anticoagulation should be strongly considered when extension of the clot to the transverse sinus or cavernous sinus is suspected or documented. Other considerations in these deteriorating patients include neurosurgical decompression and steroids. Intravenous thrombolytics are not routinely used in the presence of the infected vessel wall. Similarly, routine ligation of the jugular vein in the neck seems unnecessary, but it should be considered whenever there is evidence of extension of the clot into the neck, and should be strongly considered when septic emboli are present.

The sinus is usually addressed only after mastoidectomy. The sinus and adjacent dura are addressed by removing the overlying bone. The surgeon passes an 18- or 20-gauge needle through the sinus wall, and if there is no free blood on aspiration, a linear incision is made through the sinus wall, and the abscess and any infected clots are evacuated. Further sinus incision can enable clot evacuation proximally and distally until free bleeding occurs. The mastoid and cerebellar walls of the sinus are usually thick and indurated as a result of the chronic infection. The surgeon can safely scrape them gently with a broad flat instrument such as a Freer elevator to remove the infected tissue. Syms and colleagues[33] reported treating six patients with lateral sinus thrombosis and concomitant intracranial complications with mastoidectomy, but without opening and evacuating the lateral sinus clot. All patients survived, but the average hospital stay was more than 49 days; it was 38 days when the patient with the longest stay was not included. In contrast, patients reported by Kaplan and Kraus[32] underwent surgery that included incision of the sinus and evacuation of the clot or abscess, and their mean hospital stay was only 17 days.

Otitic Hydrocephalus

Otitic hydrocephalus is an entity wherein an otologic condition has resulted in signs and symptoms of acute hydrocephalus. The condition seems to result from diminished venous drainage of the cranium. With reduced venous outflow, intracranial pressure increases, brain edema ensues, and signs and symptoms of acute intracranial hypertension manifest. In most cases, otitic hydrocephalus results from initial occlusion of the sigmoid or lateral sinus, with or without extension to the transverse sinus, inferior petrosal sinus, or cavernous sinus. The likelihood that symptoms will develop after occlusion of the lateral sinus adjacent to the mastoid reflects the following: (1) the size of the involved lateral sinus compared with the opposite lateral sinus; (2) the adequacy of the collateral venous network, including the cavernous sinus and opposite inferior petrosal sinus; and (3) the likelihood that propagation of the process will involve additional venous outflow.

Some authors view otitic hydrocephalus as a distinct clinical entity consisting of intracranial hypertension and resolved or resolving (usually acute) otitis media, having no relationship to lateral sinus thrombophlebitis.[24] Others view it more as a pathophysiologic consequence of lateral sinus thrombosis that occurs more commonly as a result of AOM than COM and depends on the three factors mentioned in the previous paragraph. The distinction is less important than recognizing the relationship between the symptom complex, ear disease, lateral sinus, and emergent nature of the treatment.

In the early stages, a diffuse severe headache dominates the clinical picture. In uncomplicated cases with (or occasionally without) medical management, the continuous headache gradually ameliorates and dissipates over 3 to 7 days. If collateral venous drainage is inadequate, and intracranial pressure remains sufficiently elevated long enough, signs of dulling of the sensorium or decreased visual acuity from retinal vein occlusion appear. Progression to coma and death is possible. CT scanning and immediate neurologic and neurosurgical consultation are appropriate.

CHAPTER ONE HUNDRED AND FORTY-ONE

Tympanoplasty and Ossiculoplasty

Meredith E. Adams

Hussam K. El-Kashlan

Key Points

- The ultimate goals of tympanoplasty are to restore middle ear function by eradicating infection and middle ear pathology, to re-establish a tympanic membrane that resists infection and epithelial ingrowth, and to secure a durable connection between the tympanic membrane and the inner ear.
- Medial and lateral techniques refer to the placement of the graft either medial or lateral to the tympanic membrane remnant. The graft is placed medial to the malleus handle in either technique.
- The success of any given technique depends on how well it is performed by the surgeon, rather than on the technique itself. There are no absolute indications for a particular technique.
- The lateral technique tympanoplasty is an extremely useful technique for challenging and revision cases of chronic suppurative otitis media with drum pathology. Its utility lies in considerable potential for inviting vascular ingrowth to promote graft healing and epithelialization. Success with lateral tympanoplasty requires that the surgeon summon refined techniques in preparing the external canal and the middle ear. To prevent blunting after lateral technique tympanoplasty, the acute angle between the anterior canal wall and the tympanic membrane should be developed with effective canalplasty. The lateral technique is more technically demanding and should be considered carefully by the novice or inexperienced ear surgeon.
- Good graft support in the anterosuperior quadrant is important to avoid failure in anterosuperior and total perforations.
- Temporalis fascia and perichondrium are the most commonly used materials for tympanic membrane reconstruction. Cartilage may be considered for reinforcement of retraction pockets, atelectatic membranes, and other conditions associated with increased failure rates with traditional techniques.
- The goal of ossiculoplasty is to re-establish the transfer of induced vibratory energy from the tympanic membrane to the undersurface of the stapes footplate, maximizing the postoperative gain in hearing.
- Allograft prostheses are gaining popularity. In particular, good hearing results, low extrusion rates, and ease of use have led to widespread application of titanium implants.
- Decisions regarding the appropriate reconstructive technique should be based on a careful assessment of the mobility, position, orientation, and integrity of the remaining ossicles.
- Postoperative conductive hearing loss may persist even with a perfectly placed prosthesis owing to ongoing middle ear disease.

Tympanoplasty

Tympanoplasty is a surgical procedure performed to eradicate infection and restore the function of the middle ear.[1] Wullstein[2,3] introduced a classification for tympanoplasty that is based on two things: (1) the remaining structures of the middle ear after all pathology has been eradicated, and (2) how sound is transferred to the oval window while the round window is being protected. The basic principles behind this classification still hold true today, but the practice of tympanoplasty has been modified by advances in the fields of optics, microsurgical instruments, middle ear prostheses, and surgical techniques. The presence of different tympanoplasty techniques is an indication that the otologic surgeon should be flexible when tailoring the procedure to fit the disease, rather than having a "one-size-fits-all" approach to surgery for chronic ear disease. This chapter reviews various tympanoplasty techniques and techniques for reconstructing the ossicular chain. Tympanoplasty is often performed in conjunction with mastoidectomy in cases of active chronic suppurative otitis media. Mastoidectomy techniques are reviewed in Chapters 127 and 142.

Functional Considerations

Restoration of the middle ear transformer mechanism requires a secure connection between an intact tympanic membrane and inner ear fluids. The tympanic membrane should close an air-filled, mucosa-lined middle ear cavity. Traditional teaching attributes most of the middle ear gain to the hydraulic effect, which is the ratio of the effective vibrating area of the tympanic membrane to the area of the mobile stapes footplate.[4] Round window protection to avoid phase cancellation (i.e., when sound impacts the oval and round windows at the same time) was also thought to be an important contributor to effective sound transmission to the inner ear. More recent investigations of human

middle ear mechanisms modified these classic teachings in the following ways[5]:

1. Sound can be transmitted from the ear canal to the cochlea by two mechanisms: ossicular and acoustic coupling. Ossicular coupling is the sound pressure gain that occurs through the tympanic membrane and the ossicular chain. Acoustic coupling is the difference in the sound pressure that is acting directly on the oval and round windows. In normal ears, acoustic coupling is negligible, but it may play a significant role in diseased and reconstructed ears.

2. When sound input to the cochlea depends solely on acoustic coupling (e.g., ossicular interruption behind an intact tympanic membrane, complete absence of the tympanic membrane and ossicles), the stimulus to the cochlea depends on the relative magnitude and the phase (timing difference) of the oval and round window pressures. The magnitude difference is more important than the phase difference.

3. The pressure gain that results from ossicular coupling in normal ears is frequency-dependent, and its magnitude is less than traditionally believed. The mean middle ear gain is about 20 dB between 250 and 500 Hz, reaches a maximum of about 25 dB around 1 kHz, and then decreases at about 6 dB per octave at frequencies greater than 1 kHz.

4. There is also a contribution of the stapes-cochlear impedance and the round window membrane to middle ear function. Normally, motion of the stapes footplate is "opposed" by the annular ligament, the cochlear fluids and partition, and the round window membrane. Pathologic changes in the impedance of the annular ligament, the cochlea, or the round window can cause hearing loss, such as that caused by otosclerotic stapes fixation. Also, in a nonaerated middle ear, the presence of fluid or fibrous tissue within the round window niche can increase the round window impedance and cause conductive loss.

5. Aeration of the middle ear plays an important role in sound transmission. In addition to contributing to normal stapes-cochlear impedance (see previously), aeration is crucial for normal ossicular coupling. The compressible air within the middle ear allows the tympanic membrane and the ossicles to move.[6,7] Impaired middle ear aeration can adversely affect ossicular coupling by altering a pressure difference that is important to middle ear function. In the normal human middle ear, sound pressure in the ear canal is higher than sound pressure within the middle ear; tympanic membrane motion is driven by this pressure difference. Reductions in middle ear air volume that result from disease or surgery lead to elevated middle ear airspace impedance and an increase in middle ear sound pressure. This leads to a reduction in the pressure difference across the tympanic membrane, with a subsequent reduction in tympanic membrane and ossicular motion.[5] The minimum amount of air required to maintain ossicular coupling within 10 dB of normal has been estimated to be 0.5 mL.[8]

A perforation of the tympanic membrane causes hearing loss by reducing the difference in sound pressure across the two sides of the tympanic membrane, causing decreased ossicular coupling.[9] Hearing loss is proportional to the size of perforation and is frequency dependent, with the largest losses occurring at the lowest sound frequencies.[10] It also varies inversely with volume of the middle ear airspace (including the mastoid); this may explain why seemingly identical perforations in size and location produce different degrees of hearing loss, and why hearing loss may fluctuate in a given perforation with the presence or absence of otorrhea, which would decrease middle ear and mastoid airspace, causing increased hearing loss. More recent investigations also suggest that hearing loss does not vary appreciably with the location of perforation, in contrast to the long-held belief that posteroinferior perforations result in greater hearing loss than perforations at other locations owing to increased phase cancellation at the round window.[10,11]

Preoperative Evaluation

A detailed history and careful physical examination are essential to the planning of the surgical approach and the counseling of patients regarding the expected outcome. The extent of tympanic membrane perforation and the condition of the ossicular chain are evaluated. The health of the remaining membrane is assessed, paying particular attention to atrophic areas and the degree of myringosclerosis. The size of the external canal is evaluated, and canalplasty is planned if a prominent anterior canal wall prevents complete visualization of the perforation. Comprehensive audiometric evaluation is performed, and tuning fork tests are used to confirm the audiogram. Radiographic evaluation is usually not needed if clinical examination reveals a dry central perforation.

As mentioned previously, postoperative aeration of the middle ear is key to the success of tympanic membrane repair and the restoration of hearing. The otologic surgeon has no direct control over this factor, however, which depends mostly on eustachian tube function. There is currently no test that accurately predicts postoperative eustachian tube function. Some indicators—the aeration of the opposite ear, increased age in children, fewer episodes of otorrhea, and normal middle ear mucosa—may suggest reasonable eustachian tube function. In many cases, however, surgery is the ultimate test, and may result in improved eustachian tube function by preventing recurrent infections through contamination from the external auditory canal.

This chapter deals mainly with techniques for repair of dry tympanic membrane perforations. Techniques for handling active chronic otitis media with or without cholesteatoma are described in other chapters. In brief, it is recommended that the ear be dry for 3 to 4 weeks before proceeding with tympanoplasty. There are situations, however, in which the ear cannot be successfully treated medically, and tympanoplasty with or without mastoidectomy may be the best therapeutic option.

Graft Materials

Temporalis fascia is the most commonly used material for the repair of tympanic membrane perforations; it was introduced for this use in the early 1960s.[12] Temporalis fascia can be harvested at the time of tympanoplasty through a small incision posterosuperior to the helix in the hair-bearing scalp when using a transcanal approach, or via superior dissection from a postauricular or endaural incision. Other grafting materials have also been used.[13-15] In 1960, Shea[15] described the use of vein grafts in tympanoplasty. Perichondrium is frequently used in tympanoplasty, particularly if there is no temporalis fascia available (e.g., in cases of multiple revisions) or if a composite cartilage/perichondrium graft is needed to prevent retraction of the reconstructed membrane when there is suspected persistent eustachian tube dysfunction. The periosteum on the medial surface of the temporalis muscle can also be used as a graft material when temporalis fascia is unavailable if the surgeon wishes to avoid the additional incision needed to harvest tragal perichondrium.

Ringenberg[14] used free autologous fat grafts in the early 1960s. A more recent study reported success rates with fat grafts to be comparable to success rates with temporalis fascia.[16] AlloDerm (LifeCell Corporation, Branchburg, NJ) has also been studied and used as a graft material.[17-20] To support the use of AlloDerm as a possible alternative to autologous fascia, advocates cite the avoidance of external incisions, potential reduction of surgical time, and comparable success rates.[20]

Minimalist Techniques

There are some clinical situations in which a minimalist approach to tympanoplasty is possible or desirable. Small, uninfected, established perforations of 1- to 2-mm diameter can often be managed in an office setting in this way. The epithelium at the margins of the perforation is cauterized or removed, and a fat plug that is slightly larger than the diameter of the perforation is removed from the lobule to use as a graft. It is placed through the opening in a dumbbell fashion and covered with a dressing such as Gelfoam or Gelfilm (Pharmacia & Upjohn Company, Kalamazoo, MI, a division of Pfizer Inc., New York, NY). Other surgeons prefer simply to cauterize the perforation edges with trichloroacetic acid or phenol and apply a patch of Gelfoam, Gelfilm,

cigarette paper, or a hyaluronic acid film (Epidisc; Medtronic Xomed Inc., Jacksonville, FL). Traumatic perforations also are often managed by patching only after the perforation edges are realigned. In addition, a more recent study described the use of a simple device in the shape of a sealed tympanostomy tube (Medtronic Xomed Inc., Jacksonville, FL) that is designed to be inserted into tympanic membrane perforations in patients when surgery is contraindicated or refused by the patient.[21]

Formal Tympanoplasty (see Key Indicator Video on website)

Anesthesia

Tympanoplasty can be performed under local or general anesthesia. In children and anxious adults, general anesthesia is preferred. In either case, the ear canal skin is injected with lidocaine (usually 1%) with epinephrine (1:100,000) for vasoconstriction. Care should be taken to avoid the formation of fluid blebs in the skin, which can occur if excessive force is used to inject, especially if a larger syringe is used. Injection should be done using a microscope, preferably before preparing the ear so that there is time allowed for vasoconstriction to occur. If liquid povidone-iodine (Betadine) is used to prepare the ear, its entry into the middle ear should be avoided.

Approaches and Incisions

Three main approaches are used in tympanoplasty: transcanal, endaural, and postauricular. The approach used depends on the perforation size, the anatomy of the external auditory canal, and the surgeon's preference. Most importantly, the approach used should provide complete visualization of the perforation. The transcanal approach is usually employed for small posterior perforations or for medium-sized perforations when the ear canal anatomy is favorable, and the entire perforation and an anterior tympanic membrane rim can be seen; it should be avoided in cases in which the anterior margin of the perforation is not well visualized, particularly in the hands of surgeons with less experience. The endaural approach can be used with all perforations and is more commonly used in Europe; it is most useful if a limited atticotomy is anticipated in conjunction with tympanoplasty. A self-retaining retractor can be used with this approach. The postauricular approach is the most commonly used approach for tympanoplasty in the United States. It can be used with all perforation sizes, and offers a better angle of visualization of the anterior tympanic membrane, even without canalplasty. The use of self-retaining retractors allows for easier use of both hands for instrumentation and suctioning.

Transcanal incisions outline a medially based tympanomeatal flap. Superior and inferior incisions start at 12 o'clock and 6 o'clock. Either the incisions converge to meet on the posterior canal wall, forming a triangular skin flap (Fig. 141-1A), or each incision may be extended laterally for 6 to 7 mm, at which point the lateral ends of the incisions are connected by a horizontal incision that forms a rectangular flap (Fig. 141-1B). Before the elevation of the flap, the edge of the perforation is excised. A sharp straight pick is used to create small holes around the periphery of the perforation, similar to those of a postage stamp (see Fig. 141-1A); this outlined edge can be removed with a cupped forceps.

The excision of the perforation edge to disrupt the epithelial union is an integral part of any tympanoplasty procedure, whatever the approach, incision, or technique used. Any large areas of tympanosclerosis should be removed. The outlined skin flap is elevated medially usually using a round knife. Care is taken to minimize suctioning on the flap. Suctioning should be done between the instrument used to elevate the flap and the bony canal. Elevation should be performed along the entire breadth of the flap rather than by the creation of a tunnel in the middle. After the anulus is reached, it is elevated from the tympanic sulcus, exposing the middle ear mucosa, which is divided to enter the middle ear. Elevation of the anulus from the sulcus is continued superiorly and inferiorly under direct vision; this minimizes the risk of injury to a dehiscent, high-riding jugular bulb. Care should be taken to avoid injury of the chorda tympani with superior elevation of the flap. When elevation has reached the limits of the incision, it is usually possible to tuck the tympanomeatal flap anteriorly, where it is not interfering with the surgical field.

The endaural incision has a vertical limb that usually starts at 12 o'clock at the bony cartilaginous junction and extends laterally and superiorly into the cartilage-free incisura terminalis between the superior aspect of the tragus and the root of the helix (Fig. 141-2A). The incision is deepened to expose the inferior edge of the temporalis muscle, where a fascial graft can be taken. The vertical limb can be combined with one of the medially based tympanomeatal flaps described previously, an inferiorly based skin flap (Fig. 141-2B), or a laterally

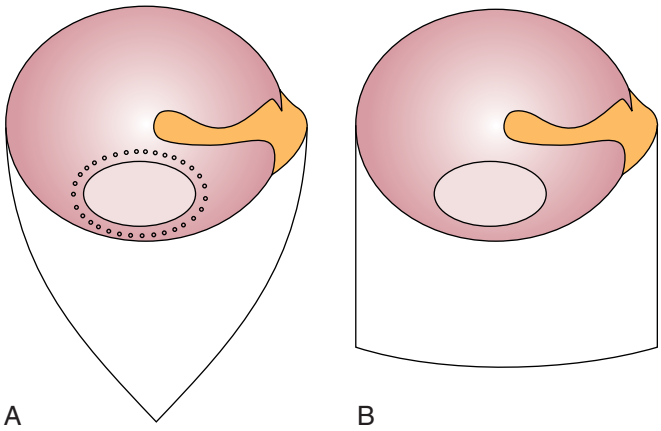

Figure 141-1. A, Triangular tympanomeatal flap; perforation edge is prepared for excision by creating small holes along the perimeter. **B,** Rectangular tympanomeatal flap.

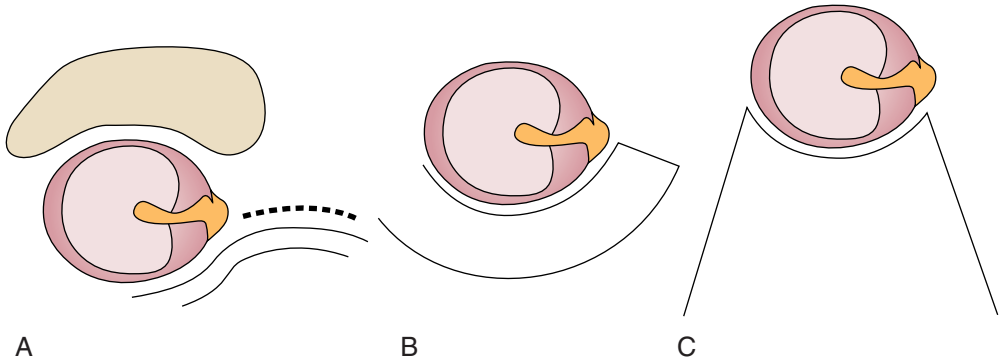

Figure 141-2. A, *Hatched line* shows the vertical limb of the endaural incision starting at the bony cartilaginous junction and extending laterally and superiorly into the cartilage-free incisura terminalis, between the superior aspect of the tragus and the root of the helix. **B** and **C,** The vertical limb can be combined with an inferiorly based skin flap **(B)**, or a laterally based Koerner flap extending onto the concha **(C)**.

based Koerner flap extending onto the concha (Fig. 141-2C) (allowing cartilage excision and meatoplasty), depending on the planned surgery.

The postauricular incision usually extends from the mastoid tip to just above the attachment of the helix, about 5 to 6 mm from the postauricular crease. The incision is deepened in layers, with care taken not to injure the periosteum. Care is also taken not to elevate the auricle as a separate layer from the periosteum because this can lead to a lop-ear deformity postoperatively. The temporalis muscle and fascia are exposed. The periosteum is incised in a "7" or "T" fashion. The presence of this acute angle allows for the precise repositioning of the periosteum during closure, avoiding any misalignment of the auricle or any change of its vertical position postoperatively. The periosteum is elevated forward, exposing the spine of Henle and the ear canal.

There are several options for handling the posterior canal wall skin. The canal skin can be elevated from behind with care taken not to tear the skin, particularly at its attachment at the tympanomastoid and tympanosquamous suture lines. If there is a very prominent tympanosquamous suture line, it is often helpful to incise the fibrous tissue within the suture line using a sickle knife or a 59-10 Beaver blade. The skin is elevated down to the anulus, which should be left intact at this time; vascular strip incisions can be made from behind to access the ear canal. Vertical incisions placed at the 6 o'clock and 12 o'clock positions are connected by a horizontal incision just lateral to the anulus to create a long vascular strip. The other option is to perform the vascular strip incisions through the ear canal before starting the postauricular incision.[22] In cases in which there is no perforation, and surgery is performed for a second look or for ossiculoplasty (especially if an incus interposition is contemplated), it is possible not to do any canal incisions, and instead to elevate the canal skin and anulus in continuity, entering the middle ear for inspection and ossicular reconstruction.

Graft Placement

Medial and lateral techniques refer to the placement of the graft either medial or lateral to the tympanic membrane remnant. Although some surgeons advocate a certain technique for graft placement in a particular situation, the success of any technique depends on how well this technique is performed by the surgeon, rather than on the technique itself. Consequently, there should not be an absolute indication for a particular technique in a certain perforation. Medial technique can be used to repair total perforations or in revision cases if done properly by an experienced surgeon.

Lateral Graft Technique

In lateral technique tympanoplasty, which is also known as the overlay technique, the graft is placed lateral to the fibrous layer of the tympanic membrane remnant, but medial to the malleus handle. This technique requires complete removal of the squamous epithelium from the lateral surface of the tympanic membrane remnant to avoid iatrogenic cholesteatoma formation. During elevation of the tympanomeatal flap, the anulus is left in the tympanic sulcus, and the dissection is transitioned from the bony external canal onto the lateral surface of the tympanic membrane, separating the superficial squamous layer from the middle fibrous layer. If the perforation is of medium size, the dissected epithelium can be left attached anteriorly and can be replaced on top of the graft. In total perforations, it is usually necessary to remove the skin of the external canal completely to ensure complete removal of squamous epithelium.

Canalplasty can be performed to remove the prominent anterior canal wall to visualize the entire perforation without having to move the microscope.[23] This is accomplished by connecting the lateral ends of the vascular strip incisions along the anterior canal wall just medial to the bony-cartilaginous junction (Fig. 141-3A). The skin is dissected

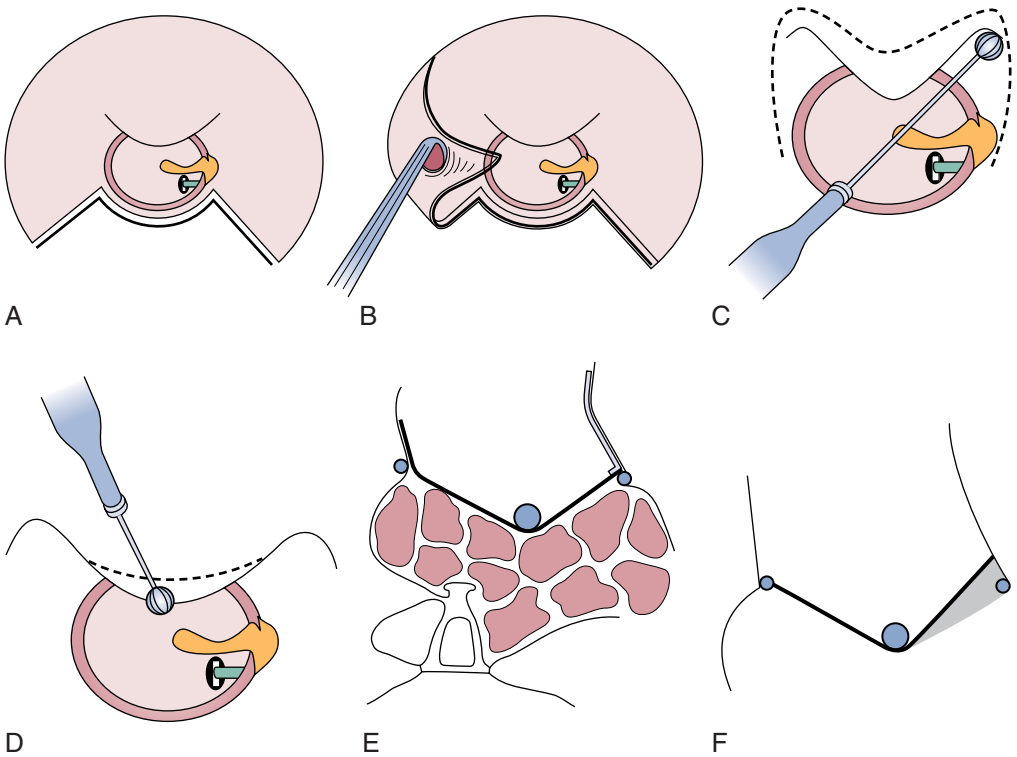

Figure 141-3. **A,** Vascular strip incisions on posterior canal wall; the lateral ends of the vertical incisions are connected along the anterior canal wall just medial to the bony-cartilaginous junction. **B,** The canal skin is dissected medially toward the anulus. **C,** Visualization of the anterior sulcus may require removal of a significant amount of the anterior canal bone; bone is first removed in the superior and inferior corners of the anterior bony canal. **D,** The bony bulge is gradually taken down between the two corners. **E,** Placement of the graft *(thick black line)*, with its anterior edge at the anulus supported by Gelfoam in the middle ear; the medial end of the replaced anterior canal skin *(gray)* should cover only 1 to 2 mm of the anterior end of the graft. **F,** Anterior blunting *(gray)*; this is the result if the graft is placed on the anterior canal wall, or if the anterior canal skin covers a large area of the graft without maintaining the acute anterior tympanomeatal angle.

medially toward the anulus (Fig. 141-3B). When the elevation reaches the area medial to the anterior canal bulge, the dissection is usually done by feel until the anulus is reached. The elevation of the epithelium from the tympanic membrane remnant is performed by developing a plane superiorly or inferiorly at the level of one of the original canal incisions, near the anulus. The squamous epithelium of the tympanic membrane remnant is usually left in continuity with the previously elevated canal skin. The anterior canal skin is trimmed of irregular tags and stored in a moist sponge.

To ensure optimal graft placement, the anterior sulcus should be well visualized. This may require removal of a significant amount of the anterior canal bone (Fig. 141-3C). This removal is accomplished by using an otologic drill first to remove bone in the superior and inferior corners of the anterior bony canal. The bony bulge is gradually taken down between the two corners, keeping in mind that the prominent middle portion represents the posterior wall of the temporomandibular joint (Fig. 141-3D). It is of paramount importance to avoid violating the temporomandibular joint because this can lead to erosion of the condyle into the ear canal, which is extremely difficult to correct. In cases in which there is no anterior tympanic membrane remnant, placement of the graft may be facilitated by drilling a small trough just lateral to the anulus to create additional support for the graft anteriorly. Another alternative is to elevate the anulus from the sulcus anteriorly in continuity with the mucosa of the lateral wall of the eustachian tube, which provides a pocket to support the anterior portion of the graft.

If there is enough tympanic membrane remnant to support the graft, Gelfoam may be unnecessary in the middle ear. In large perforations, Gelfoam is placed in the middle ear to support the graft. The graft is trimmed to the proper size. The graft should be wide enough to cover the entire tympanic membrane region and long enough to drape onto the posterior canal wall. In placing the graft, care should be taken not to overlap any portion of the anterior canal wall, or blunting may occur (see later). Although the graft is placed lateral to the anulus, it should be placed medial to the malleus handle to prevent lateralization. This is usually accomplished by cutting a vertical slit in the anterosuperior corner of the graft to accommodate the malleus handle. If a significant tympanic membrane remnant is still attached to the malleus, incisions should be made sharply on either side of the malleus handle to allow for medial placement of the graft.

The trimmed anterior canal skin is repositioned with its thin medial part overlying approximately 1 mm of the graft (Fig. 141-3E). The anterior tympanomeatal angle should be maintained at an acute angle (≤90 degrees) by placing pressed, rolled, dry Gelfoam in the sulcus during healing. If the graft is placed on the anterior canal wall, or the acute anterior tympanomeatal angle is not preserved, a dead space is created that gets filled with fibrous tissue, resulting in blunting (Fig. 141-3F). This reduces the area of the vibratory portion of the tympanic membrane and causes persistent conductive hearing loss. Additional Gelfoam is placed over the graft except for the portion of the fascia that extends onto the posterior canal wall. The vascular strip skin is placed back, with care taken to unfurl the skin edges to avoid burying epithelium. Ideally, the vascular strip should be long enough to overlie a portion of the graft that is resting on the posterior canal wall. The periosteum is closed, with care taken not to lift the ear forward to avoid displacement of the vascular strip. After several sutures are placed in the periosteum, the vascular strip position is reinspected through a speculum, and the ear canal is filled with Gelfoam or antibiotic ointment. The postauricular wound is closed.

Advantages of the lateral technique include wide exposure and the ability to use it for all perforation sizes. The disadvantages include a longer healing time because of extensive dissection; a more technically demanding and difficult-to-master procedure for the surgeon who performs ear procedures only occasionally; epithelial pearls, and possibly iatrogenic cholesteatoma as a result of incomplete squamous epithelium removal; blunting; and lateralization that occurs as a result of the separation of the graft from the middle fibrous layer (this generally occurs only if the graft was placed lateral to the malleus). The gap becomes filled with fibrous tissue, and this results in a significant conductive hearing loss. The tympanic membrane loses all landmarks, and the ear canal becomes significantly reduced in depth.

Medial Graft Technique

The medial technique can be used with any of the aforementioned approaches. The tympanomeatal flap is elevated as described earlier in the transcanal approach. If a prominent canal wall prevents complete visualization of the anterior edge of the perforation, canalplasty can be performed. A segment of the anterior canal skin overlying the canal bulge can be removed, and the bulge can be drilled down. The skin can be replaced as a free graft at the end of the procedure. Another option is to create a medially based anterior canal skin flap down to the level of the anulus, which is left intact. The skin flap is laid over the tympanic membrane and covered by a template of suture packet aluminum foil to protect it from accidental injury during drilling. Canalplasty can be performed to remove the anterior canal bulge; the anterior canal skin is then reflected back in place, where it usually stays owing to surface tension. This technique can routinely expose the anterior anulus, allowing the use of this technique even for total perforations.

For anterior perforations, the attachment of the tympanomeatal flap to the malleus can prevent adequate visualization of the anterior part of the mesotympanum (Fig. 141-4A). Several techniques can be used to overcome this difficulty. The tympanomeatal flap can be divided from the lateral edge to the perforation; the resulting flaps can be reflected like an open book, allowing for easier access to place the graft. Another technique allows for complete exposure of the middle ear and better placement of the graft medial to the anterior anulus for total perforations. The attachment of the tympanic membrane remnant to the malleus is divided by using a sickle knife to incise the periosteum on the posterior aspect of the malleus, and the tympanic membrane is dissected forward and can be reflected upward on the anterior canal wall (Fig. 141-4B and C). The middle ear and anterior anulus are completely exposed. The middle ear is prepared for grafting, and the area of the eustachian tube is packed well with Gelfoam to provide adequate support to the graft in this area (Fig. 141-4D).

The most common area of tympanoplasty failure when repairing total perforations is the anterosuperior area owing to a lack of support. A platform of Gelfilm is prepared and placed lateral to the Gelfoam, but medial to the malleus and anterior anulus (Fig. 141-4E and J). The anterior edge of this platform extends into the protympanum area, which is packed with Gelfoam to support the platform and get it in contact with the anulus. It acts as a smooth surface over which the graft can slide and be tucked anteriorly medial to the anulus (see Fig. 141-4J).

The fascial graft is fashioned with a small hole in the anterosuperior part (Fig. 141-4F); this hole accommodates the manubrium of the malleus. The umbo is introduced through the hole, and then the graft is pulled superiorly where the hole surrounds the malleus neck (Fig. 141-4G and H). This provides good stability of the graft and prevents its movement if it is accidentally caught in the suction tip; it also provides a fulcrum around which the graft can be rotated for optimal positioning. The tympanomeatal flap is returned back to its native position (Fig. 141-4I). Advantages of the medial graft include the avoidance of the disadvantages of the lateral technique, an easier to master technique for the general otolaryngologist, and, if the graft is performed properly, the achievement of high success rates compared with lateral technique. Experienced surgeons should be successful in closing tympanic membrane perforations in approximately 90% of cases, regardless of the technique of graft placement.[24,25]

Special Considerations

Tympanosclerosis

The tympanic membrane remnant often contains areas of myringosclerosis, which, if extensive, can make repair of the perforation more difficult. Smaller areas of myringosclerosis have no effect on hearing and can be left alone. Tympanosclerosis that affects a large area of the tympanic membrane remnant should be removed and replaced with the fascial graft.

Atrophic and Atelectatic Tympanic Membrane

When eustachian tube function is normal, small areas of atrophic tympanic membrane away from the perforation can also be left alone.

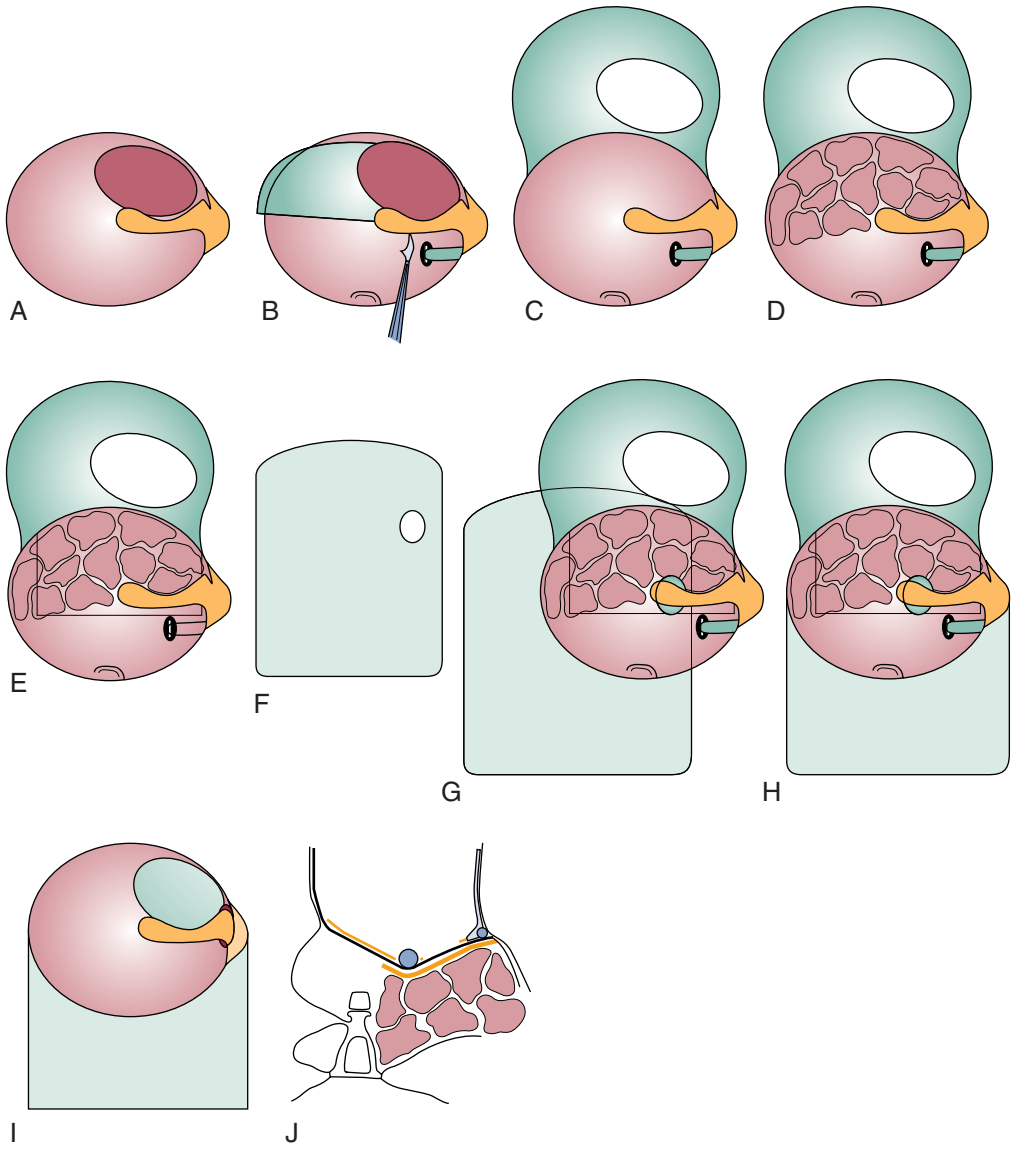

Figure 141-4. **A,** Anterior tympanic membrane perforation. **B,** Reflected tympanomeatal flap still attached to the malleus; the periosteum is incised along the posterior aspect of the malleus. **C,** Tympanomeatal flap freed from the malleus, dissected forward, and reflected upward onto the anterior canal wall, which shows through the perforation. **D,** Gelfoam is placed anteriorly to support the graft. **E,** A platform of Gelfilm is placed lateral to the Gelfoam and medial to the malleus and the anterior anulus. **F,** Fascial graft with a small hole created in the anterior superior aspect. **G,** The umbo is passed through the hole in the graft. **H,** The graft is pulled superiorly so that the hole surrounds the malleus neck; the anterior edge of the graft is tucked medial to the anterior anulus and lateral to the Gelfilm platform. **I,** The tympanomeatal flap is returned to its position; the graft is showing through the perforation. **J,** Schematic diagram that shows the placement of the Gelfilm platform and graft medial to the anterior anulus supported by Gelfoam in the anterior tympanum.

In many instances, however, much of the dystrophic tympanic membrane is removed in an attempt to obtain a healthy mobile tympanic membrane from the graft. The atrophic posterosuperior quadrant, whether retracted or not, presents a special situation. Tympanoplasty that involves a composite cartilage/perichondrial graft to provide structural support for this area while preserving tympanic membrane mobility is gaining wide acceptance. The cartilaginous graft can be made quite thin and of a small enough diameter to bolster only the weakened portion of the involved tympanic membrane.[24]

The atelectatic ear also poses a special problem. Many such ears are dry and produce no symptoms other than hearing loss. Many otologists think of the atelectatic ear as an end-stage ear with very poor eustachian tube function, and they recommend only regular follow-up to ensure the absence of cholesteatoma. Other otologists believe that hearing loss should be corrected and recommend cartilage tympanoplasty for such ears.[26] (*Note*: The risk here is that a dry, asymptomatic ear may be converted into one requiring ongoing care and revision surgeries. The risk-to-benefit ratio of proceeding with surgical management of the atelectatic ear should be carefully considered.)

Cartilage Tympanoplasty

Although high tympanic membrane closure rates and good hearing results have been reported for temporalis fascia and perichondrial grafts, certain situations are associated with graft atrophy and failure, regardless of placement technique.[27] The tissue rigidity of cartilage and its resistance to resorption and retraction, even in the setting of ongoing eustachian tube dysfunction, has led to the growing acceptance of its use in middle ear reconstruction.[28] Cartilage grafts placed between the tympanic membrane and an ossicular prosthesis decrease extrusion risk and can augment the prosthesis-tissue interface, allowing for better long-term hearing results.[29] If a second-stage ossiculoplasty with an allograft is anticipated, a cartilage graft may be placed beneath the

central portion of the membrane at the time of tympanoplasty. In addition to the more common use of cartilage to provide structural support to posterosuperior retraction pockets,[24] more recent literature supports the use of cartilage for the atelectatic ear and other conditions associated with increased failure rates with traditional techniques (e.g., revision surgery, perforation >50%, drainage at time of surgery, bilateral perforations) and, although more controversial, for reconstruction after cholesteatoma.[30-32]

Several different techniques and types of cartilage grafting have been described, including placement of composite cartilage/perichondrial grafts of varying sizes and shapes, and creation of cartilage palisade arrays. Cartilage may be harvested with its attached perichondrium from the tragus or the concha. Tragal cartilage is thicker and flatter than conchal cartilage, and may be more suitable for larger perforations.[30] A composite cartilage/perichondrium graft may be constructed by carving an eccentrically located disk of cartilage that remains attached to its perichondrial flap. The cartilaginous graft can be made quite thin and of a small enough diameter to bolster only the weakened portion of the involved tympanic membrane, or may be shaped to fill a pantympanic perforation. It also may be modified to allow space for the malleus handle, the incus, or a prosthesis. The graft is placed in an underlay fashion, and the remaining perichondrium is used to augment the tympanic membrane repair or to drape over the posterior canal wall.[30] Other modifications of this concept can be seen in the tragal cartilage shield graft[28,33] and the butterfly cartilage graft inlay technique.[34,35]

After noting that larger plates of cartilage may become distorted with time, Heermann and colleagues[36] proposed the used of palisades, or strips, of cartilage for membrane reconstruction. The traditional palisade technique involves the placement of thin rectangular cartilage slices medial to the bony anulus and parallel to the malleus handle. Modifications have been described, including the placement of custom-carved slices of cartilage to reconstruct the round shape of the tympanic membrane.[30,32] The reconstruction may be covered with perichondrium or fascia.

Many studies have established the efficacy of cartilage grafts in tympanoplasty and shown no detrimental effect on hearing.[28,32,35,37-43] Here, the acoustic transfer properties of cartilage seem to depend on cartilage thickness. Reducing cartilage thickness optimizes acoustic transfer properties, with thickness 500 µm or less resulting in a highly favorable vibratory transfer.[43] In his analysis of 636 cartilage tympanoplasties, Dornhoffer[30] reported a successful graft take and membrane closure in greater than 95% of cases performed for high-risk perforations and atelectatic ear drums. Hearing results were not significantly different from fascial or perichondrial repairs. Because of the increased thickness and opacity of cartilage grafts, postoperative monitoring for effusion and cholesteatoma is challenging, and tympanometry may be unreliable.

Pediatric Tympanoplasty

Traditionally, tympanoplasty was not recommended in children younger than 7 years because it may affect the normal growth of the bony external canal, and because it was thought to have a high rate of recurrence owing to immature eustachian tube function. Several studies have shown that tympanoplasty, even in children as young as 2½ years old, has a good success rate and long-term stability.[44-49] It was suggested that evidence of ongoing eustachian tube dysfunction (as shown by otitis media with effusion and negative middle ear pressure in the contralateral ear) may predict poor outcome in pediatric tympanoplasty.[50]

Ossiculoplasty

Pathophysiology

Ossicular Fixation

Tympanosclerosis can hinder motion of the eardrum and the ossicles, and, in severe cases, can totally immobilize the stapes, malleus, and incus. It appears as a chalky white mass that involves the tympanic membrane and the middle ear (or attic), and is the end product of chronic infection or inflammation. Microscopically, there is increasing collagen and fibrous tissue with hyaline degeneration within the lamina propria of the pars tensa and the middle ear mucosa. The deposition of hyaline occurs in layers similar to the rings of an onion and may reach a thickness of a few millimeters.

Tympanosclerosis most commonly involves the tympanic membrane—myringosclerosis—but this condition usually does not have much of an adverse effect on hearing. Significant conductive hearing loss is usually a result of the fixation of the ossicles in the middle ear or epitympanum. With roughly equal frequency, the disease fixes the stapes in the oval window region, and the incus and malleus in the attic, or involves the ossicles in the oval window and the attic simultaneously. Ossicular fixation from tympanosclerosis should be suspected as the cause of conductive hearing loss when there is a history of chronic infections, or when tympanosclerosis is seen on the tympanic membrane.

Bony fixation of the ossicles can occur as a result of infection, surgical trauma, or temporal bone fracture, or as a congenital anomaly. Infection is the most common of these, and it is usually associated with a current or past history of either cholesteatoma or chronic otitis media with granulation tissue. Isolated fixation of the malleus is the most common manifestation, and usually occurs at some location on the anterior surface of the malleus head. Fixation of the incus is the next most common manifestation, and it can bind any of the free surfaces of the incus body to an adjacent wall of the attic. Combined fixation of the malleus and incus occurs as commonly as isolated incus fixation. Nonotosclerotic bony fixation of the stapes is uncommon and is usually manifested by a small bridge of new bone between the fallopian canal and one of the crura.

It may be possible to diagnose malleus fixation preoperatively by microscopic observation during pneumatic otoscopy. In these cases, the umbo and the anterior (short) process of the malleus can be seen to move less than in normal ears or not at all.

Ossicular Discontinuity

Chronic otitis media in almost any form can result in the disruption of the integrity of the ossicular chain. Chronic eustachian tube insufficiency and tympanic membrane retraction that results in prolonged contact of the tympanic membrane with the tip of the incus can cause this type of erosion, even without active infection. Cholesteatoma is the most common cause, however; chronic otomastoiditis without cholesteatoma can also cause erosion of the ossicles. The pathology can be restricted to the incudostapedial joint with loss of the lenticular process, sometimes with preservation of a soft tissue connection; usually, however, there is a complete loss of some portion of the distal incus. The entire long process of the incus can be eroded, particularly in cases of cholesteatoma, along with the stapes superstructure. In some cases, the incudostapedial erosions are associated with partial or total malleus fixation.

Surgical removal of the ossicles during cholesteatoma removal is another obvious and common cause of ossicular discontinuity. In most instances, this involves the entire (remaining) incus and the head of the malleus.

Trauma can also result in ossicular discontinuity, especially longitudinal temporal bone fractures. The force of the fracture tears the incus from its articulations with the malleus and stapes, and the incus does not completely return to its normal position. The stapes superstructure may also be fractured.

Audiometric Correlates

With complete ossicular discontinuity, the most common audiometric pattern is that of a near-maximum (55 to 60 dB) conductive hearing loss across all frequencies.[51] This is because, as mentioned previously, sound input to the cochlea depends solely on acoustic coupling. The intact tympanic membrane presents a barrier to the sound trying to reach the oval and round window membranes. The limited sound reaching those membranes strikes them at the same time (no phase protection) with a similar low sound pressure (absent ossicular coupling). When a significant tympanic membrane perforation is present, along with ossicular discontinuity, that barrier is removed, and hearing is improved by 10 to 15 dB. An interesting variation is the uncommon situation of a partial incudostapedial separation (fibrous union of the incus and stapes). Audiometrically, the air-bone gap is greater in the

high frequencies than in the low frequencies. Tympanometry also helps to identify cases of complete ossicular disruption because the discontinuous ossicular chain allows a wide excursion of the tympanic membrane in response to changing ear canal pressure, and a deep tympanometric pattern results.

Audiometrically, ossicular fixation presents contrasts to ossicular discontinuity. Because the fixation of the ossicles restricts the motion of the malleus and the tympanic membrane, the tympanogram is flatter than normal; a Carhart notch is usually seen. This is a 5-, 10-, 15-, and 5-dB depression in bone-conduction thresholds at 500, 1000, 2000, and 4000 Hz. This is not a true depression in bone conduction, but rather an artifact caused by a lack of the normal contribution of the mobile ossicular chain to bone conduction. This depression improves after the mobility of the ossicular chain is restored. The Carhart values are averages from numerous subjects, and in some cases, changes are much greater. The air-conduction thresholds in ossicular fixation are poorest in the low frequencies. When the air-conduction and the bone-conduction thresholds are plotted, the pattern looks like an hourglass on its side; the air-conduction thresholds are best in the midfrequencies and poorer at high and low frequencies. Air-conduction and bone-conduction thresholds in cases of ossicular discontinuity look like parallel lines 50 to 60 dB apart across the frequencies, without better hearing at the midfrequencies and without the bone-conduction depression seen in ossicular fixation.

Materials

The materials used in the reconstruction of the ossicular chain are autografts, homografts, and allografts. Autografts are either bone or cartilage. Autograft ossicles are removed from the patient and sculpted to serve as an interposition graft; the incus is used most commonly. The advantages include immediate availability, obvious biocompatibility, low cost, and a low extrusion rate. Disadvantages include concerns about possible disease recurrence when used in patients with cholesteatoma, the potential for fixation to adjacent bone of the promontory or the canal wall, and ossicle unsuitability owing to demineralization or erosion. In addition, autografts and homografts require time and skill to shape appropriately in the operating room. Autograft cartilage is usually taken from the tragus or occasionally from the auricular cartilage. Homograft ossicles and en bloc tympanic membranes with attached ossicles are available through regional tissue banks, and graft rejection is extremely rare. Their usage has decreased considerably, however, largely as a result of the fear of potential transmission of human immunodeficiency virus, hepatitis, and Creutzfeldt-Jakob disease.

During the past 20 years, there has been increasing interest in and use of allografts. The major advantages are sterility, availability, and, for some, the ability to bond to tissues. During their developmental history, the disadvantages of allografts have been difficulties with biocompatibility (extrusion) and cost. There have been three principal groups of allografts: polymers, ceramics, and metals. The polymers include polyethylene, polytetrafluoroethylene (Teflon; DuPont, Wilmington, DE), and silicone rubber (Silastic; Dow Corning, Midland, MI). Polycel and Plasti-Pore are high-density polyethylene sponge products. The ceramics include the glass ceramics Ceravital (Ernst Leitz, Wetzlar, Germany) and Bioglass and the calcium phosphate ceramic hydroxyapatite. Hydroxyapatite can achieve real integration with bone without encapsulation, and it can be made in a porous and a dense form; it is brittle and difficult to sculpt or modify.[52]

Allografts have been manufactured in two basic configurations: total ossicular replacement prosthesis (TORP) and partial ossicular replacement prosthesis (PORP). There are many variations in the shape of the platform of the tympanic membrane portion of the prosthesis. Some contact the undersurface of the tympanic membrane, whereas others are designed to conform to the undersurface of the malleus. In addition, prostheses are designed to be used for ossicular discontinuity that is restricted to separation of the incudostapedial joint.

Attempts have also been made to combine various allografts. A hydroxyapatite platform is frequently combined with a Plasti-Pore shaft. The hydroxyapatite has less extrusion potential and can bond to tissue, whereas the Plasti-Pore can be cut to the appropriate length more easily. Other materials have been used in such composite prostheses. These include Polycel (thermal-fused Plasti-Pore), polytetrafluoroethylene, a mixture of hydroxyapatite and Silastic, and hydroxyapatite-reinforced polyethylene composites.[53,54]

The choices and preferences of ossicular prostheses by U.S. otologists have changed over time. In a 1989 survey, autograft and homograft bone prostheses were used by 93% of respondents, cartilage prostheses were used by 78%, and Plasti-Pore prostheses were used by 81%. Hydroxyapatite had just been introduced as a biomaterial.[55] Ten years later, a similar survey revealed that hydroxyapatite prostheses were used by 82% of respondents, autograft and homograft bone prostheses were used by 72%, and autograft or homograft cartilage prostheses were used by 62% (only 4% listed cartilage as their first preference). Plasti-Pore prosthesis use had declined to 59% of respondents.[56] The trend toward increasing use of allografts over autografts was confirmed in a 2005 survey of British otolaryngologists.[57]

More recently, titanium prostheses have been gaining popularity.[58-62] The titanium prosthesis combines low weight (<4 mg) and high rigidity. The prosthesis is the closest in mass to the ossicles it tries to replace. These characteristics lead to reduction in acoustic impedance and sound damping, particularly for higher frequencies.[63] All of the current designs of titanium prostheses have an open head plate (toward the tympanic membrane) that allows the surgeon better visualization of the medial end of the prosthesis during placement. The medial end of the titanium PORP fits better over the stapes head because of its clawlike design, which achieves a secure connection. In addition, titanium prostheses are not top heavy similar to hydroxyapatite prostheses, and tend to stay upright. Titanium was also found to be more user-friendly by most surgeons compared with hydroxyapatite and other allograft materials.[64,65] These properties may ease the learning curve for titanium ossiculoplasty, allowing less experienced ear surgeons to achieve good results. Cartilage is used to interpose between the prosthesis and the tympanic membrane to prevent extrusion. A cartilage interface that is equal to the diameter of the prosthesis head has been shown to have little effect on acoustic transmission in cadaver studies.[66]

The numerous types of prostheses available attest to the fact that no one implant is perfect. A review of alloplastic materials in ossiculoplasty showed that results are still comparable for the alloplastic materials that are currently in use, with different series reporting different success and extrusion rates using the same prosthesis.[67] In 2001, House and Teufert[68] reported on the use of Plasti-Pore in 1040 cases. The air-bone gap was less than 20 dB in 69% of PORP cases and in 61% of TORP cases. In 1990, Grote[69] reported on the long-term results achieved with hydroxyapatite prostheses with an air-bone gap less than 20 dB in 84% of PORP cases and in 64% of TORP cases. Dalchow and colleagues,[70] in 2001, reported on more than 1300 cases that involved the use of titanium prostheses, with 76% achieving an air-bone gap of less than 20 dB; PORPs and TORPs were combined. Since then, other groups have reported on titanium ossiculoplasties, with achievement of an air-bone gap less than 20 dB in 50% to 85% of PORP cases and 40% to 50% of TORP cases.[60,71-75] In a more recent comparative study of titanium versus hydroxyapatite PORP and TORP results, no statistically significant differences were found between the two groups at 2 months.[75] Based on an analysis of studies reporting long-term follow-up of ossiculoplasties, Yung[76] estimated that the 5-year success rate for PORPs and TORPs is two thirds for PORPs and one third for TORPs.[76]

Factors That Affect Surgical Decisions

The goal of ossiculoplasty is to re-establish efficiently the transfer of induced vibratory energy from the tympanic membrane to the undersurface of the stapes footplate, maximizing the postoperative gain in hearing. Many factors have a bearing on the potential success of such operations. The technical skills of the surgeon have a major effect. Independent of surgical judgment and experience, the psychomotor skills necessary to perform this type of surgery and obtain optimal results are substantial. In addition, sufficient general otologic experience is necessary so that the surgeon may obtain adequate exposure for the operation in the face of difficulties such as a small external auditory canal, the limited ability of the patient to turn the head, or a large body habitus, especially in the neck and shoulder areas. Inadequate or mar-

ginal exposure greatly increases the degree of difficulty of the procedure. The presence of concomitant tympanic membrane perforation also elevates the degree of difficulty because a separate graft is required for the perforation.

A major decision to be made during surgery for chronic otitis media (especially for cholesteatoma) is whether to perform ossiculoplasty at the time of the cholesteatoma excision or to perform ossiculoplasty as a planned procedure some months later.[71] Important factors relevant to this decision include the following: (1) status of the middle ear mucosa, (2) amount of bleeding, (3) advisability of reoperation for possible cholesteatoma recurrence, and (4) eustachian tube function in the involved ear and the contralateral ear. Middle ear mucosa that is thickened, infected, traumatized, or partially missing is likely to heal with fibrous tissue formation that may displace a perfectly placed prosthesis. Middle ear bleeding not only obscures visualization and makes the surgery more difficult, but it also increases the risk of unfavorable fibrosis.

Some surgeons perform ossiculoplasty in the same setting with every cholesteatoma operation, even when a second-look procedure for recurrent or residual disease is planned. When economic considerations prevent the second look, this approach seems appropriate, although hearing restoration is always a goal that is secondary to complete cholesteatoma excision. Other surgeons prefer to defer ossiculoplasty and, at the first operation, to try to decrease postoperative middle ear fibrous tissue formation by placing a sheet of Silastic, Gelfilm, or Epidisc between the promontory and the tympanic membrane (graft). After healing is complete, these surgeons assert that the level of the tympanic membrane vis-à-vis the promontory is established and will be stable after the second-stage ossiculoplasty; this makes it easier to judge the appropriate length for a prosthesis that connects the tympanic membrane or malleus to the stapes capitulum or footplate.

The major factor that affects the choice of the prosthesis is the status of the ossicles. When the undersurface of the manubrium of the malleus anchors the prosthesis laterally, consideration must be given to the anteroposterior distance from the manubrium to the footplate compared with the mediolateral distance between them, which is really the depth of the middle ear. A favorable relationship should allow the interposed prosthesis to lie in a more vertical position (Fig. 141-5A). With a wide anteroposterior distance and a narrow middle ear, an unfavorable vector for energy transfer would exist, and the hearing result would be poor (Fig. 141-5B). In that situation, it is preferable to anchor the lateral portion of the prosthesis to the posterosuperior quadrant of the tympanic membrane, which is more directly lateral to the stapes capitulum or footplate (Fig. 141-5C).

Goldenberg and Driver[77] reported a higher incidence of closure of the air-bone gap (<20 dB) when a hydroxyapatite prosthesis interfaces with the malleus versus the tympanic membrane (67% versus 42%), a finding consistent with the idea that prosthetic reconstruction to the malleus may preserve the benefits of the caternary lever.[78] Another malleus consideration exists when the umbo is chronically retracted and lies near the promontory; this restricts malleus motion and tympanic membrane motion. In these cases, the platform of a TORP or PORP lies at an unfavorable angle to the tympanic membrane surface and cannot be at the desired right angle to the shaft of the prosthesis. Severing the tensor tympani tendon allows the tympanic membrane to lateralize to a more favorable angle and level, and increases the prosthesis efficiency.

Surgical Techniques (see Key Indicator Video on website)

Ossicular Fixation

Tos[79] has written extensively about the surgical treatment of ossicular fixation that results from tympanosclerosis. Whenever possible, an intact ossicular chain is preserved. When the disease is restricted to the attic, a wide atticotomy is performed, with preservation of a bony bridge lateral to the ossicles. Tympanosclerosis is progressively removed from the lateral, anterior, superior, and medial surfaces of the malleus and incus. When the tympanosclerosis is restricted to the stapes, radical removal of the plaques without opening into the vestibule or removing the footplate is preferred. The dissection is performed without separating the incudostapedial joint, and from a posterior to an anterior direction, using slow motions and using the stapedius tendon for stability. When attic and stapedial tympanosclerosis are present, the attic is addressed first to see if a mobile intact malleus and incus can be achieved. If stapedectomy is unavoidable (or desirable), it is delayed until the end of the procedure.

If the entire stapes is to be removed, it is extracted very slowly, only after a control opening has been made on the most accessible part of the footplate. Stapedotomy also has been reported in cases of tympanosclerotic fixation of the stapes. An air-bone gap of less than 20 dB was obtained in 70% of cases in one series.[80] Stapedectomy should not be performed in conjunction with tympanic membrane repair in a potentially infected ear because of the risk of labyrinthitis and profound hearing loss.

Acquired bony fixation of the malleus can be surgically managed in two ways: (1) by the direct removal of the bony fixation, with the restitution of an intact ossicular chain, or (2) by the removal of the incus and the malleus head, with the interposition of an allograft between the manubrium and the stapes. Tos[79] strongly advocates the former approach and performs an atticotomy that is large enough to provide adequate exposure. After the atticotomy, a small diamond bur is used to reduce the fixation point to a thin shell, which is vaporized with a laser to avoid transmitting mechanical energy to a mobile stapes, causing sensorineural hearing loss. The attic bone adjacent to the fixation point is removed further with a drill, and a Silastic sheet is interposed between the malleus head and the adjacent attic wall.[81]

The alternative procedure also requires an atticotomy to remove the incus and the malleus head because the malleus fixation does not allow the incus to be rotated out of its position in the usual manner. The long process of the incus often needs to be removed (after careful separation of the incudostapedial joint) before the incus can be rotated and extracted; the malleus head is then removed. The malleus to stapes

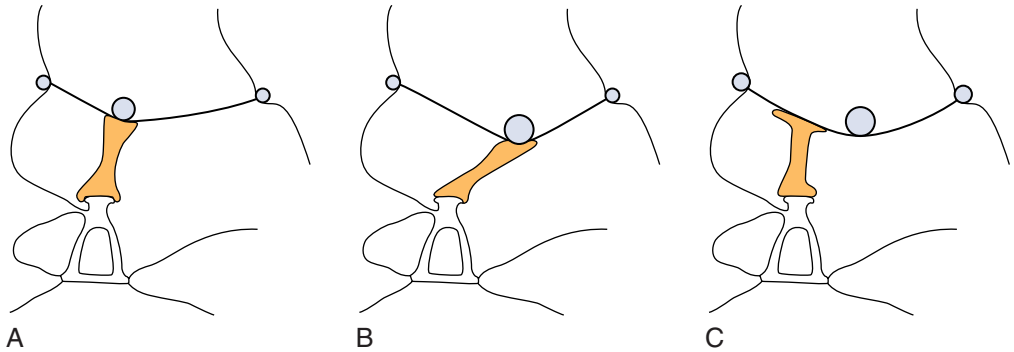

Figure 141-5. A, Favorable relationship between the malleus and the stapes, allowing a more vertical position of the interposed prosthesis. **B,** Unfavorable relationship, which results in a more horizontal position of the prosthesis. **C,** Prosthesis connecting the stapes head to the posterior superior quadrant of the tympanic membrane in an ear with an unfavorable malleus-stapes relationship.

interposition prosthesis is less stable because the malleus is hypermobile after removal of its head. Both techniques are technically difficult.

Ossicular Discontinuity

When only the tip of the incus is missing, a specially designed allograft prosthesis that fits on top of the capitulum of the stapes and has a concave arm that rests beneath and supports the distal incus works well.[82] A similar autograft cartilage prosthesis can be sculpted at surgery. Insertion requires simultaneous lifting of the incus and placement of the prosthesis on the stapes. A prosthesis that attaches to the incus, and that has a cup that fits on the stapes capitulum is also available and is reported to give good results.[83] If only the lenticular process is eroded, and the incus long process is intact, a simple cartilage block interposition can be used. Bone cement may also be used to reconstruct the missing part of the incus and the incudostapedial joint with good hearing results.[83-86]

When the long process of the incus is absent, the two factors of greatest importance are the condition of the stapes superstructure and the condition of the malleus. When the stapes superstructure is present and connected to the footplate, most surgeons prefer to attach the prosthesis to the head of the stapes as a PORP because the medial anchor of the prosthesis is stable and cannot slip. If the superstructure is absent, the stapes footplate is the medial point of fixation, and a TORP is used. Securing this medial anchor point has been more difficult, and, generally, results of TORPs are poorer than those of PORPs.

Using the medial surface of the malleus handle as the lateral anchoring point for the prosthesis is more stable than the tympanic membrane alone, and extrusion is less likely. To use the malleus successfully, however, the surgeon should be able to answer affirmatively the following questions:

1. Does the malleus have normal mobility?

2. Is there adequate space between the umbo and the promontory?

3. Is the vector between the malleus and stapes capitulum or footplate favorable?

If the answer to all three questions is yes, the malleus can be used. If not, the posterosuperior portion of the tympanic membrane is a better choice.

Causes of Failure

An occasional cause of ossiculoplasty failure is incomplete or erroneous diagnosis. Routine palpation of all three ossicles in middle ear surgery trains the surgeon to recognize the normal range of motion for each ossicle. When assessing stapes mobility, it is important to observe the footplate under high magnification and to identify one bright spot of reflected light, which is called the light reflex. The slightest motion of the footplate would cause that light reflex to move. Motion of the light reflex in response to palpation is the most accurate means of intraoperatively identifying that the footplate is mobile. Conversely, a lack of motion of the light reflex to palpation indicates that the footplate is fixed, the superstructure is fractured, or there is ossicular discontinuity between the point of palpation and the footplate. Possible misdiagnoses include (1) missing a fixed malleus in the presence of otosclerosis; (2) failing to identify a fractured stapes superstructure; and (3) failing to identify a bony incudostapedial disarticulation when the soft tissue connection is preserved.

A much more common cause of ossiculoplasty failure is extrusion of the prosthesis; this is most common with allograft prostheses that directly contact the tympanic membrane (as opposed to the undersurface of the manubrium). Although the incidence is much lower if a thin piece of cartilage is placed between the tympanic membrane and the platform of the prosthesis, extrusion still occurs.

Finally, ossiculoplasty failure occurs most commonly in ears that continue to exhibit eustachian tube malfunction or that develop the problem after surgery. As mentioned earlier, aeration of the middle ear is an important factor in sound transmission. If the middle ear is not aerated, even a perfectly placed prosthesis would still result in a significant conductive hearing loss. Although it is impossible to predict this outcome, the status of the function of the eustachian tube in the opposite ear is a reasonable guide, at least in children.

CHAPTER ONE HUNDRED AND FORTY-TWO

Mastoidectomy

Paul R. Lambert

Key Points

- Although all major components of the temporal bone are present in infants, the mastoid tip is yet to develop. The stylomastoid foramen is located more superficially, making the facial nerve vulnerable to surgical trauma.
- The temporal line approximates the level of the middle cranial fossa dural plate. The position of the tegmen and the degree of mastoid pneumatization can vary, however.
- An important landmark when performing mastoid surgery is the antrum. Key principles that assist in locating the antrum include saucerization, identification of the tegmen plate, and thinning of the posterior canal wall.
- Failure to identify the superior limit of the mastoid dissection (tegmen plate) could result in looking for the antrum too inferiorly, injuring the horizontal semicircular canal or the genu of the facial nerve, or both.
- A mastoid cavity may appear small because air cells have not been adequately removed from the back of the bony external auditory canal.
- The most important landmarks for identifying the mastoid segment of the facial nerve are the horizontal semicircular canal, the short process of the incus, and the posterior bony external auditory canal.
- An intact canal wall mastoidectomy obviates long-term postoperative concerns of a mastoid cavity, such as infection and the requirement for periodic cleaning.
- Identification of the facial nerve is key to a canal wall down procedure (i.e., appropriate lowering of the posterior canal wall) and the intact canal wall approach (i.e., opening the facial recess).
- The incidence of residual or recurrent cholesteatoma is higher in intact canal wall versus canal wall down mastoid procedures. The incidence is approximately 20% in adults and almost twice that in children.
- Dehiscence of the facial nerve in cholesteatoma cases is approximately 20%, with the most common area being in the region of the oval window.

This chapter focuses on mastoid surgery as it relates to chronic ear disease. Although a mastoidectomy is required in various other surgical procedures (e.g., cochlear implantation; access to the cerebellopontine angle, skull base, and petrous apex; labyrinthectomy; endolymphatic sac decompression; repair of facial nerve disorders; cerebrospinal fluid leaks), the principles to be reviewed in the context of chronic otitis media and cholesteatoma have broad application.

History

The first scholarly treatise on mastoid surgery for suppurative disease was by Schwartze in 1873.[1,2] The procedure he described was a cortical mastoidectomy with limited exenteration of mastoid air cells. For acute and coalescent mastoiditis, which were prevalent in the preantibiotic era, this procedure proved remarkably efficacious. As one might expect, however, the simple mastoidectomy rarely cured chronic otitis media or cholesteatoma. During the next 20 years, it became evident that creating an open cavity was necessary for these diseases, and in 1890, Zaufal described removing the superior and posterior canal wall, tympanic membrane, and lateral ossicular chain, a procedure now known as the radical mastoidectomy.[3] This procedure was modified by Bondy, who recognized that disease limited to the pars flaccida could simply be exteriorized, leaving the uninvolved middle ear alone. His description of the "modified radical mastoidectomy" or "Bondy procedure" in 1910 represented one of the first reports addressing hearing function.[1]

Interest in hearing preservation and restoration gained further attention after Lempert introduced the fenestration operation in 1938, and Zollner and Wullstein described tympanoplasty techniques in the early 1950s.[4-6] During the next decade, Jansen, Sheehy, and others extended these principles of restoring function and maintaining normal anatomy with the introduction of the intact canal wall mastoidectomy with facial recess approach.[7,8]

Anatomy

The temporal bone consists of four parts: squamous, tympanic, mastoid, and petrous (Figs. 142-1 and 142-2). The smallest part is the tympanic portion, which forms the external auditory canal. This chapter focuses primarily on the mastoid portion, which articulates with the parietal and occipital bones and houses the mastoid air cell system, which is in continuity with the air cells of the petrous pyramid. Transmastoid procedures provide access to the facial nerve, internal carotid artery, jugular bulb, labyrinth, internal auditory canal, and petrous apex.

Important surface landmarks on the mastoid include the temporal line, which extends posteriorly from the zygomatic root and is the insertion site for the temporalis muscle. There is considerable variability in the prominence of this structure among individuals. The suprameatal spine or spine of Henle is a small bony protuberance extending superficially from the posterior and superior bony external auditory canal. It is located just inferior to the temporal line, and shows

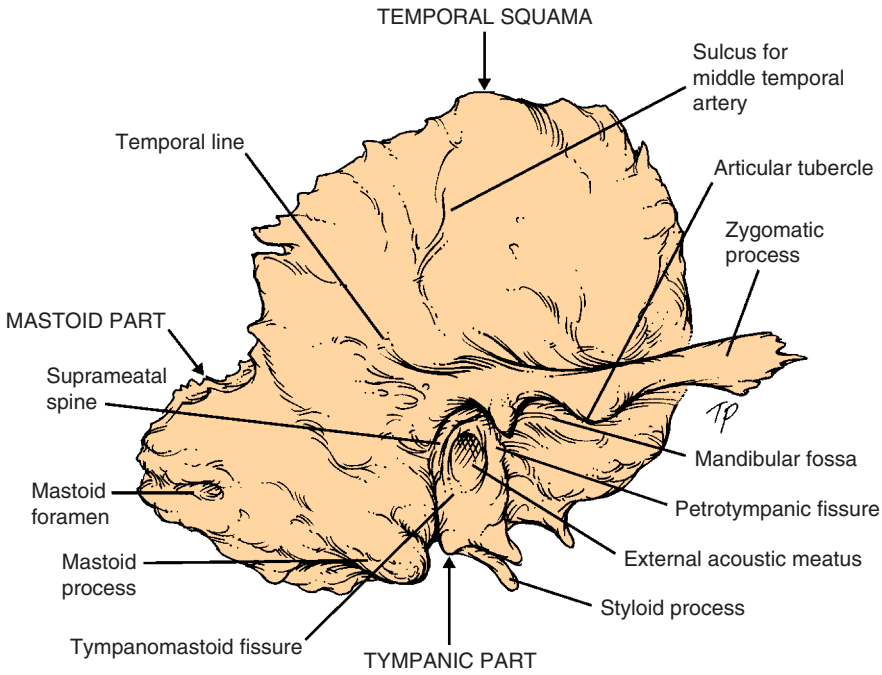

Figure 142-1. Right temporal bone. Lateral view. *(From Donaldson JA, Duckert LG, Lambert PR, Rubel EW, eds.* Surgical Anatomy of the Temporal Bone. *4th ed. New York: Raven Press; 1992.)*

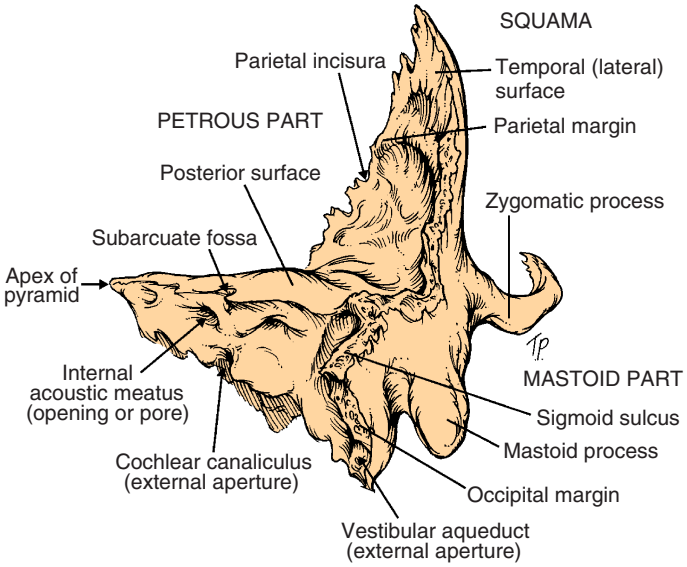

Figure 142-2. Left temporal bone. Posterolateral view. *(From Donaldson JA, Duckert LG, Lambert PR, Rubel EW, eds.* Surgical Anatomy of the Temporal Bone. *4th ed. New York: Raven Press; 1992.)*

variability in size among individuals. Just posterior to this spine is a cribriform area, which approximates the location of the underlying mastoid antrum.

All major components of the temporal bone are present in infants, but there is one notable difference that has surgical implications. In infants, the mastoid tip has yet to develop, and the stylomastoid foramen is located more superficially, making the facial nerve vulnerable to surgical trauma.

Nomenclature

The otologic surgeon has various mastoid procedures from which to choose, depending on extent of disease. In addition, variations on these standard approaches are often discussed in the literature. The nomenclature for mastoid surgery can seem confusing at first. Concomitant surgery involving the middle ear requires additional terminology, such as *tympanoplasty* or *ossiculoplasty*. Box 142-1 lists the standard mastoid procedures for addressing chronic ear disease.

Box 142-1

Mastoid Procedures

Simple mastoidectomy
Canal wall up mastoidectomy
Canal wall down mastoidectomy
Radical mastoidectomy
Modified radical mastoidectomy
Mastoid obliteration

Simple Mastoidectomy

Simple mastoidectomy involves removing the mastoid cortex and varying amounts of the air cell system, depending on the disease process. Only a limited air cell exenteration may be needed to drain a coalescent mastoiditis with subperiosteal abscess, whereas a more extensive dissection to expose the antrum would be necessary to inspect for cholesteatoma.

Canal Wall Up Mastoidectomy

Canal wall up mastoidectomy involves a more complete removal of the air cell system than simple mastoidectomy. Because this procedure and simple mastoidectomy maintain the superior and posterior canal walls intact, however, there is some potential overlap. Usually, canal wall up mastoidectomy includes a facial recess approach, and this addition uniquely qualifies the procedure. More recent variations on canal wall up mastoidectomy include removing a portion of the canal wall, then reconstructing the defect with bone, cartilage, or an alloplastic material, to maintain the normal anatomic barrier between the external ear canal and mastoid cavity.

Canal Wall Down Mastoidectomy

The canal wall down mastoidectomy involves a thorough removal of the mastoid air cells, aggressive saucerization of the cortical edges of the

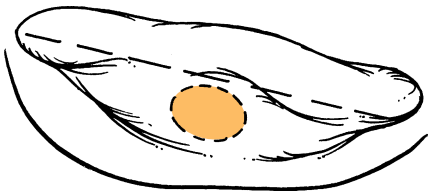

Figure 142-3. Postauricular incision is placed about 1 cm behind the postauricular crease, facilitating skin closure. *(From Sheehy JL. Surgery of chronic otitis media. In: English GE, ed.* Otolaryngology. *Philadelphia: Lippincott; 1986:1.)*

mastoid, a complete removal of the superior and posterior canal walls, and a meatoplasty.

Radical Mastoidectomy

Radical mastoidectomy is a canal wall down procedure with exteriorization of the middle ear. No attempt at restoring middle ear function is made. The eustachian tube is occluded, and the malleus and incus (and possibly the stapes superstructure) are removed. The tympanic membrane remnant is excised, and no graft is placed, leaving the middle ear open. The expectation is for squamous epithelium to grow over the middle ear and mastoid cavity. This procedure is rarely performed today, but may be indicated in situations in which cholesteatoma cannot be completely excised (e.g., cochlear fistula, disease tracking into the petrous apex).

Modified Radical Mastoidectomy

Most of the confusion over terminology centers on modified radical mastoidectomy. Frequently, the term *modified radical mastoidectomy* is used interchangeably with canal wall down mastoidectomy. Classically, modified radical mastoidectomy refers to the Bondy procedure, in which disease limited to the epitympanum is simply exteriorized by removing portions of the adjacent superior or posterior canal wall. The uninvolved middle ear is not entered, and the cholesteatoma matrix on the lateral surface of the ossicular heads is maintained in place as a lining for the created cavity. Small cholesteatomas are frequently amenable to the Bondy approach; I prefer to use the term *modified radical mastoidectomy* in that context.

Mastoid Obliteration

The indications for and extent of obliterating mastoid air cells varies considerably from surgeon to surgeon. Various materials are used, including autogenous bone and cartilage, free or vascularized soft tissue, and bioactive or biocompatible alloplastic materials. Mastoid obliteration is typically used when the canal wall has been removed to decrease the size of the mastoid cavity and make it as care-free as possible. In rare cases, the eustachian tube and external ear canal are closed, completely isolating the mastoid from the exterior.

Operative Procedure (see Key Indicator Video on website)

The surgical site is prepared by shaving 1 to 2 cm of hair around the ear and injecting 5 to 10 mL of local anesthetic with a vasoconstrictor (e.g., 1% lidocaine with 1:100,000 epinephrine) postauricularly and within the external ear canal. To facilitate closure, the C-shaped incision is placed about 1 cm behind the postauricular crease, rather than within it (Fig. 142-3). If extensive saucerization of the mastoid cavity is planned (e.g., translabyrinthine or retrolabyrinthine approach to the cerebellopontine angle, skull base tumor resection), the incision is placed more posteriorly.

Superiorly, the incision is carried down to the temporalis fascia. Inserting a small Weitlaner retractor and lifting it laterally facilitates this dissection. The subcutaneous tissues are elevated off the fascia and easily incised. Inferiorly, the incision is extended to the anterior lateral surface of the mastoid tip. An incision placed more posteriorly on the mastoid involves the insertion of the sternocleidomastoid muscle and results in more bleeding and postoperative discomfort. Making two periosteal incisions—one along the temporal line and the second perpendicular to this and extending to the mastoid tip—exposes the mastoid bone itself. The periosteum is elevated and retracted forward with the auricle.

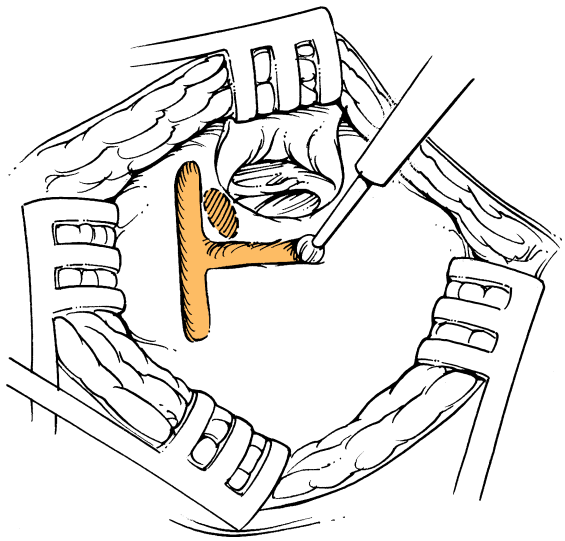

Figure 142-4. Initial bur cuts are along the temporal line and tangential to the bony canal. *(From Sheehy JL. Mastoidectomy: the intact canal wall procedure. In: Brackmann DE, Shelton C, Arriaga MA, eds.* Otologic Surgery. *Philadelphia: Saunders; 1994.)*

With the mastoid cortex fully exposed, the first bur cut is made along the temporal line, which approximates the level of the middle cranial fossa dural plate. It is important to recognize, however, the variability of the position of the tegmen, depending on the degree of mastoid pneumatization. The second bur cut is made perpendicular to this and tangential to the external bony canal; it should be carried inferiorly to the mastoid tip (Fig. 142-4).

Although various drill systems are available, several common principles relate to bur selection and fluid irrigation. When possible, larger rather than smaller burs are preferable for bone dissection. This facilitates saucerization and exposure, and it avoids creating small openings in the bone that can more easily damage underlying structures. It is important, however, to choose a bur that is not so large that it obstructs the field of dissection. It is also critical to note the backside of the bur while drilling, to prevent injuring structures opposite the point of dissection.

A variety of burs exist, ranging from burs that aggressively remove bone to those that are used more for bone polishing. A bur with a cutting or fluted surface is selected for removing cortical bone, whereas a fine diamond grain surface is required when removing the last layer of bone over the facial nerve or sigmoid sinus. When drilling over an irregular surface, a fluted bur has a tendency to "skip" in the direction of the bur rotation.

Appropriate irrigation is necessary to clear bone dust from the field of dissection, to prevent excessive heat transfer to underlying structures (especially the facial nerve), and to maintain a clean cutting surface on the bur. Whether a self-irrigating drill or a suction irrigation system is being used, appropriate adjustment of the level of irrigation facilitates accurate and safe bony dissection.

A key landmark in performing mastoid surgery is the antrum with the dome of the horizontal semicircular canal (HSCC) along its floor. The ease of locating the antrum depends largely on the degree of mastoid pneumatization. Three key principles assist this part of the dissection: saucerization, identification of the tegmen plate, and thinning the posterior canal wall. The deepest dissection is at the point where the initial cortical bone cuts intersect, but widely saucerizing toward the tegmen and especially posteriorly (from the sinodural angle to the mastoid tip) as the antrum is approached is essential. Posteriorly, one must consider the sigmoid sinus, which could be far forward in a poorly pneumatized mastoid. Appropriate saucerization helps identify

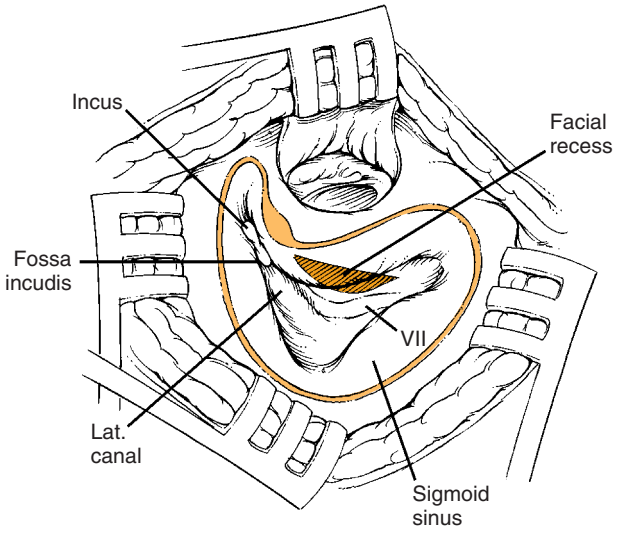

Figure 142-5. The facial recess is shown as the triangle. *(From Sheehy JL. Mastoidectomy: the intact canal wall procedure. In: Brackmann DE, Shelton C, Arriaga MA, eds.* Otologic Surgery. *Philadelphia: Saunders; 1994.)*

its lateral surface and prevent injury. The importance of identifying the tegmen plate cannot be overemphasized. All mastoid air cells should be removed superiorly, effectively skeletonizing this structure. The tegmen is followed medially, anticipating that the plane of the tegmen will vary, usually bulging slightly into the cavity midway between the cortex and the floor of the antrum. Failure to identify the superior limit of the mastoid dissection could result in opening the antrum too inferiorly, injuring the HSCC or the genu of the facial nerve, or both.

All air cells should be removed from the back of the bony external auditory canal. A mastoid cavity may appear small simply because insufficient attention was directed toward this area of dissection. In addition, a thin posterior canal wall assists localization of the facial nerve, as described later.

As the dissection is carried medially and the antrum is approached, a bony septum (Körner's septum) may be encountered. This plate is a remnant of the petrous squamous septum, and simply separates more superficial air cells from deeper ones. Dissection should be carried into the zygomatic root, thinning bone over the tegmen plate and bony external auditory canal to gain appropriate access. This dissection requires progressively smaller burs. Care must be exercised to avoid touching the heads of the ossicles with the bur, which could injure the inner ear by a transfer of excessive vibration. As noted later, however, identifying the short process of the incus provides an important landmark for facial nerve dissection.

Facial Nerve

Identifying the facial nerve is fundamental to performing good mastoid surgery. Except for simple mastoidectomy, it is always safer to define the location of this structure than simply to avoid it. In intact canal wall mastoidectomy (or when a cochlear implant is placed), the space between the facial nerve and the chorda tympani nerve—the facial recess—provides access into the middle ear (Fig. 142-5). In canal wall down approaches, identifying the facial nerve allows the surgeon to lower the facial ridge appropriately, creating a more care-free cavity.

The most important landmarks for the facial nerve are the HSCC, the short process of the incus, and the posterior bony external auditory canal; the digastric ridge is also a landmark, although I use this landmark less commonly unless full exposure of the facial nerve to the stylomastoid foramen is required (e.g., skull base procedures). The genu and proximal portion of the mastoid segment of the facial nerve lie anterior and just medial to the dome of the HSCC. The mastoid segment of the facial nerve also lies medial to the plane of the short process of the incus at the base of the posterior canal wall.

Removing air cells from the posterior bony canal wall until it is only a few millimeters thick is essential. Separating the soft tissue of the membranous canal from the bone at the lateral edge of the bony canal wall helps gauge the thickness of the wall as the bony dissection proceeds. If the canal wall is not thinned appropriately, a wall of air cells continues to cover the facial nerve, and the dissection is carried too far posteriorly, potentially exposing the posterior side of the facial nerve to injury. Ideally, the lateral surface of the facial nerve is first identified in the middle two thirds of its course, avoiding the areas just adjacent to the HSCC and the mastoid tip.

After locating the antrum, a diamond bur is used to open the aditus ad antrum, which leads into the epitympanic space. The short process of the incus is exposed. With this landmark visible, a larger cutting bur or coarse diamond bur removes bone over the area of the facial nerve, with continued thinning of the posterior bony canal wall as the dissection is carried medially. A broad plane of dissection is maintained from the canal wall back into the mastoid because the exact anteroposterior location of the nerve can vary slightly. This broad plane of dissection avoids creating a trough and helps ensure that the lateral surface of the nerve, rather than its side, is exposed. When the plane of the short process of the incus is reached, it is anticipated that the facial nerve will be 1 to 2 mm deeper, and the bur type is changed to a fine diamond.

This last level of dissection should be carried out with copious irrigation (essentially drilling beneath a layer of water) to facilitate discerning the fine capillary network on the epineurium that shows through a thin shell of bone. Bur strokes are made in a longitudinal direction, paralleling the course of the facial nerve. The facial nerve takes a slightly lateral course as it descends from the second genu to the stylomastoid foramen. Dehiscences of the mastoid portion of the fallopian canal, even in the presence of mastoid disease, are infrequent. This is in contradistinction to the tympanic segment of the facial nerve, where congenital and disease-mediated dehiscences are common.

Additional landmarks that may appear during the dissection include the chorda tympani nerve and the air cell systems of the facial recess and retrofacial area. Appropriately thinning the canal wall often exposes the chorda tympani nerve, which can be distinguished from the facial nerve by size and course of direction. If necessary, the chorda can be followed back to its takeoff from the facial nerve trunk for positive identification. In well-pneumatized mastoids, a large air cell system tracking behind and deep to the facial nerve is present. The facial nerve courses just anterior to these retrofacial air cells. Likewise, the identification of the facial recess cells indicates that the facial nerve is coursing just medial to them.

Opening the Facial Recess

The facial recess is the space bounded laterally by the chorda tympani nerve, medially by the facial nerve, and superiorly by the fossa incudis (see Fig. 142-5). This recess varies in size, depending on where the chorda tympani nerve branches from the facial nerve, and in pneumatization. Opening the facial recess provides access to the middle ear from the mastoid (Fig. 142-6). The promontory, round window niche, stapes, long process of the incus, cochleariform process, medial side of the tympanic membrane and malleus handle, and eustachian tube all are well seen.

The facial recess can be extended superiorly and inferiorly, providing a large "posterior tympanotomy." Sacrificing the chorda tympani nerve permits additional dissection inferiorly with good exposure of the hypotympanum. In such cases, the lateral limit of the dissection is the tympanic membrane anulus. Frequently, in chronic ear surgery, the long process of the incus has been eroded, and that ossicle is removed. In such cases, the fossa incudis is taken down, connecting the facial recess with the aditus ad antrum, providing wide exposure over the HSCC and the genu of the facial nerve into the epitympanum (Fig. 142-7).

Opening the Epitympanum

In intact canal wall mastoid surgery, it is frequently necessary to expose the epitympanum. Cholesteatoma can track medially to the heads of the ossicles and extend into the anterior epitympanic space, also termed the *supratubal recess*. Opening the epitympanum is much

easier if there is discontinuity of the ossicular chain (e.g., eroded long process of the incus). In such cases, the incus remnant and the head of the malleus are removed, providing good access into the anterior aspect of the epitympanum. The position of the tegmen varies, and, depending on the degree of pneumatization, the space between the dural plate and superior canal wall may be constricted. Progressively smaller burs, usually with a diamond surface, are required as the epitympanic dissection proceeds anteriorly. A thin plate of bone is maintained over the dura, and the superior canal wall is thinned in a manner similar to the thinning of the posterior canal wall.

It is important to appreciate the anatomic relationships of the facial nerve within the epitympanic space. As the nerve is traced anteriorly from the mastoid genu to the geniculate ganglion, it takes a slightly medial course. It passes superior to the oval window and cochleariform process (Fig. 142-8). The facial nerve in the floor of the anterior epitympanic space can be dehiscent, especially if extensive cholesteatoma involves this region (Fig. 142-9).

Canal Wall Down Mastoidectomy

Many of the disadvantages of a canal wall down procedure can be minimized with proper creation of the mastoid cavity. Crucial components of the procedure include the following:

- Aggressively saucerizing the cavity
- Eliminating irregularities within the cavity (e.g., deep recess and bony overhangs)
- Removing the posterior bony canal wall to the level of the facial nerve
- Creating a large meatus

Saucerization decreases the depth and the size of the mastoid cavity. The cortical edges of the cavity are taken down to the approximate level of the tegmen superiorly, sigmoid sinus posteriorly, and digastric ridge inferiorly (Fig. 142-10). The facial nerve is positively identified by removing the posterior bony canal until only a thin shell of bone remains over the nerve. This dissection is continued toward the stylomastoid foramen until there is no bony spur (inferior or posterior buttress) between the floor of the external bony canal and the mastoid cavity. In a similar manner, the anterior extent of the superior canal wall (anterior buttress) is completely removed, creating a smooth, gently curving transition from the anterior epitympanum to the anterior canal wall.

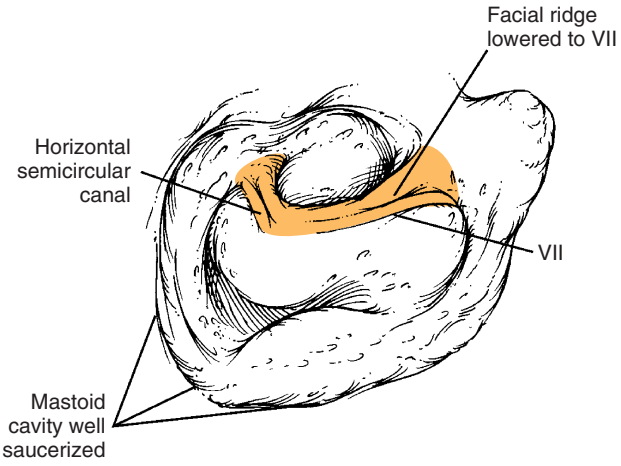

Figure 142-10. Canal wall down mastoidectomy. *(From Brackmann DE, Shelton C, Arriaga MA, eds.* Otologic Surgery. *Philadelphia: Saunders; 1994.)*

Ideally, the contours of the cavity itself should be smooth, without bony recesses or overhangs. Small amounts of bone plate collected during saucerization of the cortical edges can be used to fill irregularities within the cavity. Obliterating these areas, however, should not be performed if one is not confident that all cholesteatoma remnants have been thoroughly removed. Last, a large meatus ensures adequate ventilation of the mastoid cavity and appropriate access for postoperative cleaning. Conchal cartilage must be removed to create a properly sized meatal opening.

Intact Canal Wall versus Canal Wall Down Procedures

The intact canal wall and canal wall down mastoidectomy procedures each have inherent advantages and limitations that involve ease of disease removal, incidence of recurrent or residual disease, and extent of postoperative care.[9] For cholesteatomas involving the middle ear, epitympanum, and mastoid, the superior and posterior canal walls partially obscure the disease. An intact canal wall approach necessitates more surgical manipulations (e.g., facial recess approach and alternately working on the canal and epitympanic sides of the canal wall) and usually more operative time. As described later, cholesteatoma that has extended into the sinus tympani and adjacent recesses may be difficult to remove, regardless of whether the canal wall is left intact or removed.

Because disease exposure is more difficult when the canal wall is left intact, inadvertently leaving a small focus of squamous epithelium behind is possible. Maintenance of the canal wall also provides potential spaces into which retraction pockets can form. The resulting increased incidence of residual or recurrent cholesteatoma is not trivial, especially in children. Studies have shown the incidence to be 20% in adults and 35% to 45% in children.[3,10-13] As a result, the decision to maintain the canal wall necessitates more surgical procedures to ensure disease eradication than would a canal wall down approach.

Several possible reasons can be considered for the higher incidence of residual and recurrent disease in children compared with adults. First, children frequently have well-pneumatized temporal bones with deep cell tracks, which can complicate complete disease removal. In contrast, the mastoids of adults are typically sclerotic. Second, the poor eustachian tube function in children predisposes to retraction pockets and recurrent disease. It also predisposes children to otitis media and secondary infection of the cholesteatoma, causing it to behave in a more aggressive fashion. Also to be considered is the fact that the growth potential of tissue is greater in children than in adults because of the normal elaboration of various growth factors. Studies have shown a greater tendency of squamous cell proliferation in pediatric cholesteatomas compared with adult cholesteatomas. There may be a true biologic difference in the disease process.[14]

The principal advantages of the intact canal wall technique are more rapid healing postoperatively and, more importantly, the obviation of many long-term postoperative concerns. Epithelialization of the mastoid cavity in canal wall down cases may be a slow process (months), and certain areas may require various topical therapies to promote healing. There is also the potential need for long-term care of the cavity because the self-cleaning character of the normal external auditory canal has been altered. The irregular contours of the new canal/mastoid disrupt the normal migration of keratin debris, which can accumulate and foster bacterial or fungal growth. Proper creation of the mastoid cavity, as previously described, can significantly ameliorate this potential problem.

Patients requiring mastoid surgery for cholesteatoma may need amplification in the future because of a residual conductive hearing loss. If so, patients with a canal wall down cavity are at slightly more risk for infection because decreased ventilation of the canal and mastoid from the hearing aid compounds the keratin accumulation problem. In contrast, healing of the intact canal wall down mastoidectomy is usually rapid, periodic ear cleanings are unnecessary, and the incidence of external ear infections is not increased. There are no limitations of water activities, which is a particular issue for pediatric patients. If needed, an in the ear canal–type hearing aid is well tolerated.

The advantages of the canal wall down procedure usually relate to the improved access into the mesotympanum and epitympanum at the time of surgery. Cholesteatoma removal is made easier, resulting in a significantly decreased incidence of residual disease.[6] In addition, it is much easier to detect any residual disease postoperatively in these cases because the only area inaccessible to direct visualization is the mesotympanum covered by an intact tympanic membrane. Although the epitympanum and mastoid cavity are lined by squamous epithelium, the close approximation of this tissue layer to the underlying bone enables early detection of any cholesteatoma growth in these areas. An exception is cases in which tissue flaps, bone plate, or other obliterating materials have been used in the mastoid cavity. The ear is not unequivocally safe from complications of chronic otitis media simply because a canal wall down procedure has been performed. I have encountered abscesses in the petrous apex and in the epidural and intradural spaces in patients with a canal wall down mastoidectomy.

Intact Canal Wall versus Canal Wall Down Indications

Intact canal wall and canal wall down mastoid surgery for cholesteatoma, when properly performed, can manage this disease process effectively. Despite the fact that the literature is replete with reports advocating one approach as superior to the other, a definitive prospective, randomized clinical trial to address this controversy has not been performed, and may never be. Most surgeons with a large chronic ear practice perform both procedures. Typically, surgeons have a bias for one approach and specific indications for choosing the other.

I prefer the intact canal wall approach primarily because normal anatomy is preserved, and the potential for long-term care issues is diminished. The canal wall down technique may be preferable, however, in certain preoperative settings, or if specific intraoperative findings are encountered. Preoperative concerns that would favor a canal wall down procedure include a patient with an only-hearing ear, a patient who is a poor anesthetic risk, or a patient in whom follow-up is problematic. In these circumstances, eradicating the disease and preserving or restoring auditory function in a single operation is desirable. Because the canal wall down approach has a lower incidence of recurrent and residual disease, it is preferred.

In most cases, the decision to remove the canal wall is made intraoperatively on the basis of mastoid anatomy and specific disease findings. A low-lying middle cranial fossa dura and an anteriorly positioned sigmoid sinus create a small mastoid cavity and limit access into the epitympanum. Removing the canal wall under such circumstances facilitates disease removal, and if proper attention is given to creating the mastoid cavity, minimal long-term care is needed.

A fistula of the HSCC may also necessitate a canal wall down approach. Depending on the extent of bone erosion over the semicir-

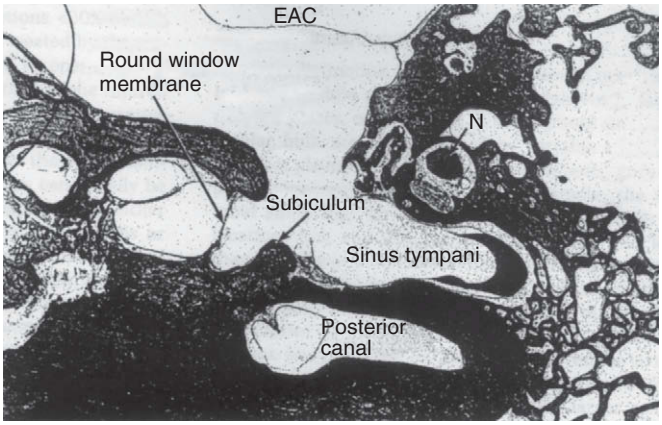

Figure 142-11. Histologic section showing a deep sinus tympani. EAC, external auditory canal; N, nerve. *(From Schuknecht HF. Pathology of the Ear. 2nd ed. Philadelphia: Lea & Febiger; 1993.)*

cular canal, it may be prudent to maintain the cholesteatoma matrix over the fistula. In this circumstance, the canal wall must be removed, and the cholesteatoma over the labyrinth simply becomes part of the epithelial coverage of the mastoid cavity.

In many cases, the most difficult aspect of cholesteatoma surgery, whether the canal wall is left intact or taken down, is removal of disease from the posterior mesotympanum.[8] Squamous epithelium that deeply infiltrates the posterior recesses, especially the sinus tympani, presents a special challenge (Fig. 142-11). The size and depth of extension of the sinus tympani varies. In some cases, the sinus is just a shallow indentation medial to the bone overlying the fallopian canal. Conversely, the sinus tympani may be large, extending deep and posterior to the canal wall and mastoid segment of the facial nerve. In such cases, performing a canal wall down mastoidectomy affords only modest benefit because the overlying facial canal continues to limit access. Extensive posterior mesotympanic disease is not an indication for a canal wall down approach. Techniques to improve exposure include drilling away the posterior anulus and skeletonizing the anterior aspect of the mastoid segment of the facial nerve. With deep posterior recesses, blunt instrumentation is still required to remove cholesteatoma matrix. Complete removal is ensured only if the retraction pocket remains intact without any tears visible. Rigid telescopes are advised for inspecting the posterior recesses after removal of cholesteatoma is considered complete. A second-look procedure 6 to 12 months later is also recommended.

Complications

Potential complications in mastoid surgery include damage to the dura, facial nerve, labyrinth, and sigmoid sinus and jugular bulb.

Dura

Exposure of a small area of dura without significant surface abrasion is common in mastoid surgery and is rarely of consequence. A dural tear or significant abrasion with herniation of arachnoid tissue with or without a cerebrospinal fluid leak requires repair. Instituting a broad-spectrum antibiotic with cerebrospinal fluid penetration should also be considered. Dural defects are best repaired with a layered closure using soft tissue such as fascia or perichondrium combined with a more rigid support material such as bone or cartilage. If an actual dural tear has occurred, part of this packing is placed intradurally into the subarachnoid space. Firmly packing the mastoid (or epitympanum) with absorbable gelatin sponge (Gelfoam) (with or without fibrin glue) can be used to support the repair as needed.

Horizontal Semicircular Fistula

A fistula of the HSCC should always be considered when performing chronic ear surgery, regardless of the patient's preoperative history or computed tomography scan findings. In a study of 416 consecutive surgeries for cholesteatoma, HSCC fistula was noted in 6.5%.[15] The incidence of a fistula was more than twice as high in patients who had a facial nerve dehiscence. At surgery, a flattened HSCC dome suggests labyrinthine erosion. In such cases, the cholesteatoma sac is opened, the desquamated epithelium is removed, and the matrix is left intact over the canal. This area is palpated for any underlying bony defect as the matrix is slowly dissected away. In cases in which the canal has been "blue lined" (i.e., exposure of the endosteum, without penetration into the perilymphatic space), the overlying disease tissue can be safely removed.

If an actual erosion into the fluid space of the HSCC is encountered or suspected during palpation, the cholesteatoma matrix should be left in place. When all other disease is removed, several options are possible: remove all matrix, and cover the defect with soft tissue or bone wax; perform a canal wall down procedure, and allow the matrix to remain in place as part of the mastoid cavity; or perform an intact canal wall procedure and leave the matrix in place to be removed at a second stage when the ear is sterile. Experience and extent of erosion dictate the approach used. A broad-spectrum antibiotic and steroids should be considered if the canal has been entered.

An iatrogenic injury to the HSCC requires immediate closure, usually with bone wax. Although soft tissue can provide an adequate seal, its use is problematic if continued drilling and use of irrigation fluid are necessary. A short course of a broad-spectrum antibiotic and steroids can be considered. The risk is bacterial labyrinthitis with resulting vertigo and severe sensorineural hearing loss. If the iatrogenic injury is recognized and treated immediately, however, the sequelae can be minimized. Some degree of dizziness is expected, but this may be transient without loss of sensorineural function.[16]

Facial Nerve

Most otologic surgeons agree that the key to mastoid surgery is the facial nerve. Identification, rather than avoidance, of this structure is fundamental for the canal wall down procedure (i.e., appropriate lowering of the posterior canal wall) and the intact canal wall approach (i.e., opening the facial recess). Although the use of the facial monitor has merit in chronic ear surgery, it is not a substitute for a thorough knowledge of facial nerve anatomy. Rarely is a facial nerve injury secondary to an anomalous course of the nerve; rather, it is usually caused by excessive manipulation of a disease-exposed or congenitally dehiscent tympanic segment, or misadventure with the drill at the second genu or mastoid portion of the nerve.

A study of 416 consecutive surgeries for cholesteatoma revealed a facial nerve dehiscence rate of almost 20%.[15] The most common area of dehiscence (80%) was just superior or adjacent to the oval window. Even in cases of extensive disease, only 1% of the patients had a dehiscence involving the mastoid segment of the nerve. As noted previously, the facial nerve can be dehiscent in the anterior epitympanic space. In this study, 7% of the dehiscences were located in this area. A statistically significant correlation existed between patient age and rate of dehiscence, with patients 19 years old and older having a 3.6 times greater likelihood of a facial nerve dehiscence than patients 18 years old and younger.

Opening the fallopian canal with exposure of the epineurium is of no consequence, and even minor abrasion of the nerve sheath usually causes no immediate or delayed dysfunction. A more penetrating injury causing frayed nerve bundles does require attention. In such a situation, it is important to gauge the depth of injury. Generally, nerve transections less than 30% to 40% of the diameter of the nerve can be treated by decompression. The fallopian canal should be opened for at least 3 to 4 mm proximally and distally to the injured segment, and the epineurium should be incised. Intraoperative and postoperative steroids are administered. If the transection is more than 40% to 50% of the nerve diameter, superior long-term facial function usually can be achieved by resecting the injured segment, and mobilizing the two ends for primary anastomosis or placing an interposition graft. The zone of injury extends beyond the apparent physical disruption of the nerve. Consulting a colleague intraoperatively for an objective assessment of the extent of neural damage is always appropriate.

A postoperative facial paralysis that is delayed (days) in onset can usually be treated expectantly. Steroids are administered, and if there is a paresis only, no further intervention is required; a good recovery is anticipated. In cases of a delayed complete paralysis, the patient needs periodic electrical testing (Hilger or electroneurography) to determine the degree of injury. Loss of electrical excitability greater than a 90% degeneration by electroneurography within 2 weeks of mastoid surgery is an indication for nerve exploration.

Care for a patient with an immediate postoperative facial paralysis is dictated by intraoperative circumstances. If the surgeon recognized the injury and decompressed the nerve, no immediate intervention is required. Periodic electrical testing provides prognostic information. If the surgeon did not recognize nerve damage intraoperatively, more immediate attention is necessary. The often quoted dictum, "the sun should not set on a postoperative facial paralysis without first exploring the nerve," is ill advised, however. Logistically, returning to the operating room immediately may be difficult. Allowing 1 to 2 days for the emotional impact of this outcome on the surgeon and family to defuse is advantageous. A short delay also allows time for consultation with a colleague who can provide objective advice and, as needed, become involved in the re-exploration surgery. Most importantly, the delay would have no adverse impact on outcome.

At the time of re-exploration, the facial nerve first should be identified, if possible, in an area not involved in the initial surgery (i.e., the distal mastoid or proximal tympanic segments). The normal nerve is followed to the area of injury. Exposure of the sides of the fallopian canal, not just its lateral surface, aids in determining the depth of injury. As described previously, depth of injury dictates whether decompression versus resection with primary repair or interposition graft is necessary.

Sigmoid Sinus and Jugular Bulb Injury

In contradistinction to the fixed location of most mastoid and middle ear structures (i.e., labyrinth, facial nerve, ossicles, carotid artery), the sigmoid sinus and jugular bulb are characterized by variable anatomy. This fact places these structures at risk for inadvertent injury. In poorly pneumatized mastoids, the sigmoid sinus may be very superficial and anterior in location, just beneath the mastoid cortex and less than 1 cm from the posterior canal wall. Similarly, the jugular bulb may be small with minimal presentation in the mastoid cavity, or it may be high in the mastoid just inferior to the posterior semicircular canal. Injury to these low-pressure, but high-volume, venous structures is initially treated with digital pressure. For small tears, bone wax may suffice; for larger rents, cellulose-type surgical packing is required. Packing beneath remaining bony ledges helps maintain appropriate pressure. If additional drilling is required, covering the packing with bone wax protects it from being dislodged by the bur.

Although infrequent, a significant injury to the sigmoid sinus can result in thrombosis of that vessel. Depending on collateral and contralateral venous drainage, otitic hydrocephalus can develop secondary to increased venous pressure and decreased cerebrospinal fluid absorption from the arachnoid villi. Postoperative occurrence of persistent headache or visual change should prompt magnetic resonance imaging/magnetic resonance venography studies and funduscopic examination by an ophthalmologist.

CHAPTER ONE HUNDRED AND FORTY-THREE

Clinical Assessment and Surgical Treatment of Conductive Hearing Loss

Alejandro I. Torres

Douglas D. Backous

Key Points

- The external ear and middle ear serve to aid sound localization, augment sound pressures through resonances, and perform the vital function of impedance matching wherein sound waves are effectively transferred to the fluid medium of the cochlear scalae. Impedance matching of sound pressure delivered to the inner ear through the conductive pathway results from the interaction of the catenary, ossicular, and hydraulic lever systems.
- Sound amplification from the middle ear impedance matching system is 35 dB. Amplification from the pinna and external auditory canal can be up to 15 dB, depending on the azimuth of sound delivery.
- Radiologic imaging is rarely necessary in cases of conductive hearing loss and should be ordered based on findings from the history and physical examination.
- Conductive hearing loss in the presence of normal acoustic reflexes and elevated bone thresholds should prompt radiologic investigation for superior semicircular canal dehiscence syndrome before middle ear exploration.
- Surgical repair for conductive hearing loss occurring as a result of superior semicircular canal dehiscence syndrome remains controversial.
- The type of reconstruction is heavily influenced by comfort and preferences of the operative surgeon.
- The Baha system is effective in treating conductive hearing loss by bypassing the damaged middle ear system, transmitting vibromechanical energy to the cochlea via direct bone conduction. Baha is also very effective as an alternative to surgical reconstruction in patients with auricular atresia.
- Tuning fork testing is an effective method to screen for hearing loss, determine conductive versus sensorineural loss, and validate audiometric findings.

An applied understanding of the mechanics of the conductive portion of the auditory periphery and a physiologically directed assessment of the external and middle ear are the cornerstones to optimizing hearing results and minimizing the incidence of complications after surgical reconstruction for conductive hearing loss. This chapter summarizes fundamental physical properties of the conductive portion of the auditory system, outlines an appropriate diagnostic evaluation, and proposes a framework for planning surgical treatment of external auditory canal (EAC) and middle ear defects (Box 143-1).

Mechanical Properties of the Conductive Hearing Pathway

Sound Transfer in the Middle Ear

Sound, defined in the physical dimension, is vibratory energy produced by an object that possesses inertia and elasticity. Within the frequency range for human sound perception, 10 Hz to 24 kHz, there are no limitations to the type of vibration required to generate audible sensations of sound, provided that the source moves from one position to the other and back again. Alternating condensation and rarefaction of sound pressure passes through the external ear structures to the tympanic membrane. The speed of the sound wave is proportional to the density of the medium through which it passes.[1,2]

The acoustic resistance to the passage of sound through a medium is termed *impedance*. The transduction of vibratory energy from the air in the EAC (low impedance) to the cochlear fluids (high impedance) is possible as a result of the impedance matching function of the middle ear. This complex system consists of frequency-dependent stiffness and inertia reactances, along with a frequency-independent frictional component. Conditions that alter ossicular stiffness, such as otosclerosis, produce prominently low-frequency hearing loss. Changes in the mass of the middle ear structures, classically described as producing high-frequency deficits, actually result in hearing losses that vary according to where the mass change occurs on the tympanic membrane or ossicular chain.[3] Tympanosclerosis, which affects the mass and the stiffness

of the ossicular chain, results in a flat hearing loss recorded at high and low frequencies.

In 1868, Helmholtz[4] defined the principles of impedance matching by the middle ear. He proposed three levers to accomplish the required pressure transformation. The tympanic membrane, which is rigidly fixed at the periphery and mobile centrally, acts as a catenary lever, exerting its force on the malleus handle in response to pressure changes transmitted through the EAC.[5] A twofold gain in sound pressure level is generated at the malleus. Although the pars flaccida seems to allow free movement of the malleus head in the epitympanum and may decrease middle ear/external ear atmospheric pressure differences, it has only a minor acoustic role in humans.[6]

The ossicular lever is produced when the incus and the malleus rotate as a unit around an axis extending from the anterior mallear ligament through the incudal ligament.[7] The ossicular lever taken alone produces a small mechanical advantage for sound transmission. Further studies by Tonndorf and Khanna[5] showed the catenary lever was tightly coupled to the ossicular lever because the tympanic membrane is extensively adherent to the malleus handle. Corrected calculations revealed a combined catenary and ossicular lever ratio of 1:2.3. According to studies done on fresh cadaver human temporal bones, the mean sound pressure gain produced by the human middle ear is 26.6 dB, and is centered around its resonant frequency (0.9 to 1 kHz). Beyond 1 kHz, the pressure gain measured at the stapes footplate decreases at a rate of −8.6 dB/octave.[8]

The hydraulic lever assists the transmission of the sound pressure, which is collected over the larger tympanic membrane and passed on to the much smaller stapedial footplate. For the hydraulic lever to be

functional, the stapes should move in a "piston-like" fashion, which has been elegantly described by Guinan and Peake.[9] The increased force is proportional to the ratio of the areas of the tympanic membrane to the footplate. The area of the tympanic membrane is approximately 85 mm^2, and that of the stapes footplate is 3.2 mm^2.[10] After studying 43 human temporal bones, Saunders[11] concluded that the "areal ratio" was the most important component of the middle ear impedance matching system. Ratios varied from ear to ear, but averaged 20.8 : 1.

In a nondiseased ear, sound is transmitted to the oval window with increased energy and at an earlier phase than to the round window. Intensity differences and phase protection cause differential displacement of cochlear fluids, which sets a fluid wave in motion along the tectorial membrane, producing mechanical stimulation of sensory hair cells.

The pinnae gather sound from an arc of 135 degrees relative to the direction of the head and increase sound pressure by 6 dB. They reject sounds arriving from the rear, which assists in the determination of sound origin.[2] The EAC is a closed cylinder approximately 2.5 to 3.5 cm in length. Because ear canal resonance occurs at a frequency whose wavelength is four times the canal length, the corresponding resonant frequency is roughly 3500 Hz. The addition of the conchal component of the pinna increases the EAC length, resulting in a lower resonant frequency, which has been measured at 2700 Hz. The overall increase in sound pressure transduction caused by external ear structures and measured at the tympanic membrane is estimated at 15 to 22 dB.[10,12]

The increased gain in sound pressure level from the impedance matching system of the middle ear and tympanic membrane measures roughly 34 dB. The EAC and auricle, primarily the conchal component of the pinna, provide an additional increase of up to 15 dB, depending on the azimuth of sound delivery and functional length of the canal.

Specific Defects in the Conductive Auditory Periphery and Resultant Hearing Loss

In his 1978 review, Austin[1] identified five categories of anatomic defects in the middle ear sound-conducting system and described each within the context of the associated prototypic hearing loss (Table 143-1). In the first category, tympanic membrane perforation with undisturbed ossicular continuity produced a hearing loss that was linearly proportional to the size of the perforation (loss of areal ratio plus loss of catenary lever). The degree of hearing loss, flat across speech frequencies, was not altered by the location of the perforation on the drumhead.

In the second category, tympanic membrane perforation combined with ossicular disruption occurred in approximately 60% of Austin's patients, and was the most common form of conductive hearing loss requiring surgical therapy. Incudostapedial joint erosion was the most frequent ossicular anomaly. Caution was taken when interpreting audiograms in these patients because underestimation of the magnitude of the conductive loss frequently occurred. Falsely depressed bone-conducted hearing levels (≤10 dB in speech frequencies) resulted from impedance variation occurring at the oval window caused by the ossicular discontinuity. Correction of the ossicular problem typically increased bone levels, reflecting the re-establishment of impedance matching at the oval window. The predicted 38.3-dB hearing loss, when adjusted for falsely depressed bone levels, was primarily a result of decreased function of the hydraulic lever added to dysfunction in the catenary/ossicular lever. Perforation size and the condition of the stapes footplate accounted for variations in this patient group.

In the third category, total loss of the tympanic membrane and ossicles created a condition wherein sound pressure contacted the oval and round windows simultaneously, resulting in partial phase cancellation of the sound wave in the cochlear fluids. Conductive hearing loss was flat across speech frequencies and averaged 50 dB when corrected for the previously described misleading bone levels. More complete phase cancellation caused increased hearing loss compared with patients with partial perforations.

The fourth category included patients with ossicular disruption behind an intact tympanic membrane. This defect resulted in a maximal conductive hearing loss of 55 to 60 dB. The intact eardrum reflected sound energy back into the EAC, causing an additional 17-dB conductive loss beyond what was expected from removal of the hydraulic and catenary/ossicular lever action. The decreased sound pressure also reached the round and oval windows nearly simultaneously, inducing phase cancellation in the labyrinthine fluids.

The fifth category described various congenital malformations with ossicular disruption and closure of the oval window; also included were cases of obliterative otosclerosis with closure of the oval and round windows behind an intact drum. The expected flat loss from such a defect is 60 dB.[2]

Diagnostic Evaluation

The use of advanced audiometric testing, laboratory studies, or diagnostic imaging is rarely indicated in patients with isolated conductive

Table 143-1

Specific Lesions of the Conductive Apparatus and Associated Hearing Loss

Classification	Component Disrupted	Expected Loss (dB)
Perforation of tympanic membrane	Loss of areal ratio, catenary lever	Proportional to size of perforation
Perforation of tympanic membrane with ossicular interruption	Hydraulic lever, areal ratio, catenary lever	38.3
Total loss of tympanic membrane and ossicular chain	Hydraulic lever, areal ratio, catenary lever, phase cancellation	50
Ossicular interruption with intact tympanic membrane	Hydraulic lever, areal ratio, catenary lever, phase cancellation, reflection of sound energy away from middle ear at tympanic membrane	55-60
Ossicular interruption with intact tympanic membrane and closure of oval window (distinct congenital malformation)	Hydraulic lever, areal ratio, catenary lever, phase cancellation, reflection of sound energy away from middle ear at tympanic membrane	55-60

From Austin DF. Sound conduction of the diseased ear. *J Laryngol Otol.* 1978;92:367; and Austin DF. Acoustic mechanisms in middle ear sound transfer. *Otolaryngol Clin North Am.* 1994;27:641.

hearing loss. Complete assessment of a patient with hearing loss begins with a careful history. A thorough head and neck examination with cranial nerve testing and otoscopy is mandatory. Otomicroscopy is useful to remove foreign bodies and to examine the tympanic membrane and middle ear structures more precisely, and is a prudent step in preoperative evaluation. The use of 256-Hz, 512-Hz, and 1024-Hz tuning forks assists in the localization of the side of greatest auditory deficit and verifies audiometric findings.

The Weber test is effective in lateralizing hearing loss. The fork is gently struck by the examiner and placed on the forehead or on the vertex of the skull, and the patient states on which side he or she hears the tone more clearly. Placement of the tuning fork over the nasal bones or on the teeth may present a stronger stimulus for Weber testing in difficult-to-test patients.[13] Lateralization of the tone represents either a conductive loss ipsilateral to the side of localization or a sensorineural loss greater in the contralateral ear. The 256-Hz tuning fork is the most sensitive of the available frequencies,[14] but it can yield an unacceptable number of false-positive results. The most clinically useful single fork is the 512-Hz fork.[15]

Rinne testing using all three fork frequencies can accurately estimate the conductive component of a hearing deficit (Table 143-2).[16] The test is performed by activating the tuning fork and by placing it firmly on the skin over the cribriform area of the mastoid bone. When the tone can no longer be heard, the fork is placed, tines oriented parallel to the head/frontal plane, in front of the meatus of the EAC. The patient indicates whether the tone is present or absent. A negative or abnormal Rinne result is found when bone conduction is perceived longer than air conduction. A positive, or normal, result occurs when the air conduction is greater than bone. Tuning fork testing should be carried out in any patient before surgery for a conductive anomaly to verify audiometric results and to establish a baseline for comparison for postoperative assessment.

Table 143-2

Degree of Hearing Loss Estimated by Rinne Testing

Rinne Test Result*	Estimated Conductive Loss (dB)
Negative, 256 Hz	Mild conductive loss of 20-30
Positive, 512 Hz and 1024 Hz	
Negative, 256 Hz and 512 Hz	Moderate conductive loss of 30-45
Positive, 1024 Hz	
Negative, 256 Hz, 512 Hz, 1024 Hz	Severe conductive loss of 45-60

*Negative Rinne test = bone conduction greater than air conduction (abnormal). Positive Rinne test = air conduction greater than bone conduction (normal).
From Miltenburg DM. The validity of tuning fork tests in diagnosing hearing loss. *J Otolaryngol.* 1994;23:254.

Pure-tone audiometry and speech testing follow in the workup. The diagnosis of a conductive loss is made in the presence of an air-bone gap on the pure-tone audiogram with speech testing commensurate to the results measured audiometrically (Fig. 143-1). Concurrent sensorineural deficits should be noted. Falsely depressed bone-conducted hearing levels can present in patients with ossicular abnormalities secondary to earlier discussed impedance mismatching.[1]

Acoustic immittance testing may be useful in distinguishing between conductive and sensorineural hearing loss. Voluntary responses are not required for successful measures of static compliance, tympanometry, and acoustic reflexes, making them an important component of the auditory test battery. A probe is placed in the EAC to form an airtight seal. The middle ear static compliance is determined by subtracting the compliance at 200 mm H_2O from the total compliance when pressure is equal on both sides of the tympanic membrane. Normal values range from 0.3 to 1.6 mL, mainly reflecting the condition of the tympanic membrane. Tympanometry, a graphic representation of the compliance of the middle ear during dynamic pressure conditions, tests tympanic membrane integrity and ossicular mobility. The type A tympanogram indicates normal middle ear compliance; the type A_s tympanogram indicates ossicular fixation, and the type A_d tympanogram indicates ossicular discontinuity. The type B tympanogram suggests otitis media with effusion, cerumen impaction, or a perforated tympanic membrane. Conditions with negative middle ear pressure result in a type C tympanogram.[17]

Acoustic reflex testing assesses a reflex arc bridging the cochlea, auditory nerve, cochlear nucleus, trapezoid body, medial superior olivary complex, motor nucleus of CN VII, and facial nerve. Conductive hearing loss produces an abnormal result by interfering with the afferent limb of the reflex arc. The absence of acoustic reflexes in the presence of a conductive hearing loss indicates an ossicular anomaly. Normal acoustic reflexes in the presence of a conductive hearing loss suggests either a partial ossicular fixation or the possibility of a "third window" effect, such as seen in superior semicircular canal syndrome.

A subset of patients with superior semicircular canal syndrome experience conductive or mixed hearing loss. In a series of 20 superior semicircular canal syndrome patients with conductive hearing loss and

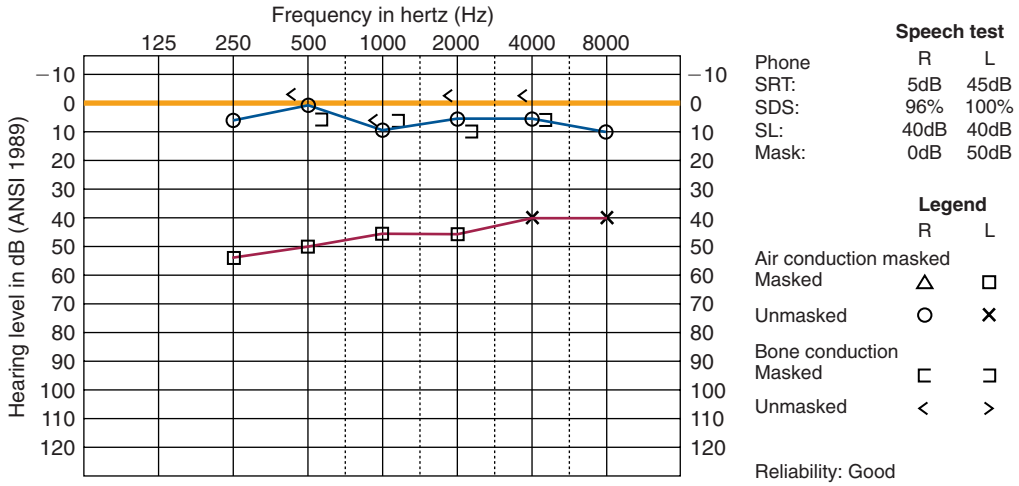

Figure 143-1. Audiogram showing a clinically significant left-sided conductive hearing loss. Note the air-bone gap, normal speech discrimination, and normal masked bone conduction in the left ear.

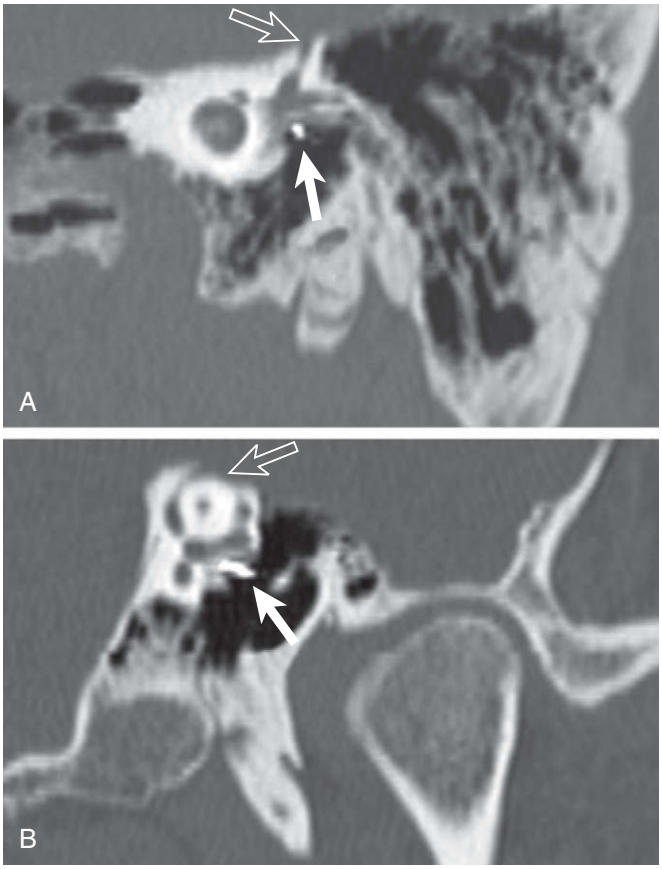

Figure 143-2. Thin-cut CT scan of the left temporal bone after a stapedectomy with no improvement of conductive hearing loss. **A,** Coronal view with the superior canal dehiscence (*open arrow*) and stapes piston prosthesis in good position (*closed arrow*). **B,** Reformatted sagittal or "bagel" view of the same structures.

no vestibular symptoms, Merchant and colleagues[18] identified six common findings. First, 10- to 60-dB air-bone gaps primarily occurred in frequencies less than 2000 Hz. Second, in some cases, bone-conduction thresholds less than 2000 Hz were negative. Third, the acoustic (stapedial) reflex was present. Fourth, measurement of umbo velocity by laser Doppler vibrometry showed slight hypermobility of umbo motion. Fifth, the vestibular-evoked myogenic potential response was present, with thresholds that were abnormally low. Sixth, the middle ear was normal at exploratory tympanotomy, including normal mobility of the ossicles and a patent round window niche.

The dehiscent superior semicircular canal is theorized to form a "third window" in addition to the oval and round windows found in the normal labyrinth. This third window is capable of dispersing incoming vibromechanical energy resulting in an improvement in bone conduction, a decrement in air conduction, and possibly a Carhart notch noted with routine audiometry.[19] Conductive hearing loss in a patient with normal acoustic reflexes and elevated bone thresholds less than 2000 Hz should prompt a high-resolution temporal bone computed tomography (CT) scan to rule out superior semicircular canal syndrome before surgical exploration (Fig. 143-2). Because of the risk of iatrogenic sensorineural hearing loss, surgical repair of a superior semicircular canal dehiscence to correct a conductive hearing loss in patients without disabling vertigo is not recommended (Box 143-2).[18]

Treatment

Treatment of conductive hearing loss requires appropriate patient selection and intraoperative localization of the site of the abnormality. Planning a reconstruction hinges on understanding the impact of the specific defect and repair on normal conduction mechanics. The choice of prosthesis and the particular reconstructive technique also depend heavily on the skills and preferences of the operating surgeon.

Conditions of the External Auditory Canal Contributing to Conductive Hearing Loss

Narrowing of the EAC to less than 3-mm diameter results in loss of high-frequency sound perception. As the diameter of the EAC lumen narrows further, low-frequency stimuli are blocked from making contact with the tympanic membrane.[20] Removal of offending foreign bodies, eradication of infection when present, and correction of anatomic aberrations to maintain long-term patency are essential for normal conduction of sound pressure to the oval window.

Foreign bodies in the EAC require complete removal in a controlled environment. Children may require restraint, sedation, and occasionally general anesthesia. Otomicroscopy is necessary when the object is medial to the bony canal isthmus, when the tympanic membrane is perforated or not clearly visualized, or in any situation with heightened risk for iatrogenic damage to the EAC or tympanic membrane.

External otitis is managed with aggressive aural toilet and acidifying otic solutions to bring the pH of the EAC skin to a normal acidic level (pH 4 to 5). Antibiotic (with or without steroids) solutions or suspensions should be reserved for resistant infections. In cases with significant soft tissue edema and narrowing, otowicks can be inserted into the inflamed canal to optimize delivery of topical medicines to more medially located tissues. Oral or intravenous antibiotics are necessary in patients with extensive cellulitis extending beyond the EAC meatus and in patients presenting with major risk for malignant external otitis. Severe pain with ipsilateral cranial nerve deficits in immunocompromised hosts should prompt aggressive evaluation of skull base osteomyelitis (Fig. 143-3).

Furuncles should be drained and managed with topical antibiotics and otowicks as necessary. Otomycosis usually resolves with aural toilet followed by instillation of compounds that mildly acidify the external canal skin. Occasionally, the application of antifungal or steroid creams, or both, onto the external canal skin may be necessary.

Most cerumen impactions are easily removed otoscopically. More tenacious cerumen most often is seen in older patients or in patients with previous radiation exposure to the temporal region. Ototopical antibiotic preparations or docusate sodium 1% solution for 1 to 2 weeks often softens cerumen to facilitate subsequent manual removal. External canal irrigations should be avoided in patients suspected to have tympanic membrane perforations. When used, body temperature irrigant is optimal to avoid caloric stimulation and discomfort to patients with external canal blockage. Management of keratosis obturans requires patience by the clinician to avoid excessive pain to the patient during removal of debris. Careful otomicroscopic inspection should follow cleaning to exclude the presence of bony canal erosion, tympanic membrane perforation, or external canal cholesteatoma.

Soft tissue stenosis of the EAC can occur as a result of local inflammation or as a manifestation of systemic disease. If possible, the cause of the soft tissue proliferation should be identified and treated. Hypertrophied soft tissue that persists after adequate medical management can be initially treated with local infiltration of steroid. If persistent, fibrosed skin can be resected to enlarge the external canal diameter. Circumferential endaural incisions, down to periosteum, are placed laterally to the stenotic segment. Next, elevation of the thickened skin, as for tympanoplasty, is carried out with removal of all scar tissue and involved canal epithelium. The tympanic anulus is left undisturbed, and a plane is developed between the fibrous and the squamous layers of the drumhead. The squamous layer of the drum typically is involved with the stenotic process.

After removing any bony obstruction in the external canal with the otologic drill, the lateral tympanic membrane and exposed bony canal are grafted with split-thickness skin. The technique described by Jahrsdoerfer[21] for skin grafting the external canal after congenital atresia surgery or the use of small "pinch grafts" of postauricular skin to denuded areas provides resurfacing. The external canal is packed as for tympanoplasty (Fig. 143-4). Although rarely necessary, the surgeon should be prepared to perform a formal tympanoplasty to repair defects on the residual drum. Restenosis is more common in patients with

Otoacoustic emissions

systemic (i.e., connective tissue) diseases or when underlying chronic infection is not controlled preoperatively. Hearing results typically are excellent, particularly when the tympanic membrane and ossicles are not disrupted.[22]

Bony and soft tissue overgrowth can cause stenosis of the EAC. Exostoses and osteomas are thought to originate along the tympanomastoid and tympanosquamous suture lines during phases of bony growth and after prolonged or repetitive exposure of the ears to cold water. Most of these lesions require no specific treatment. In patients with continued debris buildup between the narrowed portion of the canal and the tympanic membrane, or in whom conductive hearing loss develops, the osseous growths should be removed. Skin incisions can be placed postauricularly or endaurally with careful dissection of canal skin off the lateralmost portion of the aberrant bone. Careful drilling into the bony overgrowth while maintaining a thin shelf of bone between the neocanal and the tympanomeatal flap protects the canal skin. Curettage of the residual bony shelf removes the remaining abnormality with minimal damage to residual canal skin.[23] Skin flaps are replaced, and the external canal is packed (Fig. 143-5). Tympanoplasty may be necessary if the bony lesions traverse the tympanic anulus. Recurrence is rare, and hearing results should be excellent.

Conditions of the Tympanic Membrane Contributing to Conductive Hearing Loss

Perforation of the tympanic membrane affects the areal ratio and catenary lever system in sound conduction. The condition of the ossicles and middle ear ligaments, the health of the middle ear mucosa, the degree of chronic inflammation, and the presence or absence of cholesteatoma should be assessed before surgical intervention. Successful ossiculoplasty depends on a mobile and properly oriented tympanic membrane, normalized middle ear pressure and mucous clearance, and an efficient sound-conducting mechanism.[24] An array of techniques can be used to repair the tympanic membrane and to reconstruct the ossicular chain. The technique chosen for repairing the perforation should provide adequate vascular and structural support to the healing drum.

The overlay or lateral graft can be used to reconstruct any type or size of perforation. The drawbacks of this method include graft lateralization, blunting of the anterior sulcus, and excessive tympanic membrane thickness. The canal skin is completely removed, and the drum remnant is de-epithelialized to prevent cholesteatoma formation or delayed healing. When the ear canal is drilled to expose the tympanic anulus fully, the tympanic membrane graft is positioned, and the ear canal skin is replaced.

Underlay or medial grafting is more commonly used by many surgeons and is particularly reliable when performed through a postauricular incision. The main limitation with this method is the added difficulty in obtaining sufficient vascular and structural support of the anterior aspect of the graft. Recurrent perforation in a medial grafted tympanic membrane most commonly occurs at the anterior sulcus region, where perforators from the tympanic anulus weakly perfuse the drumhead.[25]

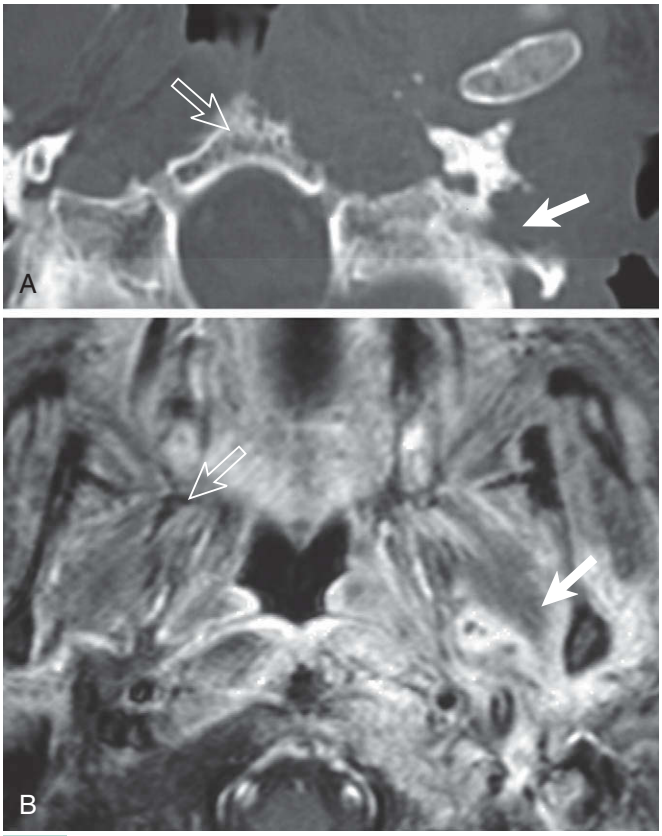

Figure 143-3. Malignant external otitis. **A,** Temporal bone CT scan without contrast material at the level of the foramen magnum showing bony demineralization crossing the midline (*open arrow*) and significant demineralization of the mastoid and hypotympanic structures (*closed arrow*). **B,** Axial MRI with gadolinium of the skull base. Ipsilateral parapharyngeal soft tissue involvement (*closed arrow*); contralateral uptake reflecting crossover beyond the midline (*open arrow*).

Although both techniques can be used on any type of perforation by a surgeon, lateral grafting is recommended for perforations located anterior to the malleus and involving the anterior sulcus of the tympanic ring. Medial grafting is most useful in perforations posterior to the long process of the malleus where the mallear artery provides a hearty blood supply. The use of alloplastic materials for tympanic membrane reconstruction is rarely necessary.

Conditions of the Middle Ear Contributing to Conductive Hearing Loss

When middle ear disease is eradicated, and the middle ear mucosa appears healthy and well aerated, ossicular reconstruction can be done with the highest chance of success. Dornhoffer and Gardner[26] studied 200 ears operated in 185 patients who had either total ossicular replacement prostheses (TORPs) or partial ossicular replacement prostheses (PORPs) placed. They found that the absence of the malleus, mucosal fibrosis, revision ear surgery, and the removal of the ear canal wall had a significant detrimental impact on hearing outcome.[26] Adequate stabilization of the reconstructed ossicles at the time of surgery assists healing and optimization of hearing. Avoiding direct contact of prosthetic materials with the tympanic membrane prevents drum erosion and extrusion. Placement of thinly sculpted conchal or tragal cartilage between the graft and the tympanic membrane avoids this complication. The prosthesis, positioned perpendicular to the tympanic membrane and in the vertical plane from the center of the stapes footplate, is stabilized with the mild tension from the drum.[27] Stapes footplate fracture, subluxation, and perilymph leak are avoided by properly sizing the prosthesis before placement.

Patient selection for ossicular reconstruction is largely based on findings on the preoperative audiogram and on the potential to regain serviceable hearing. Ossiculoplasty in patients with preoperative speech reception threshold of 30 dB or less or within 15 dB of the opposite ear is controversial. Alternatively, patients with speech reception threshold values greater than 30 dB often require amplification to gain access to conversational speech levels. Even small gains in hearing after surgery are appreciated by these patients and may decrease the power needs of a hearing aid or free the patients of continued amplification. Bringing the operative ear to within 15 dB of the contralateral ear enhances binaural input to auditory centers.[24] Salient points in preoperative assessment of patients being considered for hearing reconstruction are presented in Box 143-3.

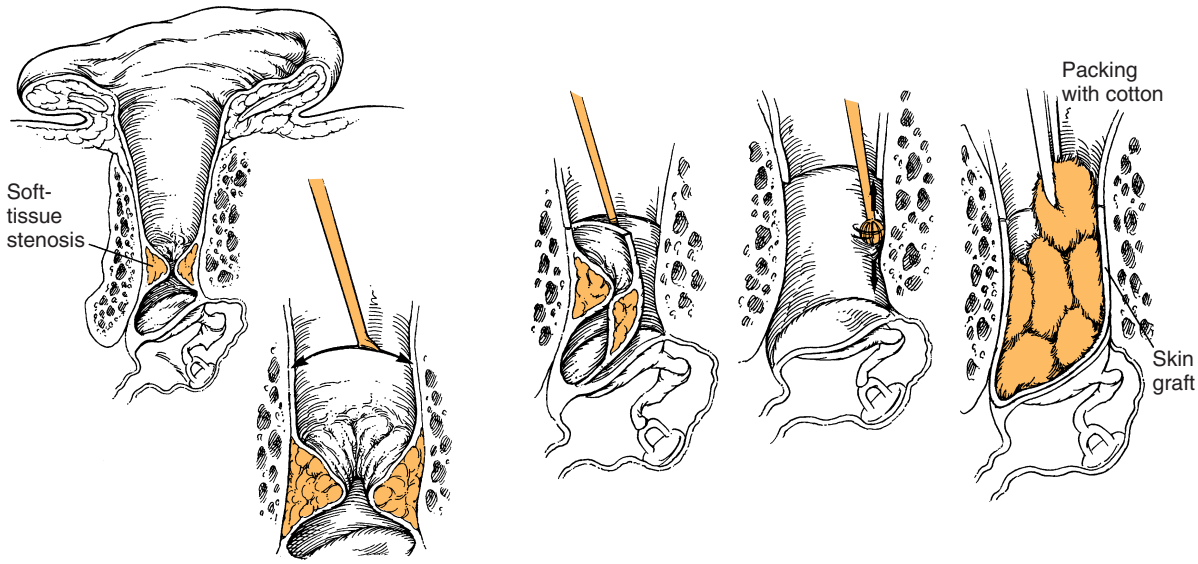

Figure 143-4. Repair of soft tissue stenosis of the external auditory canal. Circumferential skin incisions are made in the canal after opening with a postauricular incision. The stenotic tissue is dissected off the canal bone and from the fibrous layer of the tympanic membrane. The squamous layer of the drum is taken with the specimen. Sculpting of the bony canal is performed with a diamond bur before applying skin grafts and canal packing.

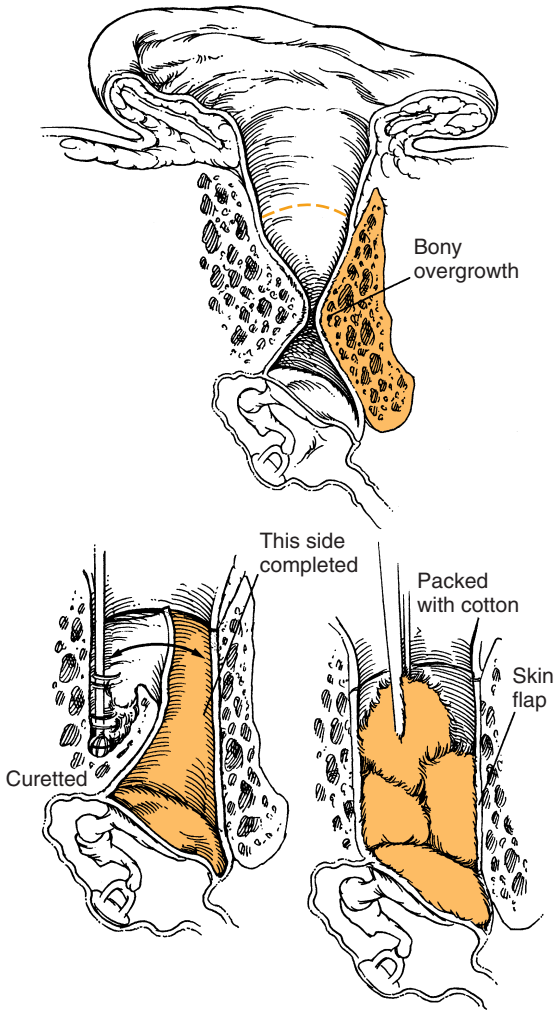

Figure 143-5. Repair of external auditory canal exostosis. Care is taken to elevate the canal skin from the osseous deposition, to drill away the pathology while maintaining a thin eggshell of bone to protect the skin flap, and to curet away the bony remnant before packing the external canal.

Box 143-3

Key Points in Preoperative Assessment of Patients Considering Ossicular Reconstruction

- A preoperative air-bone gap >20-25 dB is consistent with ossicular discontinuity or fixation.
- Elective ossicular reconstruction in the presence of an open mastoid cavity often is unsatisfactory.
- Patients with a preoperative air-bone gap <30 dB should be approached with caution because even slight decreases in hearing levels may require amplification.
- Reconstructive results in patients with bone (sensorineural) levels >30 dB often are unsatisfactory if avoidance of amplification is a priority.
- In patients with severe mixed hearing loss, ossicular reconstruction can be considered because it may enhance the use of amplification.[46]
- Improving the threshold of a poorer hearing ear to within 15 dB of the contralateral ear may facilitate binaural inputs to central auditory pathways.[24]

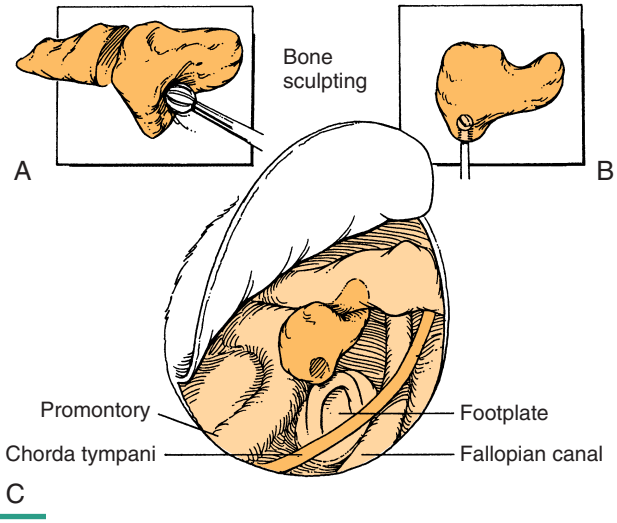

Figure 143-6. Incus interposition. **A** and **B,** Incus is sculpted to fit between the capitulum of the stapes and the malleus handle. **C,** The modified incus is positioned to restore continuity in the ossicular chain.

Assessment of the ossicular chain intraoperatively provides the most accurate information needed for reconstructive planning. An absent lenticular process of the incus is the most commonly encountered ossicular abnormality. Provided that the stapes superstructure is intact, and the malleus long process is present and in a favorable position without head fixation, the preferred method of reconstruction is with a sculpted incus interposed as a strut from the capitulum to the malleus handle or a PORP. For incus interposition, after the incus is removed from the middle ear, the residual long process is shortened with the malleus nipper, and a shallow cavity is drilled into the short process to facilitate placement on the stapes capitulum.[28] The posterior scutum is curetted to prevent contact between the graft and the canal wall. The fashioned ossicle is positioned between the malleus handle and the capitulum in such a way as to tent the tympanic membrane slightly. The graft should hold its position without stabilization by absorbable gelatin sponge (Gelfoam) (Fig. 143-6). Silastic sheeting or hyaluronic acid gel can fill the middle ear to prevent fixation of the graft to the promontory or to the facial ridge. If the interposed incus does not bridge the vertical distance between the capitulum and the malleus, the incus can be resculpted according to the technique by Wehrs.[29] Alternatively, PORPs can be used (Fig. 143-7). Reconstruction prostheses should be fitted with a cartilage cap placed directly against the posterior and superior drum to reduce extrusion.[30]

In patients with an absent stapes superstructure, a TORP reconstruction is necessary. The particular prosthesis chosen is less important than the ability of the surgeon to gauge accurately the optimal size and orientation of an implant. Extrusion rates and the incidence of secondary retraction pockets are reduced with the interposition of cartilage between the tympanic membrane and the prosthetic material. The perichondrium should be stripped from the cartilage graft on the surface in contact with the prosthesis and left intact on the surface contacting the tympanic membrane. The orientation of the implant and the tension of the tympanic membrane on the prosthesis are critical to maximizing sound transmission (Figs. 143-8 and 143-9).[24]

Ossicular fixation should be ruled out before reconstruction. Disarticulating the incudostapedial joint and removing the incus are key to managing malleus head fixation. The epitympanum is opened either by curettage of the scutum or by atticotomy, and the bony union is released.[31] The head is removed with the malleus nipper. Incus interposition or another ossiculoplasty techniques can proceed with the expectation for good results. The fixed incus is managed with removal and interposition or prosthetic graft placement. Stapes footplate fixation should be ruled out and, if present, can be managed with stapedotomy or stapedectomy. Staging the stapedotomy may be necessary to avoid opening the inner ear fluids to an infected middle ear. Tym-

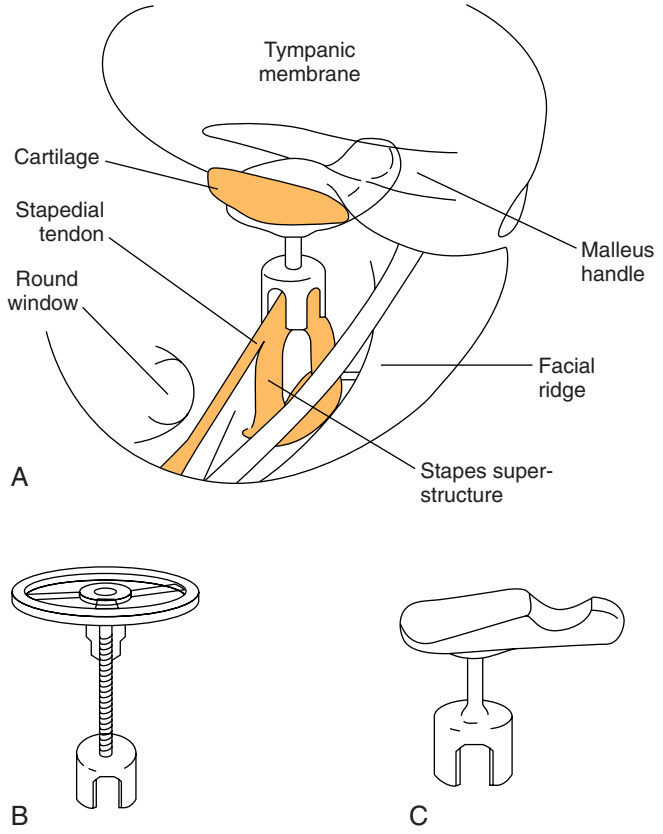

Figure 143-7. **A,** Ossicular defect repaired with a partial ossicular replacement prosthesis (PORP) bridging the stapes capitulum to the malleus handle. Note cartilage is placed between the head of the prosthesis and the tympanic membrane to prevent extrusion.

panosclerosis is the clinical presentation of dystrophic calcification and hyaline deposits in the submucosal tissues of the middle ear caused by recurrent acute or chronic infection. Any of the bony or ligamentous structures in the middle ear can be involved.[32] Conservatism is in order when managing tympanosclerosis because of the high rate of recurrence of the underlying disease process, regardless of middle ear reconstruction.

Traditionally, autographs and homographs fashioned from the body of the incus or the head of the malleus were considered the gold standard for ossicular reconstruction. Concerns of infectivity of transplanted tissue, the need for often time-consuming intraoperative sculpting of autograph and homograph tissue, and a desire to avoid tissue banking have led to the development of alloplastic materials for ossiculoplasty. In the early 1960s, Austin and Shea[33] pioneered the use of polyethylene and polytetrafluoroethylene (Teflon) implants, but found an unacceptably high extrusion rate. Shea and Emmett[34] later introduced Proplast and Plastipore implants with the concept of increased biocompatibility as a result of the porous properties of these materials. Extrusion rates and hearing results with these implants did not match those of homographs. Calcium phosphate–containing materials, such as hydroxyapatite, glass, and glass and ceramic (Cervital), and titanium offered advantages of biocompatibility and decreased resorption.[35] The propensity for implants to coalesce with adjacent bone offers the theoretical advantage of direct coupling to the stapes superstructure or footplate.

Tension between the malleus or tympanic membrane and the stapes head or footplate is affected by the length of the prosthesis, which can alter the sound transmission across the middle ear. A short prosthesis causes a reduction of sound transmission at higher frequencies and increases the risk of dislodgment as the ear recovers from tympanoplasty. Long prostheses can produce excessive tension, and may be

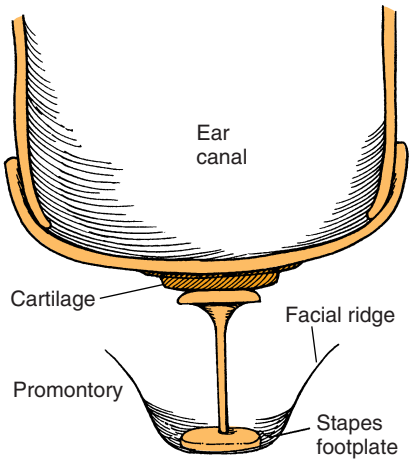

Figure 143-9. Schematic of a total ossicular replacement prosthesis positioned between the stapes footplate and the tympanic membrane. An adequate amount of tension is present on the reconstructed drum, and the prosthesis is as close to perpendicular to the footplate as possible to ensure optimum sound transmission. Also, note the cartilage between the drum and the prosthesis.

acoustically inefficient at low frequencies because of increased dampening of ossicular vibration secondary to stretching of the annular ligaments of the stapes and the suspensory ligaments of the malleus and possibly the tympanic membrane.

In recent years, more surgeons are choosing titanium prostheses because of the advantages of improved visualization during insertion,

low extrusion rate, and easy handling. Studies comparing titanium prostheses with other biomaterials are limited; however, Hillman and Shelton[36] compared Plastipore with titanium prostheses and found that there was no significant difference in the hearing results, or extrusion rates. The Plastipore prosthesis performed better when a TORP was needed. These results are consistent with studies comparing hydroxyapatite with titanium prostheses.[37]

Dalchow and colleagues[38] suggested that titanium middle ear implants offer an ideal implant material. They performed 1304 titanium implants, including PORPs and TORPs, from which 790 were reviewed. Of the patients with titanium prostheses, 76% had a postoperative air-bone gap of 20 dB or less. The results were limited to short-term follow-up and did not separate partial from total prostheses.[38] Table 143-3 lists the reported extrusion rates and hearing results observed with the various implant materials. It is expected that 5-year and 10-year follow-up will determine the efficacy and true extrusion rates of titanium in ossiculoplasty. Follow-up to 15 years after ossiculoplasty in patients with chronic otitis media revealed a slowly progressive deterioration in hearing levels regardless of the implant material chosen.[24]

Management of Conductive Hearing Loss in Children

The most common cause of childhood conductive hearing loss is otitis media followed by congenital anomalies, trauma, and otosclerosis. Theringer and coworkers[39] studied Swedish children 5 years and younger, and found an incidence of hearing loss severe enough to require amplification of 0.6 in 1000. Of these subjects, 64% had genetic etiologies.

Age-specific audiometric testing is mandatory for children as soon as hearing loss is suspected. Amplification optimizes speech and language development and should be implemented as early as possible. Elective surgical correction of ossicular fixation lateral to the stapes can be done at any age. Treatment of stapes fixation in children should be delayed until the child is old enough to contribute to the decision for surgery or can be managed with a traditional head band–type bone-conducting hearing aid or Baha system (Cochlear Corp., Lane Cove, Australia). Bilateral conductive losses require surgical attention before the child enters school, particularly if hearing aids are not providing necessary sound perception to assist speech development.[39a]

Raz and Lustig provide a complete review of the treatment of conductive hearing loss in children.[39a] General anesthesia is essential because children rarely can remain still during a local or sedation anesthetic. The middle ear is most commonly approached through a postauricular incision, which allows for maximal exposure of the middle ear structures and easily assists mastoidectomy when necessary. Thorough middle ear inspection identifies concurrent congenital or infection-related processes. Ossiculoplasty techniques are identical to the techniques used in adults, and long-term follow-up is necessary. Patients with an only-hearing ear should be advised against elective tympanoplasty.[40]

Expanding Role of Implantable Devices

In children and adults, the Baha system offers amplification up to the level of cochlear reserve without risking potential complications with manipulating the middle ear. Baha provided significant improved benefit compared with traditional hearing aids in cases of chronic serous otitis media. McNamara and associates[41] reported 84% of patients with decreased frequency of episodes and no cases of increased incidence of otorrhea in a large cohort of patients with average follow-up of 24 months. Baha was a useful alternative in cases of Treacher Collins syndrome where atresia repair routinely produces poor hearing outcomes.[42]

When used as a primary treatment or as a bridge to later atresia repair, Baha provides near-complete closure of the air-bone gap with minimal risk to the facial nerve or to sensorineural hearing levels. In cases where later microtia repair is planned, the fixture should be placed 1.5 to 2 cm more posterior than the 5.5 cm from the external meatus site normally recommended.[43] Baha is also suggested as the "third option" for surgical treatment of patients with otosclerosis.[44] Maximal conductive hearing losses incurred after lateral skull base surgery can be overcome safely and effectively with Baha placement either at the time of resection or at a second stage. Bilateral Baha has shown enhanced auditory performance compared with unilateral bone conduction alone.[39]

Siegert and colleagues[45] described the use of the Otologics (Boulder, CO) fully implantable middle ear system in five patients with congenital auricular atresia. The middle ear transducer was attached via a modified Kurz PORP to the stapes capitulum. Follow-up was limited to 3 months. The mean functional gain measured at four frequencies (1 kHz, 2 kHz, 3 kHz, 4 kHz) was 36 dB with an average improvement of 70% in speech discrimination at a sound level of 65 dB hearing loss. This technique is under further investigation, and long-term results are needed to determine true efficacy. Although the Otologics device has the promise for better sound localization, the Baha implantation requires much less complicated surgery with minimal risk to the facial nerve or loss of cochlear reserve.[45]

Conclusion

Practical knowledge of the basic physics of the middle ear sound-conducting mechanism is paramount to planning optimal surgical intervention for conductive hearing loss. Adherence to general guidelines facilitates consistency in obtaining the best possible reconstructive outcomes with minimal complications. Surgical management should be individualized to fit the needs of the patient and the comfort level of the operating physician.

CHAPTER ONE HUNDRED AND FORTY-FOUR

Otosclerosis

John W. House

Calhoun D. Cunningham, III

Key Points

- Otosclerosis is the most common cause of progressive conductive hearing loss in adults.
- The prevalence of otosclerosis is greater in women, with a 2:1 female-to-male distribution.
- The typical age of onset of noticeable hearing loss is in the third decade of life, and hearing loss is bilateral in 70% of cases.
- Otosclerosis is transmitted in an autosomal-dominant fashion, with variable penetrance.
- The pathologic changes of otosclerosis begin as spongification of the bone of the otic capsule.
- Assessment of hearing with tuning forks provides important information on which to base clinical decisions.
- Management options include stapes surgery or hearing aids; rarely, cochlear implantation may be indicated.
- Stapes surgery options include total stapedectomy, partial stapedectomy, or small fenestra stapedotomy. Footplate fenestration may be accomplished with a laser or microdrill.
- Prosthesis options include pistons, wires, or clips (MRI compatible); prosthesis measurement is taken from the incus to the footplate.
- Complications of stapes surgery include sensorineural hearing loss, vertigo, fistula, infection, and tympanic membrane perforation.
- The surgeon performing stapes procedures should be aware of the possibility of a fixed malleus accounting for a conductive hearing loss.
- Cochlear otosclerosis manifests with sensorineural hearing loss and may be amenable to stabilization with fluoride therapy.

Otosclerosis is a disease of bone that is unique to the otic capsule. It may cause a conductive hearing loss, a mixed conductive-sensorineural hearing loss, or occasionally a purely sensorineural hearing loss. In 1860, Toynbee[1] first described the condition causing a hearing loss by fixation of the stapes. In 1893, Politzer[2] referred to the fixation of the stapes as *otosclerosis*. Siebenmann[3] revealed on microscopic examination that the lesion seemed to begin as spongification of the bone and termed the process *otospongiosis*.

Clinically, otosclerosis patients present with progressive hearing loss. If the otospongiotic process primarily involves the stapes, the hearing loss is conductive. The most common area for stapedial fixation is the anterior crura. The process may progress to involve the entire footplate or may continue anteriorly toward the cochlea, causing a sensorineural hearing loss.

Otosclerosis is an autosomal-dominant hereditary disease with variable penetrance and expression. Two thirds of patients are women. The hearing loss usually begins in the late teens or early 20s, but may not occur until the 30s or early 40s. At the House Ear Clinic, the youngest patient with surgically confirmed otosclerosis was 6 years old.[4] It may be accelerated by pregnancy. Many female patients first report hearing loss during or shortly after their first pregnancy.

The prevalence of otosclerosis varies with race and its expression (Table 144-1). In whites, the disease is found in 7.3% and 10.3% of temporal bones for men and women. The stapes appears fixed in only 12.3% of patients with histopathologic evidence of otosclerosis. Clinical otosclerosis is rare in blacks, Asians, and Native Americans.[5-11]

Histopathology

Early lesions appear adjacent to the fissula ante fenestram as sheets of connective tissue replacing bone. Bone is absorbed by osteoclastic activity, and new bone is deposited by osteocytes. The osteocytes are found at the advancing edge of the lesion, which extends into the otic capsule in finger-like projections. These lesions contain vascular spaces in the center. The result is disorganized bone rich in osteocytes with enlarged marrow spaces rich with blood vessels and connective tissue. These lesions have an affinity for hematoxylin, which makes the bone appear darker. Healthy surrounding bone has few viable osteocytes and chondrocytes, and is relatively avascular. The osteoclasts are multinucleated and appear in the center of the lesion, absorbing the already disorganized bone.

The extent and location of these lesions vary. Some are small and do not involve the stapes. Lesions that have ceased all activity appear sclerotic. As the disease advances, the lesions spread across the stapedial annular ligament, causing stapedial fixation. If the lesion progresses medially to involve the endosteum of the cochlea, sensorineural hearing loss results (Fig. 144-1). It may spread in both directions, resulting in a mixed sensorineural conductive hearing loss (Fig. 144-2).

The type of stapedial fixation varies depending on the site of the lesion. If the lesion begins in the posterior oval window and spreads to the stapes through the anterior and posterior annular ligament, it causes bipolar stapes fixation. When the lesion flows across the ligament onto the footplate, it totally obliterates any remnant of the original annular ligament. If the center of the footplate remains uninvolved, it retains its characteristic cartilaginous vestibular and bony tympanic surface.

Table 144-1

Occurrence of Clinical Otosclerosis

Reference	Prevalence
Fowler and Fay, 1961, U.S.[44]	5% of patients with hearing loss*
Morrison and Bundey, 1970, England[45]	0.3% of East London's population
Surján et al, 1973, Hungary (two sites)[46]	5.1% of patients with hearing loss; 2.4% of patients with hearing loss
Hall, 1974, Norway[47]	0.3% of Norway's population
Pearson et al, 1974, U.S.[48]	239:100,000 in Rochester, MN, in 1970
Moscicki et al, 1985, U.S.[49]	0.52% of a cohort study begun 29 years earlier
Huang and Lee, 1988, Taiwan[50]	1.13% of patients with hearing loss
Reference	**Incidence**
Hall, 1974, Norway[47]	56:100,000 for Norway's population (1960-1969)
Pearson et al, 1974, U.S.[48]	13:700,000 in Rochester, MN, from 1950-1969; 8.9:100,000, from 1950-1959
Stahle et al, 1978, Sweden[51]	12:100,000 yearly
Levin et al, 1988, Sweden[8]	6.1:100,000 for 1981

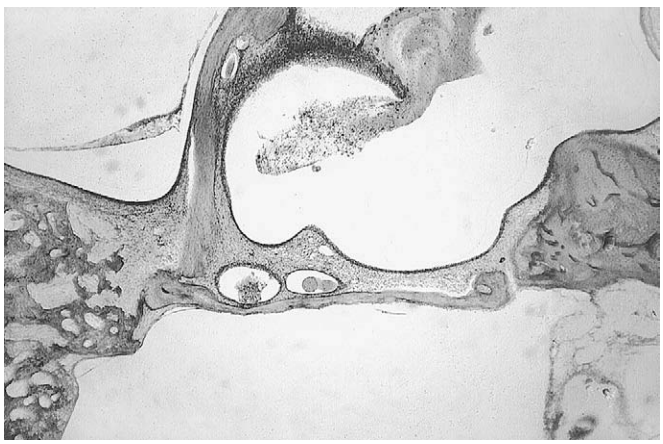

Figure 144-1. Stapes footplate and anterior crus adjacent to an anterior oval window otosclerotic process seen on the left. There is a small extension of otosclerosis in the annular ligament extending to the stapedial footplate and causing minimal fixation.

Figure 144-2. Three otosclerotic lesions involving the cochlear capsule. The largest one in the anterior oval window area also is fixing the stapedial footplate. This patient had sensorineural hearing loss and conductive loss caused by stapedial fixation.

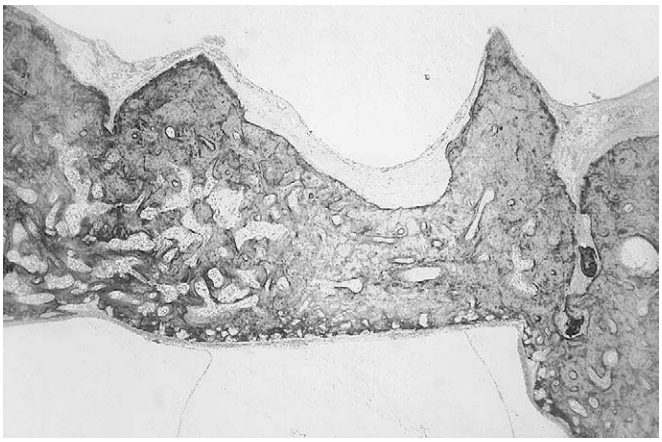

Figure 144-3. A solid stapedial footplate wherein the annular ligament has been totally replaced with otosclerosis.

The lesion may replace the entire footplate, causing a solid footplate (Fig. 144-3).

Occasionally, the lesion may involve only the cochlea, causing an isolated sensorineural hearing loss (Fig. 144-4). Sometimes the entire cochlea is surrounded by otosclerosis, causing total deafness. In the United States, 20 of the first 57 patients to have a cochlear implant were made deaf by otosclerosis.[12]

Evaluation

History

History is one of the most important aspects of the evaluation. Typically, with otosclerosis, hearing loss is of gradual onset and progresses slowly over several years. Approximately 70% of otosclerosis cases are bilateral and become apparent in individuals in their late teens or 20s. Hearing loss may not become apparent to the patient until age 30 or 40 years. Because most patients with otosclerosis have a conductive hearing loss, the patients report difficulty hearing conversation while chewing and may hear better in noisy rooms because of a phenomenon known as paracusis of Willis. This phenomenon is characteristic of conductive hearing loss and occurs because people speak louder in noisy surroundings. Unilateral hearing loss is less noticeable to the patient. With unilateral hearing loss, patients tend to have difficulty with direction of sound and in noisy rooms.

There is usually a positive family history of hearing loss and often of surgical correction of hearing loss. The patient usually has a negative

Figure 144-4. Large otosclerotic lesions surround the cochlea, but spare the oval window area and the stapes. This patient had sensorineural hearing loss.

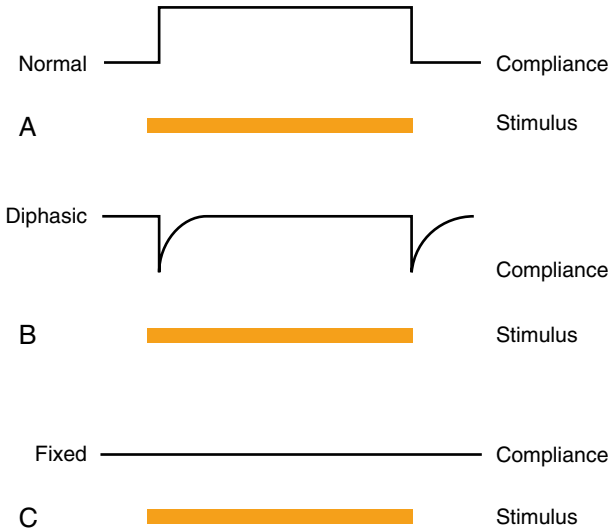

Figure 144-5. Progressive changes in the configuration of the acoustic reflex with stapedial fixation. **A,** Healthy reflex with a sustained change in compliance as long as the stimulus is on. **B,** Diphasic reflex with an on-off pattern. This is seen in cases of early otosclerotic stapedial fixation. **C,** As the stapes becomes fixed, the diphasic reflex is replaced by an absent acoustic reflex.

history for infections or trauma as a possible cause of the conductive hearing loss.

Physical Examination

Physical examination includes careful otoscopy, often with the operating microscope. Pneumo-otoscopy is important to rule out middle ear serous fluid or a small perforation that could be the cause of a conductive hearing loss. There may be a red blush over the promontory or the area anterior to the oval window, known as the Schwartze sign. Tuning forks are essential for evaluation of any patient with a hearing loss[13] because they may confirm or dispute the finding of a conductive hearing loss on audiometry.

The Weber test is performed by placing a 512-Hz fork on the center of the forehead, bridge of the nose, or anterior incisors. The Weber test lateralizes to the ear with the conductive or greater conductive hearing loss (in the case of bilateral disease). It lateralizes with 5 dB of conductive hearing loss. The Rinne test compares the patient's perception of the relative loudness of air conduction versus bone conduction. It is performed by placing the base of a 512-Hz or 1024-Hz fork over the antrum behind the ear. The sound is compared with the loudness when the tines are placed about 2 to 3 cm from the external ear canal. The tines of the fork should be parallel with the plane of the canal. The Rinne test is sensitive and can be used to predict the degree of the conductive component of the hearing loss. When the 512-Hz fork reveals bone conduction greater than air conduction, the patient has at least a 15-dB to 20-dB conductive hearing loss. If the patient reverses the 512-Hz and 1024-Hz forks, the loss is at least 30 dB. Surgery should not be performed on a patient with a conductive hearing loss if the 512-Hz fork does not reverse.

Audiometry

The audiometric evaluation includes air conduction, bone conduction, and speech audiometry, and is usually performed by a trained audiologist. Because otosclerosis may cause unilateral conductive hearing loss, masking is important and may present problems for the tester.

The immittance audiometry battery consists of tympanometry, static compliance, and acoustic reflex testing. Immittance audiometry can be helpful in some cases of otosclerosis, confirming lack of mobility of the stapes with absent acoustic reflexes. The middle ear pressure is not affected by otosclerosis, and the tympanogram is normal with a distinct peak that occurs within the normal range. Many conditions affect the tympanogram, such as scarring of the tympanic membrane or tympanosclerosis. These conditions may coexist with otosclerosis. The peak may be lower than normal in the presence of a healthy-appearing tympanic membrane, alerting the examiner to the possible diagnosis.

Acoustic reflexes are a sensitive measure of the movement of the stapes. In the presence of otosclerosis, the reflex is absent. With early stapes fixation, the reflex may be abnormal in that there is a negative on-off effect or diphasic reflex (Fig. 144-5). With more advanced disease, the reflex is absent when the probe is in the involved ear. As the disease and hearing loss worsen, the contralateral reflex is affected as a result of the degree of conductive hearing loss in the otosclerotic ear. Hannley[14] wrote an excellent article about audiologic evaluation of a patient with otosclerosis.

Surgery

Small Fenestra Stapedotomy

Before surgery is considered, the risks, complications, and alternatives are thoroughly discussed with the patient. Although the risk of sensorineural hearing loss is low, the patient needs to be informed of this possibility. Total sensorineural hearing loss occurs in about 0.2% of cases, but the patient is told that there is a less than 2% chance of further hearing loss, and a less than 1% chance of losing all hearing in the operated ear. Because of the slight chance of further or total hearing loss. the poorer hearing ear is selected for surgery. We never operate on the only-hearing ear or better hearing ear.

There is a slight chance of dizziness postoperatively. This possible complication must also be discussed with the patient before surgery. Dizziness is usually transient and brief, but may persist, and in extremely rare cases could be permanent. The possibility of facial palsy is mentioned in written material, but is not discussed because of the extremely rare incidence of this complication. In a review of more than 700 stapedectomies at the House Ear Clinic, only 2 patients had transient facial weakness of delayed onset. Since the senior author has been performing small fenestra stapedectomy, he has not seen postoperative temporary facial palsy.

Surgery is usually performed as an outpatient procedure with the patient under local anesthesia. We prefer local anesthesia because (1) an awake patient can inform the surgeon if vertigo occurs, and (2) the surgery is usually of short duration with minimal discomfort and does not warrant the risks or costs of general anesthesia.

An intravenous line is placed, and the patient is given sedation with midazolam (0.5 to 2 mg) as needed; this is occasionally supplemented with intravenous morphine (2 to 4 mg). The ear is anesthetized with 1% or 2% lidocaine with epinephrine 1:100,000. To lessen the pain associated with the injection, 18 mL of lidocaine can be buffered with 2 mL of 7.5% bicarbonate.

Figure 144-6. The operating room during stapes surgery. The nurse is on the opposite side of the patient, and the microscope is at the head of the table.

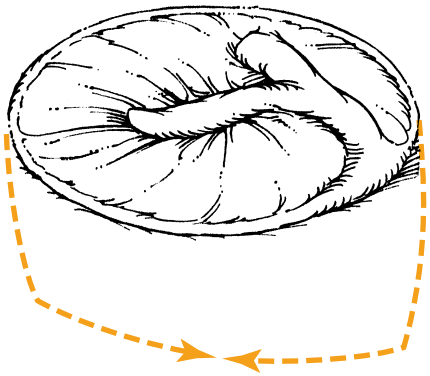

Figure 144-7. The tympanomeatal flap is elevated after the initial incisions are performed.

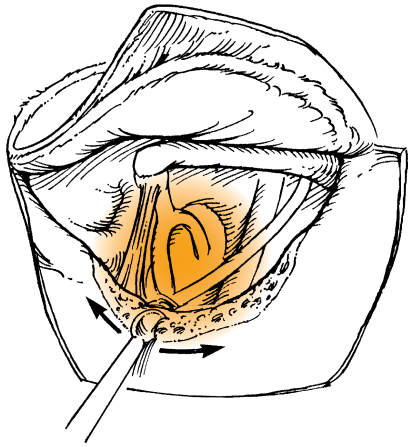

Figure 144-8. The curet is used to remove the posterior superior bony canal wall to obtain better visualization of the stapes.

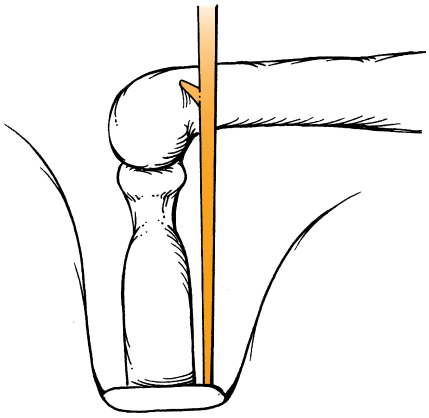

Figure 144-9. The distance from the incus to the footplate is measured from the lateral or medial surface of the incus. The usual distance from the lateral surface to the footplate is 4.5 mm.

The patient is placed supine on the operating table with the head turned away from the surgeon. The microscope is placed at the head of the table with the nurse standing across the table from the surgeon (Fig. 144-6). If general anesthesia is used, the anesthesiologist is seated at the foot of the table.

There are many variations in the basic stapedectomy technique. Any technique that produces comparably good results should be continued.

The four quadrants of the ear canal are injected at the level of the hair-bearing area. This injection works best if placed just under the skin. A fifth injection is placed in the vascular strip down to the bone. If a tissue graft is to be used, the superior postauricular area is prepared and injected. Some surgeons use a vein graft; in this case, the graft is harvested from the hand before beginning the stapes surgery.

Incisions are performed with a sickle knife (No. 1) at the lateral process of the malleus and inferiorly at about the lower one fourth of the canal extended laterally approximately 8 mm. These two incisions are connected laterally with a House canal knife (No. 2). This flap is elevated evenly from lateral to medial with a canal elevator or a round knife (Fig. 144-7). It is important to elevate all of the flap at the same time so as not to tear it. When the anulus is reached, it is carefully exposed and elevated out of its bony canal with an anulus elevator "gimmick". Care is taken during elevation to identify the chorda tympani nerve so that it is not stretched or injured. The superior elevation is carried forward to the malleus. Care is taken not to dislocate the incus. Usually the stapes is not entirely visualized because of the bony posterior superior external auditory canal overhang. This overhang is removed with a curet; alternatively, some surgeons prefer a microdrill (Fig. 144-8). The exposure is adequate when the facial nerve can be visualized superiorly, and the pyramidal process can be visualized posteriorly.

When adequate exposure is established, the malleus, incus, and stapes are palpated to ascertain mobility. The distance from the incus to the stapes footplate is measured (Fig. 144-9). The usual distance from the lateral surface of the incus to the footplate is 4.5 mm. Because the piston prosthesis is usually measured from the medial surface of the incus, 0.25 mm is subtracted to allow for this distance (incus = 0.5 mm + extension into vestibule of 0.25) (Fig. 144-10). The most common piston size is 4.25 mm.

A 0.7-mm diamond microdrill is used to create the fenestra. Usually there is adequate room between the facial nerve and the crus of the stapes to use the drill on the footplate. Despite this, part of the posterior crura is drilled to warn the patient of the drill noise, weaken the crura for easy fracture, and, at times, allow better access to the footplate (Fig. 144-11). The laser can be employed to begin the fenestra. If the footplate is thin, the drill may not be needed to complete the opening.

The fenestra is created with a light touch of the drill (Fig. 144-12). The diamond is allowed to create the fenestra without applying pressure. Excess pressure may fracture the footplate. When the drill is felt to drop into the vestibule, a perfect 0.7-mm fenestra is completed. The 4.25-mm length, 0.6-mm diameter platinum Teflon (polytetrafluoroethylene) prosthesis is placed from the incus to the fenestra (Fig. 144-13). It is crimped firmly on the incus (Fig. 144-14). The incudostapedial joint is separated, and the stapedial tendon is sectioned. The

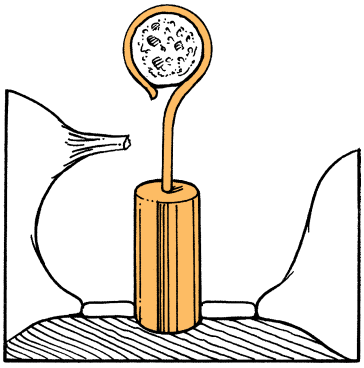

Figure 144-10. Cross section of the stapes footplate with the prosthesis extending about 0.25 mm through the footplate into the vestibule.

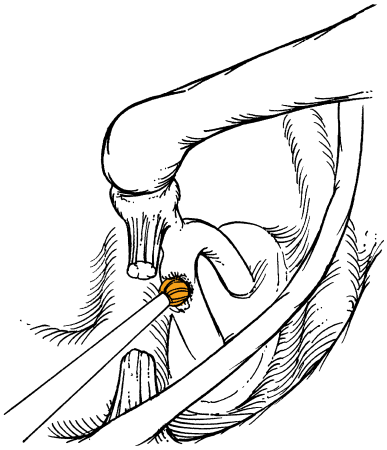

Figure 144-11. The diamond bur sometimes may be used to remove the posterior crus or weaken it.

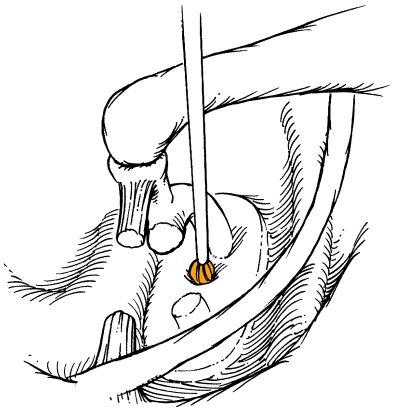

Figure 144-12. The microdrill and 0.7-mm diamond bur create a fenestra in the center of the stapes footplate. The fenestra is created before removal of the stapes superstructure.

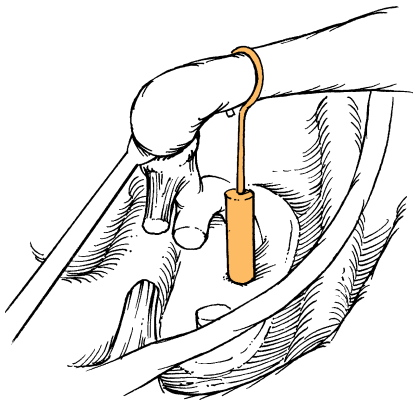

Figure 144-13. The piston is placed from the incus to the fenestra before removal of the superstructure.

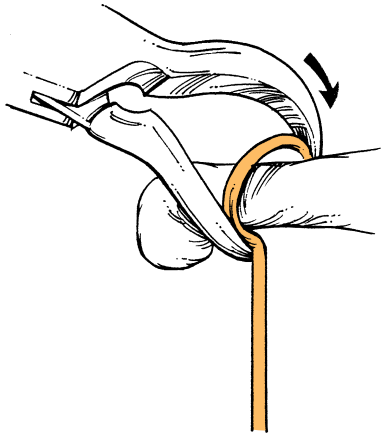

Figure 144-14. The piston is crimped around the incus before removal of the superstructure of the stapes.

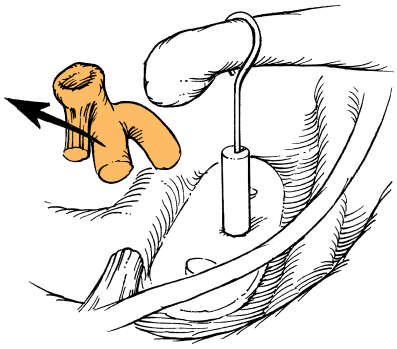

Figure 144-15. After removal of the stapes superstructure, blood is placed into the oval window as a seal.

superstructure of the stapes is fractured inferiorly with a quick, decisive movement and removed (Fig. 144-15). A test of the prosthesis is performed to check the position. The medial lateral excursion is checked with light manipulation. The patient is asked if this causes vertigo. If it does, the prosthesis may be too long. If it does not, the anterior posterior movement is checked. If the prosthesis is properly in the fenestra, there is no anterior posterior displacement.

Blood is placed around the prosthesis as a seal in the oval window, and the tympanomeatal flap is returned to its normal position. Minimal packing is required on the flap, a cotton ball is placed in the meatus, and a bandage is applied to the ear.

Postoperative Care

Immediately after surgery, the patient's head is elevated about 30 degrees to reduce the perilymph pressure in the vestibule. The patient is kept at bed rest for about 1 hour and then allowed to get up. If no vertigo or dizziness is present, the patient may go home about 2 hours after surgery. Most patients stay in the hospital for 2 to 4 hours. The

patient is instructed to remove the bandage and cotton the next day and return to the office in 3 weeks. Patients are also instructed to call if they experience any unusual problems, such as pain, drainage, or vertigo. The first audiogram is obtained at the 3-week postoperative visit. Patients can fly after postoperative day 5, if necessary.

After stapes surgery, some patients inquire about resuming sports such as scuba diving or skydiving, which presumably increase the risk of inner ear barotrauma and associated perilymphatic fistula. A uniform consensus on barorestrictions after stapes surgery has yet to be reached; however, review of patients who continue to participate in these activities after stapedectomy reveals no increased risk of inner ear barotrauma.[15] In our practice, postoperative guidelines typically call for dry-ear precautions for the first 3 weeks, with swimming and diving permitted 3 weeks after surgery.

Variations of Surgical Technique

Stapedectomy versus Stapedotomy

The past 50 years have seen many innovations in the surgical management of otosclerosis. The original stapedectomy as described by Shea[16] was a total stapedectomy that used picks and hooks to remove the entire footplate and replace it with a vein graft and polyethylene strut. This technique evolved to the use of a wire or piston prosthesis. House[17] used a total stapedectomy with wire over an absorbable gelatin sponge (Gelfoam) or fat graft. Glasscock and colleagues[18] reported 25 years' experience with total stapedectomy by use of a tissue seal over the oval window. Others have performed a partial stapedectomy, removing only the posterior half of the footplate. With these large fenestra techniques, the footplate is opened with either picks or a microdrill.

More recently, there has been a greater trend away from total stapedectomy and large fenestra techniques to small fenestra stapedotomy.[19-21] Proponents of small fenestra techniques argue that limited opening of the vestibule carries a lower risk of damage to the inner ear and resultant sensorineural hearing loss (particularly for the 2-kHz and 4-kHz frequencies)[19,20] or vertigo or both. Comparisons[22-24] of short-term and long-term results of stapedectomy with results of stapedotomy show slightly better early and late postoperative air-conduction thresholds at 4 kHz in patients undergoing small fenestra stapedotomy. Likewise, a lower rate of postoperative high-frequency sensorineural hearing loss is noted in the stapedotomy group. No significant difference in early or late postoperative pure-tone average, pure-tone average air-bone gap, or speech discrimination scores is noted, and outcomes in both groups remain stable over long-term follow-up. Generally, either technique can be used in the hands of an experienced surgeon to obtain satisfactory and stable long-term hearing results.

Laser versus Microdrill

Current methods of performing small fenestra stapedotomy involve various techniques, including the use of lasers, microdrills, or fine picks. Two types of lasers are being used by surgeons to create the fenestra in the footplate of the stapes: the visible argon or potassium-titanyl-phosphate (KTP-532) and the infrared carbon dioxide (CO_2). The visible argon laser beam can be carried through fiberoptic cable, whereas the CO_2 requires a series (usually ≥12) of carefully aligned mirrors and lenses to deliver the beam to the microscope. Recently, OmniGuide has developed a flexible fiber that has eliminated the need for the fixed mirrors. Perkins[25] was the first to describe the use of the argon laser to create a small fenestra. Horn and coworkers[26] modified his technique by developing a fiberoptic laser delivery system. The argon laser is similar in frequency to the KTP-532. The beam from both lasers is preferentially absorbed by red pigment, such as hemoglobin. Horn and coworkers[26] believe that the handheld probe has the advantage in that the laser beam has a greater divergence than the microscope-mounted micromanipulator, and it has less potential to damage the contents of the vestibule. The argon laser and the KTP laser have been shown to be safe and effective in creating the footplate fenestra.[24]

Lesinski and Newrock[27] prefer the CO_2 laser for primary and revision stapes surgery. These authors believe that the CO_2 laser energy is more efficiently absorbed by collagen and bone than is visible argon laser energy. In their opinion, a pulsed CO_2 laser is more effective in performing primary stapes and revision stapes procedures. Lesinski and Newrock[27] point out that because visible lasers are poorly absorbed by collagen and pass readily through perilymph, they should not be used for stapedectomy revision surgery.

Successful small fenestra stapedotomies have been performed with lasers and microdrills. Proponents of the laser argue that it may reduce the mechanical trauma to the stapes, causing decreased labyrinthine irritation and possibly better results.[24] In our experience, the microdrill is just as safe and efficacious as the laser and, in some ways, is the better choice because of its increased usefulness when one is faced with a thick footplate. One may use the laser to thin the footplate and finish the fenestra with the 0.7-mm diamond bur. Comparison of the microdrill with visible wavelength lasers (argon and KTP) in performing small fenestra stapedotomy reveals no significant differences in the postoperative pure-tone average or individual frequencies.[24] Evaluation of postoperative sensorineural hearing loss shows no significant difference between the two methods used to create the fenestra.

Laser Stapedotomy Minus Prosthesis

In addition to standard techniques of surgically treating otosclerosis, newer, alternative methods of attempting hearing restoration continue to evolve. In cases of minimal otosclerosis confined to the fissula antefenestrum, Silverstein[28] advocates a linear, laser stapedotomy at the anterior one third of the footplate followed by vaporization of the anterior stapes crus to allow the stapes to become mobile. The stapedotomy is sealed with adipose tissue. In this way, the patient's stapes and stapedius tendon can be preserved, avoiding the need for a prosthesis. At some point in the future, should the stapes become refixed, a revision procedure with the use of a prosthesis can be performed. Early hearing results in patients undergoing laser stapedotomy minus prosthesis (STAMP) are comparable to results obtained after conventional stapedotomy with prosthesis; however, long-term follow-up is required to determine whether these hearing results are maintained.

Surgical Problems

Exposed, Overhanging Facial Nerve

Exposed facial nerve occurs in about 9% of stapes procedures. Usually, it does not present a problem. Occasionally, the exposed nerve blocks access to the footplate, making the completion of the procedure impossible. It is possible to retract the nerve gently superiorly with a small suction while the drill or laser is used to create the fenestra (see Fig. 144-11). Prosthesis touching the facial nerve does not create a problem for postoperative hearing or facial function.

Fixed Malleus

Fixed malleus is a rare problem, but should be checked in every procedure. It is usually associated with stapes fixation, but it may be an isolated finding. When this occurs, the sound-conducting mechanism can be re-established with an incus replacement prosthesis or a total ossicular replacement prosthesis and tragal cartilage.

Solid or Obliterated Footplate

A solid or obliterated footplate can be managed with a microdrill to create a fenestra. It was a greater problem in the past when a total stapedectomy was performed. It was difficult to drill through the footplate, and the bony closure would commonly regrow and cause increasing conductive hearing loss. In the past, these drill-outs were associated with a higher incidence of sensorineural hearing loss.[29]

Floating Footplate

A floating footplate is rare with the use of the laser or microdrill, especially when the crura are left in place until after the prosthesis is placed. This complication can be managed by carefully drilling a small hole in the promontory at the inferior edge of the footplate. A small hook can be used to elevate the footplate gently out of the oval window. Another alternative is to place a slightly short wire or piston from the incus to the floating footplate. If the conductive hearing loss recurs, the procedure can be revised with a laser to create the fenestra.

Perilymph Gusher

A rare occurrence, a perilymph "gusher" is the profuse flow of cerebrospinal fluid immediately on opening the vestibule. It has a reported incidence of 0.03%, and is most often associated with congenital footplate fixation in pediatric patients.[30] It is advisable to obtain a high-resolution, thin-section computed tomography (CT) scan in children with congenital conductive or mixed hearing loss to rule out inner ear deformity. In this way, the gusher can be avoided. This cerebrospinal fluid leak is thought to be due to either a widened cochlear aqueduct or a defect in the fundus of the internal auditory canal. Management of a perilymph gusher typically involves placement of a tissue graft over the oval window and completion of the procedure, if possible, rather than packing the ear and terminating the surgery. A lumbar drain can also be used to reduce cerebrospinal fluid pressure.

Tympanic Membrane Perforation

A perforation of the tympanic membrane may occur during elevation of the tympanomeatal flap. This complication usually occurs during elevation of the tympanic membrane from the sulcus in the posterior inferior area and can be avoided with careful identification of the annular ligament. Perforation does not preclude completion of the operation, and small perforations usually heal with placement of a small piece of Gelfoam or paper patch over the hole. Larger tears may require an underlay myringoplasty using tissue.

Chorda Tympani Nerve Damage

Damage to the chorda tympani nerve may occur in 30% of cases because of stretching and mobilization of the nerve during removal of the posterior superior bony canal wall.[30] Patients may complain of temporary dry mouth, tongue soreness, or a metallic taste that usually subsides in 3 to 4 months. Less severe symptoms are reported with complete sectioning of the nerve, rather than stretching or partial tearing.

Intraoperative Vertigo

A prosthesis that is too long may induce vertigo at the time of placement, or when its mobility is checked. In this situation, a shorter prosthesis generally corrects this problem. After placement of the prosthesis, the ossicular chain should be palpated, and the patient should be questioned about the occurrence of dizziness. Rarely, postoperative patients complain of brief vertigo when they burp or push on the ear canal. They have a positive "fistula test." This vertigo is usually due to a slightly long prosthesis. If this does not resolve, and the patient is bothered by the symptom, the prosthesis can be removed and replaced with a 0.25-mm shorter piston.

Postoperative Complications

Sensorineural Hearing Loss

The most devastating complication, sensorineural hearing loss, occurs in less than 1% of cases, and the cause is often unclear. In our review of more than 1000 stapedectomies, total sensorineural hearing loss occurred in 2 cases.[31] In one, the patient had a postoperative infection, and in the second, the patient probably had concurrent Meniere's disease. In both cases, there was no associated vertigo. Sensorineural hearing loss may be mild or isolated to high frequencies. When sensorineural hearing loss is suspected, prednisone is started immediately and tapered over 10 days. The course begins with 60 mg/day for 5 days. On the sixth day, the dose is reduced to 40 mg for 1 day, followed by a 10-mg/day reduction until the 10th day.

Serous labyrinthitis is common after stapedectomy because of a certain amount of inflammation within the inner ear. Clinically, patients may exhibit mild unsteadiness, positional vertigo, or a slight decrease in high-frequency hearing. These symptoms typically resolve within several days to weeks.

Rarely seen today, postoperative reparative granuloma has previously been recognized as a cause of sensorineural hearing loss after stapedectomy.[30] Patients typically have initial improvement in hearing followed by a gradual or sudden deterioration 1 to 6 weeks postoperatively. Vertigo may also be associated with hearing loss, and clinical examination often reveals a reddish discoloration in the posterior superior quadrant of the tympanic membrane. Granuloma formation is believed to be associated with the previous use of Gelfoam or fat as a covering over the oval window. Treatment consists of prompt recognition and removal of the granuloma from around the oval window.

Vertigo

Mild vertigo or dizziness is common and occurs in about 1 of 20 cases. The vertigo usually lasts for a few hours and subsides rapidly. It is rarely prolonged or severe. Management is usually unnecessary or may be supportive only.

Facial Paralysis

Rarely, delayed onset of facial palsy occurs about 5 days postoperatively and lasts for a few weeks. It is usually incomplete and responds quickly to prednisone.

Tinnitus

After stapedectomy, most patients note an improvement in preexisting tinnitus. A few patients complain of new-onset tinnitus, however. This symptom is possibly related to serous labyrinthitis and may improve as the ear continues to heal. Patients with persistent tinnitus are treated with reassurance and routine tinnitus measures.

Taste Disturbance

Taste disturbance occurs in about 9% of patients. This is more common in patients whose chorda tympani nerve was stretched rather than sectioned. If the nerve has been stretched or otherwise injured, it is preferable to section it. Most taste disturbance resolves in 3 to 4 months.

Tympanic Membrane Perforation

If the patient returns to the office with a small marginal perforation, the edges are freshened, and a paper patch is applied. The patient should be seen about once per month so that the paper patch can be removed, and if the perforation has not healed, the edges are freshened and the patch reapplied. Most of these perforations heal quickly. If they do not heal, a myringoplasty can be performed.

Perilymph Fistula

Perilymph fistula is a rare complication after stapes surgery. The incidence varies from 3%[32] to 9% or 10%.[33-35] The most common cause of fistula in fistula exploration surgery was poststapedectomy.[36] These cases date back many years and were performed by use of total stapedectomy with a Gelfoam and wire technique. With the use of a small fenestra technique, fistula is rarely seen as a cause of failure in stapes surgery. The presenting problem with fistula is usually a mixed conductive sensorineural hearing loss. It may be associated with some vague unsteadiness and, rarely, vertigo. At revision surgery, the prosthesis is carefully removed, a tissue seal is placed over the open oval window, and the prosthesis is replaced. A laser is helpful to remove granulation and scar tissue.

Alternative Treatment

Hearing Aids

All patients with conductive hearing loss caused by otosclerosis may use hearing aids as an alternative to surgery; this should be discussed with the patient as an option. If the patient has a significant sensorineural component to the hearing loss, a hearing aid may be required even after successful stapedectomy. A patient with far-advanced otosclerosis requires a hearing aid at all times, but with a successful surgery, the patient can use a less powerful hearing aid. Many patients with far-advanced otosclerosis require time to adjust to the new hearing level and are sensitive to the sound of their hearing aid. It may take 4 months before these patients can tolerate and benefit from the hearing aid.

Fluoride Therapy

Sensorineural hearing loss often develops in patients with otosclerosis because of spongiotic foci involving the otic capsule. Injury to the inner ear is believed to occur as a result of the spread of proteolytic enzymes

to the inner ear fluids from an active otospongiotic focus, with resultant injury to the organ of Corti and spiral ligament.[37] In patients with evidence of progressive sensorineural hearing loss, fluoride therapy has been shown to reduce the progression of hearing loss.[37] The mechanism of action is believed to be the conversion of the active otospongiotic lesion to a more stable otosclerotic lesion. Patients are typically treated with Florical, 8 mg three times per day, until hearing loss stabilizes. Gastric distress is a side effect of fluoride medications; however, most patients tolerate this effect without difficulty.

Special Considerations

Far-Advanced Otosclerosis

Patients with far-advanced otosclerosis seemingly have a blank audiogram, or what seems to be a profound sensorineural hearing loss, yet they may benefit from a stapedectomy. The hearing loss seems profound only because the limit of the audiometer for bone conduction is 70 dB; if the bone conduction threshold were greater, the patient would seem to have no response. This condition is suspected if the patient can benefit from a hearing aid and has relatively normal speech and good speech comprehension. These patients typically have a positive family history for otosclerosis and a history of a progressive hearing loss since the second or third decade. At surgery, a fixed stapes is found with postoperative improvement of hearing. Such patients subsequently obtain better use of a hearing aid. Because of long-standing, severe hearing loss, these patients require time to improve their tolerance to amplification.

Patients with far-advanced otosclerosis who progress to profound hearing loss with significant deterioration in speech discrimination despite hearing aids may be candidates for cochlear implantation. Careful evaluation of these patients is undertaken to ensure that they would not benefit first from a stapedectomy and hearing aid. The patient undergoes routine evaluation through the cochlear implant program. Results at our own institution (unpublished observation) and results of other authors[38] show that these patients derive significant benefit from cochlear implantation and are capable of achieving excellent speech comprehension.

Meniere's Disease

Endolymphatic hydrops may occur with otosclerosis as two separate disease entities or as a result of otosclerosis itself. Stapedectomy in the presence of uncontrolled Meniere's disease can potentially result in a dead ear and should be avoided. Fluoride therapy and hearing aids are an acceptable treatment in such patients. Shea and coworkers[39] note that if Meniere's symptoms can be controlled for at least 1 year, as evidenced by electrocochleography, stapedectomy can be performed with a decreased risk of hearing loss. Review of patients with otosclerosis and Meniere's disease at the House Ear Clinic revealed that stapedectomy does not increase the risk of sensorineural hearing loss for patients with bone conduction thresholds of 35 dB or better at 500 Hz and no high-tone hearing loss. Stapedectomy is contraindicated for patients with levels of 45 dB or greater at 500 Hz and with high-tone loss. In this latter group of patients, postmortem histopathologic analysis revealed contact of the saccular membrane or Reissner's membrane with the stapes footplate, which increased the risk of significant postoperative sensorineural hearing loss.[40]

Stapedectomy in Children

Stapedectomy in children is performed for correction of conductive hearing loss caused by congenital footplate fixation or juvenile otosclerosis. Before considering surgery, a CT scan should be performed to evaluate abnormalities of the otic capsule, such as defects in the fundus of the internal auditory canal as seen in patients with X-linked mixed deafness. Stapedectomy in these patients may lead to a perilymph gusher and additional hearing loss.

Generally, the results of stapedectomy in children seem to be as satisfactory as results in adults. When recommending surgery to children, a good outcome can be anticipated in approximately 80% of cases.[4,41] Children younger than age 5 with a conduction hearing loss greater than 30 dB should be fitted with a hearing aid after otitis media and cholesteatoma have been ruled out. In unilateral cases with a normal contralateral ear, surgery may be postponed until the child is old enough to participate in the decision process. Children who are older than age 5 with bilateral congenital stapes fixation, an air-bone gap greater than 30 dB, and speech reception threshold greater than 35 dB may be considered surgical candidates if the child or parents do not accept hearing aids. Parents are warned of the potential risks and complications associated with surgery.

Revision Stapedectomy

Revision stapedectomy is considered to be more challenging than primary surgery, and hearing results are typically not as good. A more recent review of revision stapedectomy procedures at the House Ear Clinic revealed an overall rate of air-bone gap closure to within 10 dB and 20 dB of 60% and 78%.[42] The most common cause for failure of primary stapedectomy is displaced prosthesis (53%), incus erosion (26%), and bony regrowth (14%). The rate of postoperative sensorineural hearing loss is 7.7%, and profound loss is 1.4%. Revision stapedectomy is technically more difficult; however, acceptable hearing results can be obtained in appropriately selected patients.

We believe that revision surgery is best performed under local anesthesia so that the patient can be monitored for vertigo. If the piston has been displaced into the vestibule, it may be extracted carefully while asking the patient if he or she is experiencing vertigo. In these cases, the incus is eroded and can no longer support the prosthesis. The incus can be reinforced using Mimix bone cement, an offset prosthesis such as the Kurz angular prosthesis (www.kurzmed.de/int/angular-piston.html), or a total ossicular replacement prosthesis from the tympanic membrane to the oval window.

A wide variety of stapes prostheses are available for primary and revision stapes surgery. The magnetic resonance imaging (MRI) compatibility of the myriad types of stapes prostheses has been confirmed, with the rare exception of a line of prostheses manufactured in 1987.[43]

Summary

Hearing loss caused by otosclerosis is typically a progressive conductive loss that begins in individuals in their 20s and may progress to a mild, moderate, or, in rare cases, severe hearing loss. It is not unusual to have some degree of sensorineural component to the hearing loss. Surgery for otosclerosis has evolved over the past 70 years to a safe and effective method for restoring hearing. Complications are rare, and the surgery is performed as an outpatient procedure with local anesthesia in most cases. Hearing aids also have improved over the past 70 years, and are an option for patients who choose not to have surgery.

CHAPTER ONE HUNDRED AND FORTY-FIVE

Management of Temporal Bone Trauma

Hilary A. Brodie

Key Points

- Otic capsule disrupting fractures have a fourfold to fivefold higher risk of facial paralysis and a twofold to fourfold increased risk of a cerebrospinal fluid (CSF) fistula when compared with otic capsule sparing fractures.
- Temporal bone fractures in the pediatric population are associated with a higher incidence of intracranial complications (58%) and a lower incidence of facial paralysis (3%) than in adults.
- Seven percent of temporal bone fractures are complicated by facial paralysis.
- The most important prognostic factor in facial paralysis following temporal bone fractures is whether there is an immediate onset complete paralysis upon admission to the emergency department. Delayed-onset facial paralysis generally has an excellent recovery of function.
- In the absence of immediate onset of complete facial paralysis following temporal bone trauma, rarely is surgical exploration and decompression warranted.
- Facial nerve exploration, decompression, and repair can often be achieved via a supralabyrinthine approach without a middle fossa exposure.
- The incidence of meningitis following a temporal bone fracture without a CSF fistula is 1%.
- The incidence of CSF fistulas with temporal bone fractures is 17%.
- Meningitis occurs in 5% to 11% of CSF fistulas that persist for less than 1 week; the percentage increases to 88% if left to leak indefinitely.
- Hearing results following ossicular reconstruction in patients with temporal bone fractures is superior to the results in patients with chronic otitis media.

Epidemiology

Motor vehicle accidents commonly result in head trauma of varying degrees of severity. In the past, 75% of motor vehicle accidents resulted in a head trauma; however, the increased use of seatbelts and the advent of airbags may alter these statistics in the future. When the head trauma is of sufficient magnitude to fracture the skull, 14% to 22% of injured patients sustain a temporal bone fracture.[1,2] In the largest series of temporal bone fractures reported to date, 31% of the fractures resulted from motor vehicle accidents (Fig. 145-1).[3]

Temporal bone fractures are reported to occur across all age groups, with more than 70% of fractures occurring during the second, third, and fourth decades of life.[3] These fractures occur predominantly in men in a ratio of 3:1,[3] which is attributed to involvement in riskier activities rather than to structural weaknesses in the male skull.

Pathophysiology

The temporal bones are pyramidal structures in the thick bone of the skull base and consequently require a great force to fracture. The force of lateral impact required to fracture the temporal bones of fresh cadavers is estimated at 1875 pounds.[4] The fractures take the path of least resistance, which is along the structurally weakened points, such as the various foramina that perforate the skull base.

The temporal bone houses or encapsulates many important structures, including the facial nerve, cranial nerves IX through XI, the cochlea, the labyrinth, the ossicles, the tympanic membrane, the carotid artery, and the jugular vein. Any of these structures can be injured with a fracture of the bone. Fracture of the temporal bone can violate dura, resulting in cerebrospinal fluid (CSF) fistula, meningitis, and brain herniation. In addition to neurotologic manifestations of involved structures within the temporal bone, associated intracranial injuries, such as epidural or subdural hematomas, cerebral edema, post-traumatic encephalopathy, and elevated intracranial pressure, may occur. Neurotologic symptoms can also result from shearing strain within the brain tissue with disruption of vessels, axons, synapses, and dendrites.[5]

Sixty percent of temporal bone fractures are categorized as open fractures, presenting with bloody otorrhea, brain herniation, or CSF draining from the ear canal, eustachian tube, or penetrating wound site.[3] Eight percent to 29% of temporal bone fractures occur bilaterally.[3,6,7]

Classification

Temporal bone fractures have traditionally been divided into transverse and longitudinal categories on the basis of the relationship of the fracture line to the axis of the petrous ridge.[8] This classification has given

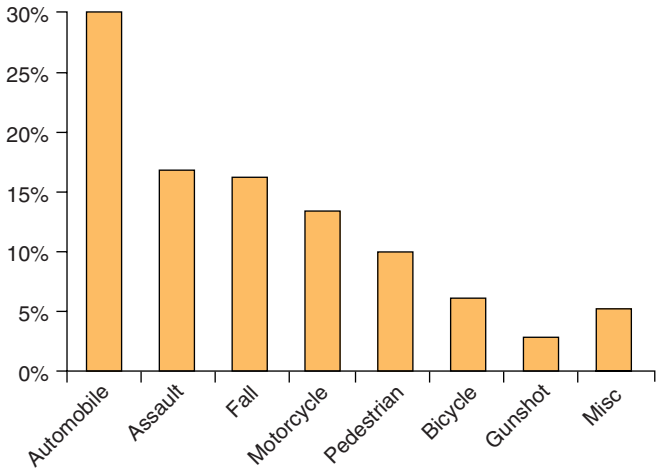

Figure 145-1. Type of injury. *(Data from Brodie HA, Thompson TC, Management of complications from 820 temporal bone fractures*. Am J Otol. *1997;18:188.)*

Figure 145-2. Axial-cut high-resolution computed tomography scan that demonstrates a longitudinally oriented fracture that is sparing the otic capsule. *Black arrows* point along the fracture line.

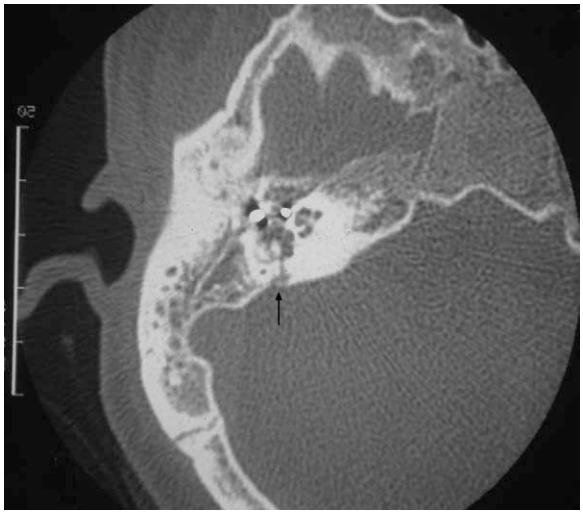

Figure 145-3. Axial-cut high-resolution computed tomography scan that demonstrates a transverse-oriented fracture resulting from a gunshot injury and disrupting the otic capsule. The *black arrow* points to the fracture line.

way to a new scheme that classifies fractures by whether they disrupt or spare the otic capsule (the bone that houses the cochlea and the semicircular canals) (Figs. 145-2 through 145-4).[3,9]

Fractures that spare the otic capsule typically involve the squamosal portion of the temporal bone and the posterosuperior wall of the external auditory canal. The fracture passes through the mastoid air cells and the middle ear and then fractures the tegmen mastoideum and tegmen tympani. The fracture proceeds anterolateral to the otic capsule, typically fracturing the tegmen in the region of the facial hiatus. Otic capsule–sparing fractures typically result from a blow to the temporoparietal region.

Otic capsule–disrupting fractures pass through the otic capsule, generally proceeding from the foramen magnum across the petrous pyramid and the otic capsule. The fracture often passes through the jugular foramen, the internal auditory canal, and the foramen lacerum; these fractures do not typically affect the ossicular chain or the external auditory canal.[10] Otic capsule–disrupting fractures generally result from blows to the occipital region.

Longitudinal fractures reportedly make up 70% to 90% of temporal bone fractures, with the remaining 10% to 30% categorized as transverse.[8-14] In two large series using the newer classification scheme, only 2.5% to 5.8% of fractures disrupted the otic capsule,[3,15] suggesting that many fractures that are oriented perpendicular to the petrous ridge do not actually cross the otic capsule. Many of the otic capsule–disrupting fractures are actually oriented in the longitudinal plane.[15]

The rationale for changing the classification scheme is to focus on the functional sequelae and complications of temporal bone fractures as opposed to merely describing the anatomic orientation of the fracture. Fractures that disrupt the otic capsule almost always result in a sensorineural hearing loss, although there are reported exceptions.[16] Otic capsule–sparing fractures tend to have conductive or mixed hearing loss,[3] whereas otic capsule–disrupting fractures have a much higher incidence of facial nerve paralysis (30% to 50% vs. 6% to 14%).[3,15] In addition, Fisch[17] reported a much higher incidence of nerve disruption in fractures involving the otic capsule. There is a twofold to fourfold increase in CSF fistula in otic capsule–disrupting fractures as

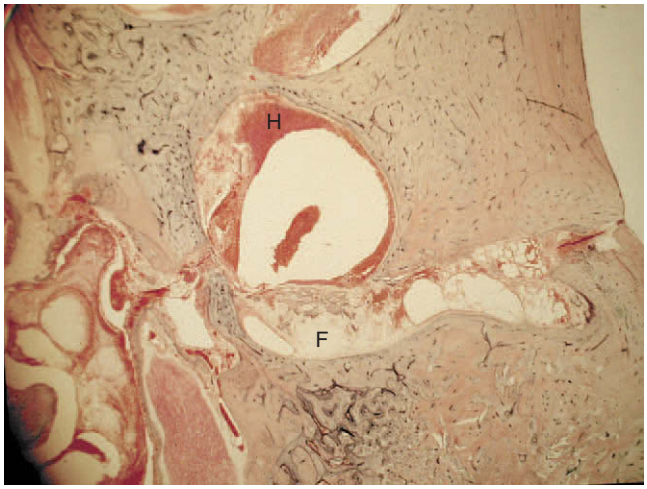

Figure 145-5. Histopathology of a patient who died of meningitis several decades after an otic capsule–disrupting temporal bone fracture. F, Fibrosis with a small amount of ossification within the fracture line in the otic capsule; H, hemorrhage and purulence.

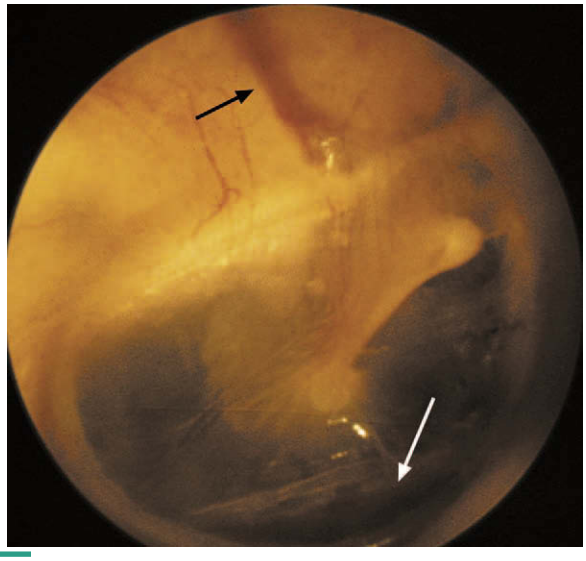

Figure 145-6. Otoscopic image that demonstrates a nondisplaced fracture along the scutum *(black arrow).* Blood is layering out inferiorly *(white arrow).*

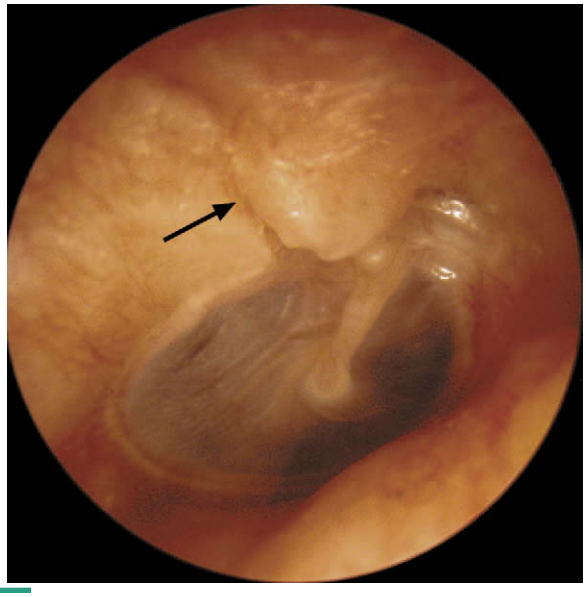

Figure 145-7. Otoscopic image that demonstrates a displaced fracture along the scutum *(black arrow).*

well as a much greater risk of intracranial injuries.[3,15] These fractures may also carry a higher risk of delayed meningitis due to an inability of the otic capsule enchondral bone to remodel and heal.[18,19] Pollak and colleagues[19] reported the case of a 51-year-old man who died of meningitis after having suffered an otic capsule–disrupting fracture during childhood. The histopathology of his temporal bone revealed pus in the middle ear extending through an unhealed fracture line across the otic capsule, and the fracture line contained a loose fibrous tissue. The membranous bone along the tegmen has the capability to heal, whereas the enchondral bone of the otic capsule does not. Fractures through the otic capsule generally partially fill with fibrous tissue and potentially seal with periosteal bone reaction on the surface of the otic capsule (Fig. 145-5).[19]

In addition to the predictive value for various complications and comorbidity, categorizing the fractures according to whether they are otic capsule sparing or disrupting guides the indications for surgical interventions for CSF fistula and facial paralysis as well as the surgical approach to be used in their repair.

Temporal bone fractures in the pediatric population differ somewhat from those in adults. There is a higher incidence of intracranial complications (58%) and a lower incidence of facial nerve paralysis (3%) in children.[20]

Evaluation

It is uncommon for temporal bone fractures to occur in isolation; consequently, the initial evaluation and management is focused on the emergent life-threatening issues of securing an airway, controlling hemorrhage, evaluating the neurologic status, and stabilizing and evaluating the cervical spine. The neurotologic examination assesses facial nerve function in the emergency department as early as possible, particularly before the administration of muscle relaxants, as discussed below. The ear examination focuses on the condition of the auricle, the ear canal, the tympanic membrane, and the middle ear.

The auricles are inspected for lacerations and hematomas. Lacerations are closed after thorough cleaning and débridement of exposed cartilage. Hematomas are drained, and pressure bolsters are sutured in place to close the dead space and prevent a recollection of blood. Untreated, the auricular hematomas result in an auricular chondropathy, which is also called "cauliflower ear."

The ear canal is inspected for fractures along the roof, CSF otorrhea, the degree of hemorrhage, and the presence of brain herniation. The ear is examined as aseptically as possible. Blood and cerumen in the ear canal should never be débrided with irrigation. After stabilization and transfer, the ear can be carefully examined with the aid of an operating microscope. Typical findings include fractures along the scutum and roof of the external auditory canal and tympanic membrane perforations. Hemotympanum or bloody otorrhea is almost invariably present (Figs. 145-6 to 145-8).

The ear canal is not packed initially unless packing is required to control significant hemorrhaging. If profuse hemorrhaging cannot be controlled with packing, the patient is taken to either the operating room for carotid ligation or the angiography suite for balloon occlusion.

When severely traumatized ear canals are identified, particularly in the presence of a penetrating injury, the patient is at high risk of stenosis or cholesteatoma formation. Although the ear canal is not stented acutely, it is imperative that the problem be identified and the patient followed closely. Early intervention with stenting at the onset of the stenosis can effectively prevent a problem that is much more difficult to address once the stenosis is mature.

The integrity of the tympanic membrane is assessed. Traumatic tympanic membrane perforations generally heal spontaneously; consequently no acute intervention is entertained.

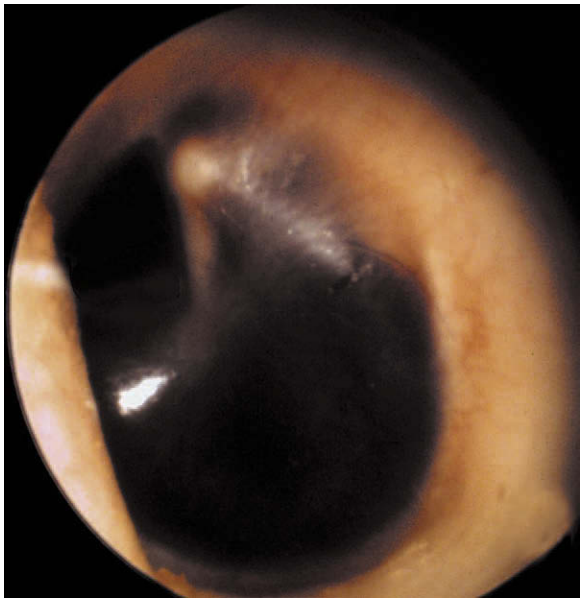

Figure 145-8. Otoscopic image that demonstrates a hemotympanum.

Figure 145-9. Otoscopic photograph that demonstrates a distracted fracture along the roof of the external auditory canal and scutum, thus allowing for the potential ingrowth of canal skin.

The neurotologic examination should also note the presence or absence of nystagmus and the type of nystagmus. Peripheral vertigo generally manifests with horizontal or rotatory nystagmus and is suppressible with visual fixation. Central vertigo may present with vertical or direction-changing nystagmus that fails to suppress and may even enhance with fixation. The most common type of vertigo after head trauma is benign paroxysmal position vertigo, which manifests with transient rotatory nystagmus with the Halpike maneuver.[21] The nystagmus occurs with the affected ear down. There is a 2- to 10-second latency followed by 10 to 20 seconds of rotatory nystagmus; the nystagmus is fixed in direction and is fatigable. Central vertigo induces direction-changing nystagmus, which has no latency and is not fatigable. Interestingly, the incidence of vertigo does not closely correlate with the severity of the trauma.[22]

The vast majority of posttraumatic vertigo cases resolve spontaneously. If the symptoms persist after discharge, an electronystagmogram can be obtained on an outpatient basis. A fistula test, which consists of applying positive and negative pressure in the ear canal with a pneumatic otoscope, is also not performed in the acute setting. The risk of additional iatrogenic injury and the potential for introducing infection or air into the inner ear outweighs the potential diagnostic benefits. If the patient continues to experience vertigo for 1 week after injury or is experiencing fluctuating or progressive hearing loss, a perilymph fistula is suspected, and a fistula test is performed. Nystagmus and vertigo suggest the presence of a perilymph fistula. The fistula test is not performed if there is evidence of a CSF fistula or of infection in the middle ear.

Hearing is assessed clinically at the bedside with a progressively louder whispered voice and with the use of tuning forks, but audiograms are not typically obtained until the patient's condition is stabilized. However, in the presence of the complications of facial paralysis or a CSF fistula, an audiogram is required before the surgical intervention, because the outcome of the audiogram significantly influences the treatment algorithm, as discussed later.

Patients with severe head trauma of the magnitude required for a temporal bone fracture generally already have had a computed tomography (CT) scan of the head to assess for intracranial hemorrhage. Additional imaging of the temporal bone with axial and coronal high-resolution CT scanning (HRCT) is indicated in the presence of facial paralysis, CSF fistula, disruption of the superior wall of the external auditory canal or scutum with potential trapping of epithelium (Fig. 145-9), or suspected vascular injury. HRCT of the temporal bone is also indicated if surgical intervention is required for the management of an otologic complication. Hearing loss (conductive or sensorineural) in the absence of other complications does not warrant additional temporal bone imaging. Demonstrating a transverse fracture through the otic capsule in a profound sensorineural hearing loss does not alter the treatment plan. Preoperative assessment with CT scanning in patients with a conductive hearing loss of sufficient magnitude to warrant exploration and ossicular reconstruction may provide useful information that may influence the surgical approach.

The role of HRCT in the evaluation of potential carotid artery injuries is unclear. Resnick and colleagues[23] reported a 5% incidence of carotid injury in basilar skull fractures if the fracture spares the carotid canal and an 18% incidence of carotid injury in patients with fractures through the carotid canal seen on HRCT. However, Kahn and colleagues[24] argues that, in an asymptomatic patient, HRCT demonstration of a fracture through the carotid canal yields no valuable additional information. Subsequent angiography performed in cases of asymptomatic carotid canal fractures yielded no evidence of carotid artery injury and provided no clinical utility.[24] Consequently, in completely asymptomatic patients who have sustained temporal bone fractures and who are neurologically intact, HRCT and angiography are not required. On the other hand, if there are any transient or persistent neurologic deficits in patients with basilar skull fractures, HRCT of the temporal bone and CT angiography are indicated (Fig. 145-10).

Conventional radiographs including Schüller, Towne, Chamberlain, Stenvers, and basal views as well as tomograms have been supplanted by HRCT scanning and no longer play a role in the evaluation of patients who are suspected of having a temporal bone fracture.

Management of Complications

The morbidity and mortality associated with temporal bone fractures result from injuries to the structures that pass through the temporal bone or that abut the temporal bone as described previously. The common complications include the facial nerve paralysis, sensorineural hearing loss, conductive hearing loss, CSF fistula, stenosis of the ear canal, cholesteatoma formation, and vascular injuries. The evaluation and management of these complications are discussed.

Facial Nerve Injury

Facial paralysis is a severely disfiguring complication of temporal bone fractures. Seven percent of temporal bone fractures result in facial paralysis; 25% of such cases involve complete paralysis.[3] The reported incidence in the literature of up to 30% is exaggerated by sampling error due to omitting simple uncomplicated temporal bone fractures that are not referred for otolaryngologic consult. The incidence of facial paralysis is also overestimated by including patients in retrospective

reviews who have been referred to the tertiary care center for the management of complications of temporal bone fractures (e.g., facial paresis). Because the entire pool of temporal bone fracture patients is not included in the statistics, the incidence of complications becomes quite biased.

If head trauma patients are carefully evaluated in the emergency department upon admission (before the administration of muscle relaxants), 27% of the facial nerve injuries will present with immediate-onset facial paralysis. Seventy-three percent will have facial motion in the initial examination and subsequently deteriorate.[3] The latency of delay in onset of facial palsy ranges from 1 to 16 days. It is crucial to differentiate "delayed onset" from "delayed diagnosis." Delayed onset of facial paralysis is defined as documented facial function in the emergency department that subsequently deteriorates; delayed diagnosis of facial paralysis occurs when the patient is given a paralytic agent and is intubated before the examination of facial function. In this situation, an assessment of facial function is delayed until extubation. These patients should be categorized as *unestablished onset* and treated in a manner that is similar to the immediate onset patients. In one large series, 10% of patients fell into this unestablished onset category.[25]

Many aspects of the management of facial nerve injuries remain controversial. One of the main issues to be resolved is that of which patients should undergo surgical exploration. Because the vast majority of traumatic facial palsies resolve spontaneously, the choice of which patients should undergo exploration is based on prognostic factors for poor outcome. The factors that are assessed to predict the recovery of facial function include the timing of onset (delayed vs. immediate onset), the severity of the injury (penetrating vs. nonpenetrating), and the presence of associated infection.

The delay of onset of paralysis after temporal bone fracture is the most important of the predictive factors. In one series of 37 delayed-onset facial palsies, five were lost to follow-up, and the remainder recovered to a House-Brackmann grade I or II.[3] McKennan and Chole[26] described their experience with 17 patients with immediate-onset facial paralysis and 19 patients with delayed-onset paralysis. Complete spontaneous recovery of facial function occurred in 94% of the patients with delayed-onset paralysis; the one remaining patient had a House-Brackmann grade II recovery. By contrast, 8 of the 17 immediate-onset paralysis patients had facial nerve transsections.

Turner[7] reviewed a large series of traumatic facial paralysis patients who were treated conservatively. His paper included 36 immediate-onset and 34 delayed-onset facial palsies. Complete recovery occurred in 94% of the delayed-onset cases and 75% of immediate-onset cases. The one patient with delayed-onset paralysis who had no recovery of function developed the facial palsy coincident with acute otitis media. By contrast, Maiman and colleagues[27] found no correlation between immediate- or delayed-onset facial paralysis (treated nonsurgically) and outcome. However, 44 of 45 of their patients (including both immediate- and delayed-onset patients) had satisfactory recovery. Review of the literature argues strongly against surgical exploration and decompression of delayed post-traumatic and facial paralysis. The natural course of delayed facial paralysis is almost always the recovery of facial function to a House-Brackmann grade I or II. There are no convincing data in the literature that demonstrate that surgical intervention in delayed-onset paralysis will increase the probability of complete recovery of function.

May[28] describes the difficulty in differentiating immediate-onset from delayed-onset facial paralysis. He explored reported delayed-onset palsies and found, on occasion, a severed nerve; this observation highlights the necessity of careful examination in the emergency department. Even in comatose patients, painful stimuli generally induce a grimace. Admittedly information about the immediate facial nerve function is not always available. Sometimes the examination is omitted because attention is given to other life-threatening complications or because the patient has already received muscle relaxants with intubation. Some patients are not responsive to pain, and a grimace cannot be induced; the critical issue is whether or not any facial function has been identified. If facial function is present in the emergency department and subsequently deteriorates, our experience is that the patient will recover without surgical treatment. When reliable information from the emergency department is unavailable, the patient is never documented to have facial function, and the diagnosis of facial palsy is delayed by a few days, these cases must be categorized as "unknown onset" and considered as part of the immediate-onset group.

The degree of facial nerve injury is also a critical factor for guiding the management algorithm. Incomplete paresis rarely fails to resolve spontaneously unless an additional insult to the nerve, such as infection, occurs.[3] Consequently, only patients with complete paralysis of immediate or unknown onset are considered for surgical exploration.

The degree of the injury can be assessed not only clinically with facial motion but also with electrodiagnostic testing using the Hilger facial nerve stimulator, evoked electromyography (EEMG), and standard electromyography (EMG). The role of electrodiagnostic testing is to assist the clinician in differentiating a neuropraxic injury from a neural degenerative injury and to assess the proportion of degenerated axons. Nerves that have sustained a neuropraxic injury proximal to the stimulated portion of the nerve maintain electrical stimulability. Partial or complete disruption of the nerve results in wallerian degeneration and consequent decrease or loss of stimulability. However, the distal segment of the nerves maintains electrical stimulability for 3 to 5 days[29]; consequently, electrodiagnostic testing cannot reliably differentiate a neuropraxic injury from a laceration of the nerve for up to 3 to 5 days.

Sunderland[30] classified nerve fiber injuries into five categories. The first-degree injury is anatomically intact, with a conduction blockade (neuropraxia); these lesions tend to recover completely. The second-degree injury transects the axons but maintains an intact endoneurium (axonotmesis); these lesions also tend to resolve without subsequent deficits. The third-degree injury transacts the axon and endoneurium but maintains an intact perineurium (neurotmesis); aberrant regeneration can occur with third-degree injuries and leave patients with some weakness and synkinesis. Fourth-degree injuries transect the entire nerve trunk but maintain an intact epineural sheath (neurotmesis). Loss of the conduit of the epineural sheath allows regenerating axons to cross into adjacent fascicles, thereby resulting in a loss of topographic organization. A proportion of the regenerating fibers are also lost as a result of the healing process and scarring. These lesions result in a high incidence of residual weakness, synkinesis, and hyperkinesis. Complete transection of the entire nerve trunk and epineurium is classified as a fifth-degree injury (neurotmesis) and is associated with poor (if any) likelihood of spontaneous recovery, depending on the degree of diastasis of the nerve ends.

The Hilger facial nerve stimulator is used to perform both the minimal nerve excitability test (NET) and the maximal stimulation test (MST). The facial nerve is stimulated percutaneously adjacent to the stylomastoid foramen and the various distal branches. In NET, the current is increased until the threshold is reached, which is manifested

with facial twitching. A threshold difference of 3.5 mA or greater between the affected and nonaffected sides of the face suggests significant neural degeneration. The test is most useful between days 3 and 14 after injury in patients with dense facial paralysis to differentiate between neuropraxic and degenerative injuries. The testing is unnecessary in incomplete paralysis, in which there is almost always 100% recovery.

May and colleagues[31] argue that the MST provides a more reliable estimation of the degree of degeneration. In the MST, stimulation is performed similar to the way it is for NET, but the intensity of the stimulus is increased until the amount of facial contraction plateaus or is limited by patient intolerance. The degree of contraction is subjectively assessed by the physician and compared with electrical stimulation of the unaffected side of the face. The difference in contraction is expressed as equal, mildly decreased, markedly decreased, or no response; the latter two categories are associated with poorer prognosis. Much like NET, MST is most useful between days 3 and 14 after injury in patients with dense facial paralysis.

EEMG has been popularized by Fisch[32] in a version called electroneuronography (ENoG). ENoG differs from EEMG only in the use of bipolar stimulating and recording electrodes. Both techniques measure the evoked compound muscle action potential (CAP) and provide similar information to the MST, but in an objective fashion. The stimulating electrode is placed adjacent to be stylomastoid foramen, and the recording electrode is placed in the nasolabial crease. The diminution in the amplitude of the CAP is indicative of the percentage of degenerated nerve fibers. EEMG has been demonstrated to be the most accurate electrodiagnostic test for prognostic information.[33] Fisch[34] reported that patients in whom the degeneration on EEMG reaches 90% within 6 days of onset of traumatic facial paralysis have a poorer outcome and consequently should undergo facial nerve decompression. Sillman and colleagues[35] demonstrated a significant association between a CAP decline of more than 90% and poor recovery of function for idiopathic paralysis, but they demonstrated no significant association between a CAP decline of more than 90% and clinical outcome in traumatic paralysis.

The value of EMG for the acute management of traumatic facial paralysis remains controversial. Standard monopolar EMG is performed with the insertion of an EMG electrode into the muscle, and the spontaneous electrical activity is then recorded. Two types of information are obtainable: voluntary activity and fibrillation potentials. If voluntary activity is present during the acute postinjury period, the patient has a very high probability of good recovery.[35] However, May and colleagues[36] reported only 75% accuracy for predicting a poor recovery and 62% accuracy for predicting a favorable result. Fibrillation potentials result from denervation of the muscle but are delayed for 2 to 3 weeks after the injury and consequently offer little additional information in the acute setting.

After defining the at-risk population for poor recovery of function, the next question to address is whether surgical intervention alters the outcome. In 1944, Turner[7] reported about 69 patients with varying degrees of facial paralysis after temporal bone trauma. Thirty of these patients had complete facial paralysis, and all were treated nonoperatively. This group of patients was unbiased in that none of this series underwent surgical decompression. Good recovery occurred in 63% of the patients, incomplete recovery with synkinesis in 23%, and poor recovery in 13%. Maiman and others[27] reported on the outcome of 21 patients with posttraumatic complete facial paralysis. Full recovery occurred in 52% of the patients and incomplete recovery in 43%; one patient had a poor outcome. Brodie and Thompson[3] studied eight patients with complete paralysis who met the criteria for facial nerve decompression and who, for a variety of reasons, did not undergo surgical exploration. Seven of the eight patients had good recovery of function, and one patient had a poor outcome. The combined rate of good recovery of function in the aforementioned three studies is 63%. The outcomes for patients who underwent facial nerve decompression in various series, as well as for those who received conservative management, are summarized in Table 145-1.[3,7,25,27,37-39]

The combined rate of good recovery of facial function after decompression was 39%; this figure excludes severed facial nerves. It is difficult to compare the results of recovery of facial nerve function of patients who have undergone surgical versus nonsurgical management. The criteria to be included in the surgical groups were that the nerves were no longer stimulable or that they demonstrated more than 90% degeneration within 6 days or 95% degeneration within 14 days. The patients included in the observation studies did not necessarily meet these same criteria. In an extensive review and analysis of the literature by Chang and Cass,[40] the authors concluded that there are no studies that prove or disprove the efficacy of facial nerve decompression.

Because wallerian degeneration is not documented on electrodiagnostic testing for 3 to 5 days after the neurotmesis, surgical intervention is delayed until several days after the nerve has degenerated. Although decompression of the facial nerve prophylactically in acoustic neuroma surgery has been proved to be efficacious, the decompression is performed before wallerian degeneration has occurred.[41] Demonstrating that decompression of a posttraumatic, nonsevered nerve is efficacious remains to be proven in a randomized, prospective study.

The key factor in the decision to surgically explore a facial nerve is whether the nerve is suspected of being severed, crushed, or impaled with bone fragments. The incidence of transected nerves in the large series ranges from 6% to 45%.[17,25,37,38,39] The high frequency of severed nerves in some of these reports is biased by patient selection. Patients are referred to the tertiary centers that perform nerve explorations when they fail to spontaneously recover. However, the vast majority of patients do recover spontaneously and are not referred to tertiary centers.

The probability of severing the facial nerve is quite low, but the outcome after observation alone of a transected nerve is poor. Because one cannot differentiate a Sunderland fifth-degree injury (severed nerve) from a third- or fourth-degree injury on the basis of electrodiagnostic testing, exploration is warranted only in patients with complete immediate-onset paralysis in whom electrical stimulability is lost; these are the patients at risk for crushed, partially severed, and transected nerves.

The site of injury of the facial nerve in temporal bone fractures is in the perigeniculate region in 80% to 93% of patients.[17,37,39] Lambert and Brackmann[39] found a second lesion in the mastoid segment of 4 of 21 patients; thus the approach used for the nerve exploration must expose these regions. Fisch[34] advocates a translabyrinthine approach for transverse fractures and a combined transmastoid/middle cranial fossa approach for longitudinal fractures. May[42] described a transmastoid/supralabyrinthine approach to the region of the geniculate ganglion for facial nerve decompression. Goin[43] studied this approach in cadaveric temporal bones and found that he could consistently expose the distal labyrinthine segment and the geniculate ganglion; however, the fundus of the internal auditory canal (IAC) could be exposed in only 60% of the temporal bones. Yanagihara[44] applied the transmastoid/supralabyrinthine approach in 36 patients; only five temporal bone fractures in his series of 41 patients required a middle cranial fossa approach to expose the geniculate region.

The translabyrinthine approach is advocated for facial nerve exploration in patients with profound hearing loss. The approach provides excellent exposure for decompression, nerve rerouting with direct reanastomosis, and cable grafting. In otic capsule–sparing fractures with ossicular discontinuity, the nerve is explored via a transmastoid/supralabyrinthine approach. This approach generally requires the dislocation of the incus and ossicular reconstruction at the completion of the operation. If the patient has any contralateral hearing loss or the anatomy is not conducive for supralabyrinthine exposure, a middle cranial fossa approach is used.

Timing of facial nerve repair has, in the past, been controversial. McCabe[45] advocated repairing the nerve within the first 3 days or else delaying facial nerve reanastomosis for 20 days after injury; this recommendation was made on the basis of the observation that regeneration and axoplasmic flow were greatest at 3 weeks after injury. Barrs[46] studied the timing of facial nerve repair in micropigs and found no advantage in waiting the 3 weeks until the neuronal cell body metabolic activity was maximal.

Fisch[47] advocates exploration when the ENoG indicates that 90% degeneration has occurred within 6 days, and he argues that decompres-

HB, House-Brackmann grade.

sion should be performed early to minimize further degeneration. May also advocates early exploration[28]; his series demonstrated a correlation of best results with a shorter interval between injury and repair.

Late exploration for potentially severed nerves is still indicated, but the role of late decompression remains controversial. Quaranta and others[48] reported on nine patients who underwent facial nerve decompression 2 to 3 months after their temporal bone fractures. Seventy-eight percent recovered to a House-Brackmann grade I or II at 1 year after decompression; the question regarding whether these patients would have recovered spontaneously to the same degree remains unanswered. Clearly, if the nerve was severed and not approximated, spontaneous recovery to a House-Brackmann grade I or II would not occur. In that scenario, a House-Brackmann grade VI would be anticipated.

The range in latency to recovery of facial function varies from 1 day to 1 year. Fifty-nine percent of facial palsies that recover spontaneously do so within 1 month after injury, and 88% recover by 3 months after injury.[3]

Summary of Facial Nerve Treatment Algorithm

Patients with delayed-onset facial paralysis are placed on a 2-week course of systemic corticosteroids (unless medically contraindicated) and observed. Although there are inadequate data in the literature to support or contradict this recommendation, the rationale for corticosteroid use is based on its antiinflammatory activity and the assumption that neural edema is a primary factor in the progression of neural injury (Fig. 145-11).[40] Patients with complete paralysis of immediate onset are tested with the Hilger nerve stimulator between days 3 and 7 after injury. If no loss of stimulability occurs, the patients are observed. If the nerve loses stimulability within 1 week of the injury, facial nerve exploration is performed.

Facial nerve injuries that occur in an otic capsule–disrupting fracture are explored via a translabyrinthine approach; for otic capsule–sparing fractures, two surgical approaches are used. In patients with well-aerated mastoid air cell systems or with ossicular discontinuity, a transmastoid/supralabyrinthine approach is chosen. If the patient has a poorly aerated mastoid air cell system or total facial nerve decompression cannot be achieved via the transmastoid/supralabyrinthine approach, a combined transmastoid/middle cranial fossa approach is used. If a severed facial nerve is encountered using the transmastoid/supralabyrinthine approach and inadequate exposure for cable grafting occurs, a middle cranial fossa approach is performed.

The transmastoid facial nerve decompression begins with a complete mastoidectomy and the skeletonizing of the tegmen mastoideum superiorly, the sigmoid sinus posteriorly, and the posterior external auditory canal (EAC) wall anteriorly. The antrum is opened, thus exposing the short process of the incus and the lateral semicircular canal. The semicircular canals are then skeletonized. The facial recess is opened, and the facial nerve is skeletonized from the second genu to the stylomastoid foramen. If there is any evidence of bony trauma in this region, a complete decompression is performed; however, the nerve sheath is not incised. The buttress to the incus is subsequently removed, and the tympanic portion of the nerve is decompressed. If there is adequate room to proceed, a supralabyrinthine decompression of the intralabyrinthine portion of the facial nerve is performed (Fig. 145-12). A laceration of the facial nerve in this region is cable grafted with a section of the greater auricular nerve. The cable graft is placed in the bony channel of the fallopian canal, abutting the sharply incised edges of the facial nerve. To improve exposure, the eggshelled tegmen can be retracted superiorly.

If the exposure remains inadequate, a middle fossa craniotomy is performed. If the fracture involves the proximal portion of the intralabyrinthine segment of the facial nerve, a middle fossa craniotomy is performed.

The squamosal portion of the temporal bone is exposed by extending the postauricular skin incision in a "lazy S" shape up toward the vertex, first extending anteriorly, then posteriorly. The temporalis fascia is reflected inferiorly, and the temporalis muscle is split vertically and elevated off of the squamosal portion of the temporal bone. The dissection should extend underneath the zygomatic arch to allow for adequate exposure for the craniotomy. The self-retaining retractors are adjusted to hold both muscle and skin. A bone window is created with a 5- or 6-mm cutting burr and suction irrigation. This bone window is 4 by 4 cm in size and is set at the level of the zygomatic root. Two thirds of the window is anterior to the vertical plane of the EAC, and the other third of the window is posterior to the canal. A rongeur is used to remove the bone at the inferior edge of the craniotomy down to the level of the floor of the middle cranial fossa; this allows for the optimal surgical line of site, with minimal temporal lobe retraction. The House-Urban middle fossa retractor is engaged, with the prongs in the edge of the craniotomy. The blade is gradually advanced as the dura is elevated off of the floor of the middle fossa. It is common to encounter dural venous bleeding at the anterior extent of the dissection; this can usually be controlled with a hemostatic agent (e.g., Surgicel, Johnson & Johnson).

The landmarks in the middle fossa are the middle meningeal artery at the foramen spinosum, the greater superficial petrosal nerve at the facial hiatus, and the arcuate eminence. The geniculate ganglion may be exposed without a bony covering on the floor of the middle cranial fossa, so care should be exercised during dural elevation. The fracture line and hematoma are generally encountered in the region of the facial hiatus. The landmark for the superior semicircular canal is the arcuate eminence, but the precise location of the canal does not uniformly correspond with the arcuate eminence. A coronal CT scan may be helpful for ascertaining the relationship between the two; it will show the contours of the middle fossa floor as they relate to the superior semicircular canal and the distance between the superior semicir-

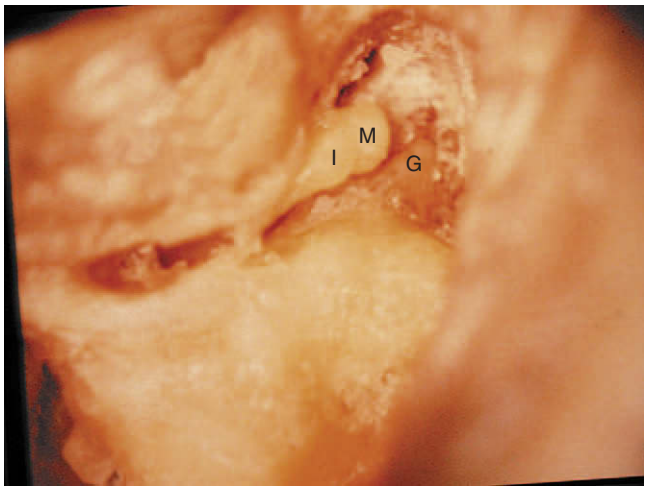

Figure 145-12. Supralabyrinthine exposure of the geniculate ganglion and the intralabyrinthine portion of the facial nerve. I, Incus; M, malleus; G, geniculate ganglion.

cular canal and the floor of the middle cranial fossa. The canal may have very little bone coverage, it may be seen as a blue line after simple dural elevation, or there may be a large number of air cells between the canal and the surface of the tegmen.

If the superior semicircular canal cannot be located by drilling over the arcuate eminence, two other methods may be considered. First, the tegmen tympani may be opened, thus exposing the ossicles. The location of the superior semicircular canal can be established by the spatial relationships. Second, the greater superficial petrosal nerve can be followed retrograde back through the facial hiatus to the geniculate ganglion. The intralabyrinthine portion of the facial nerve passes between the cochlea and the ampulla of the superior semicircular canal. The bone over the superior semicircular canal is removed using suction irrigation and diamond burrs.

A light medial to lateral stroke is used until the blue line of the superior canal is identified. After the superior canal has been identified, dissection proceeds along the meatal plane, which is the bone within a 60-degree angle from the blue line of the superior canal. Drilling within the confines of this plane will reduce the risk of inadvertent injury to the cochlea. Note that much wider drilling may be performed medially, whereas, at the lateral extent of the IAC, there is very little space between the cochlea and the ampulla of the superior semicircular canal.

The burr should hug the line of the superior canal as bone removal progresses. The dissection will appear to be quite deep before the IAC is encountered. Bone should be removed 180 degrees around the IAC, from the lateral aspect of the meatus to the porus acusticus. An eggshell thickness of bone should be left over the IAC. The last steps in the exposure of the canal are careful removal of this bone and copious irrigation to remove bone dust.

At the most lateral extent of the IAC, the vertical crest (also known as Bill's bar) is identified, with the facial nerve anteriorly and the superior vestibular nerve posteriorly. The dura of the IAC is incised in a longitudinal fashion, along the posterior edge, away from the facial nerve. If the facial nerve is lacerated, the proximal edge is freshened with microscissors. The nerve graft is secured proximally with a single 9-0 nylon suture and distally placed into the bony channel of the tympanic portion of the fallopian canal. A piece of temporalis muscle is placed in the bony defect, and the pedicled temporalis fascia flap is reflected over the floor of the middle cranial fossa. The bone flap is returned to its original position and the temporalis muscle is closed superiorly.

Cerebrospinal Fluid Fistulas

CSF fistulas and the potential for meningitis are among the most serious complications of temporal bone fractures, occurring in 17% of such fractures.[3] CSF fistulas in otic capsule–sparing fractures typically occur through the floor of the middle cranial fossa (tegmen tympani and tegmen mastoideum) and into the epitympanum, antrum, and mastoid air cell tract. The CSF flows out of the ear canal if the tympanic membrane is disrupted or into the eustachian tube, which results in CSF rhinorrhea. In otic capsule disrupting fractures, CSF flows from the posterior cranial fossa through the disrupted otic capsule into the middle ear.

The onset of CSF leakage following trauma was delayed for more than 1 week in 28% of the 192 cases surveyed by Lewin.[49] It has been theorized that the delays in CSF leakage result from either of the following: (1) herniation of dura or a brain fungus into the bony defect created by the trauma or surgery, or (2) a hematoma obstructing the outlet of the CSF flow. Eventually the CSF leaks as a result of separation of the fibers in the dural herniation, atrophy of the brain fungus, increased intracranial pressure subsiding with retraction of the herniation, or resolution of the occluding hematoma. The CSF fistula will continue to leak until fibroblastic proliferation creates a fibrous barrier that closes the subarachnoid space or the sinus or air cell mucosa covers the bony defect.[50] However, during the early stages of repair, the fibrous barrier is weak and the mucosal barrier remains fragile. If the CSF pressure gradient is greater than the healing tensile strength of these vulnerable barriers, the leak will continue. The newly formed barrier may be ruptured by nose blowing or straining.[51] A unique characteristic of a fracture through the otic capsule is the absence of healing. The otic capsule is adult size at birth and undergoes minimal remodeling throughout life.[52] After a fracture, fibrous tissue will partially fill the crevice, and the adjacent periosteal bone may seal off the fracture, but the enchondral bone itself will not heal. The potential tract places the patient at continued risk of delayed meningitis.

A CSF fistula is suspected when clear watery drainage is noted in the ear canal or from the nose. Otorhinorrhea often drains down the back of the throat, and the rate of flow of the discharge usually increases with exertion or leaning forward. Consequently, when evaluating a patient for a suspected CSF fistula, the patient is asked to lean forward with the neck flexed, and nasal discharge is collected into a sterile container. Patients often complain of headaches that are dull, continuous, and bilateral. The origin of aural and nasal drainage is often obscured by concurrent bleeding or by the lysis of an old blood clot. If a nasal discharge is suspected of being CSF, it can be differentiated from watery rhinitis, lacrimal secretions, or serosanguineous discharge on the basis of its composition. CSF has elevated glucose, less protein, and less potassium than nasal secretions. Qualitative tests, such as those that involve the use of glucose oxidase test strips, have been shown to lack specificity and result in a substantial proportion of false-positive results.[53] Quantitative glucose, protein, and potassium determinations are more accurate for the diagnosis of a CSF fistula.

A noninvasive technique for identifying and localizing a CSF fistula using protein electrophoresis for β_2 transferrin was first described by Meurman and colleagues.[54] β_2 transferrin is specific for CSF. In addition to being noninvasive, a major advantage of this technique is the small amount of CSF required for the test (50 μL).

HRCT generally demonstrates the potential sites of a CSF fistula. When a fracture is seen but the exact site of the fistula has not been identified, CT cisternography with intrathecal contrast (Omnipaque, Amersham Health Inc., Princeton, NJ) can be useful. HRCT shows bony defects in 70% of patients with a CSF fistula.[55] When a defect cannot be demonstrated by HRCT, CT cisternography or radionuclide cisternography may (rarely) detect a site of leakage.[55] Radionuclide scans tend to lack sensitivity and specificity.

Intrathecal fluorescein is a sensitive and specific test for investigating the presence of a CSF fistula. After a lumbar puncture, 0.5 mL of a 5% solution of fluorescein is mixed with 10 mL of the patient's CSF and reinjected. The otorrhea or rhinorrhea can be collected on micropledgets and examined under a Wood's lamp for green fluorescence. Although occasional reports of neurotoxicity (e.g., paraparesis, grand mal seizures) after the intrathecal injection of fluorescein appear in the literature, these complications were infrequent, occurred at higher doses of fluorescein than are currently recommended, and have not resulted in permanent damage.[51,56,57] No persistent side effects or complications have been reported with the current recommended dosing. Fluorescein is frequently successful for localizing fistulas when all other methods have failed.[57-59] Therefore, the continued use of fluorescein may be justified, and the risks of increased morbidity following failure to locate a CSF fistula preoperatively may outweigh the risks involved with its use. None of the localizing techniques are useful if the CSF leak is quiescent at the time of the test.

The incidence of meningitis in patients with CSF leaks ranges from 2% to 88%.[3,51,60-63] The wide range in incidence is a result of multiple factors, the most significant of which is the duration of leakage.[51,60,61,64] Mincy[61] and Leech and Patterson[60] compared the incidence of meningitis in patients with CSF leaks that lasted 7 days or less with those persisting for more than 7 days. Leech and Patterson found only a 5% incidence of meningitis in patients with CSF fistulas of less than 7 days' duration, and Mincy reported a similarly low incidence of 11% in his group. The incidence of meningitis in patients with leakage for more than 7 days in Leech and Patterson's series was 55%, and it was 88% in Mincy's series. Spetzler and Wilson[64] demonstrated a 33% incidence of meningitis in persistent fistulas, and Grahne[51] found that meningitis developed in 54% of his patients with chronic CSF leakage.

Many studies over the past 25 years have demonstrated no benefit of prophylactic antibiotics for temporal bone fractures in the absence of CSF fistulas.[60,62,65-71] The incidence of meningitis in this group is quite low. Rathore[72] pooled the data from many of these studies and found a 4% incidence of meningitis in patients with basilar skull fractures receiving prophylactic antibiotics and a 3% incidence in patients not receiving prophylactic antibiotics. Brodie and Thompson[3] demonstrated a 1% incidence of meningitis in 578 patients with temporal bone fractures and no CSF fistulas. Hoff and colleagues[65] conducted a prospective randomized trial that assigned patients with temporal bone fractures into a prophylactic antibiotic treatment group or to a no antibiotic group; meningitis did not develop in any patient in either group. All of these studies conclude that prophylactic antibiotics are not indicated given the low incidence of meningitis in temporal bone fractures without a CSF fistula and the lack of evidence demonstrating any benefit of prophylactic antibiotics in this situation. However, the risk of meningitis is significantly higher in patients with temporal bone fractures when CSF fistulas are present; consequently, the role of prophylactic antibiotics must be examined in relation to this subset of trauma patients. Multiple studies over the past 3 decades have concluded that prophylactic antibiotics did not have a statistically significant effect on the incidence of meningitis in patients with CSF fistulas.[62,64,66,68,71,73] However, the number of patients included in the various studies was inadequate for valid statistical analysis. Re-evaluation of the literature from the past 25 years in two independent meta-analyses revealed conflicting results. In the first study, a statistically significant reduction in meningitis using prophylactic

antibiotics in patients with CSF fistula was demonstrated. Three hundred and twenty patients were included in the analysis.[74] The incidence of meningitis in patients with posttraumatic CSF fistulas treated with prophylactic antibiotics was 2.1%. In patients who did not receive prophylactic antibiotics, the incidence of meningitis was significantly higher, at 8.7% ($P < .02$). Individually, however, none of the studies included in the metaanalysis demonstrated a statistically significant effect of prophylactic antibiotics, which points out the pitfall of statistical analysis with inadequate numbers of patients. In a second study, no statistically significant effect of antibiotic prophylaxis was demonstrated.[75] The problem with this second analysis is the inclusion of one study that reported on patients whose fistulas persisted for weeks to months.[76] In the meta-analysis,[75] 20 of 29 patients in whom meningitis developed while on prophylactic antibiotics were in this one study,[76] which permitted this very long duration of leakage.

In addition to the inadequate numbers of patients in these prior studies, there are significant problems inherent in this type of retrospective study. How do we define adequate prophylaxis? Do 3 days of perioperative antibiotics for the repair of a concomitant open femur fracture constitute adequate prophylaxis for a CSF fistula that persists for 5 days? Do therapeutic antibiotics for a concurrent infection constitute adequate prophylaxis for a CSF fistula? One very important risk factor that increases the risk of meningitis in patients with CSF fistulas is the presence of a concurrent infection. Brodie and Thompson[3] found a 20% incidence of meningitis in patients with concurrent infection and a 3% incidence of meningitis in the absence of concurrent infection. In that study, in the absence of concurrent infection, meningitis did not develop in any patient receiving prophylactic antibiotics the first month after injury. Clearly these confounding variables must be controlled in a prospective, multi-institutional study to adequately address the question of the efficacy of prophylactic antibiotics.

The most common infecting organisms in meningitis that occur in the presence of a CSF fistula are *Streptococcus pneumoniae* and *Haemophilus influenzae*.[62,77,78] Fifty-seven percent to 85% of post-traumatic fistulas that are treated conservatively cease leaking within 1 week.[49,61] Because acute posttraumatic CSF fistulas are associated with a high probability of early spontaneous closure and a low incidence of meningitis, they can be treated conservatively for 7 to 10 days; this treatment includes total bed rest with elevation of the head of the bed; stool softeners; instructions to avoid nose blowing, sneezing, and straining; and repeat lumbar punctures or lumbar drain if the leak persists. These measures are directed at maintaining the CSF pressure gradient below the healing tensile strength of the healing barrier. Because of the increased risk of meningitis after persistent CSF fistulas, the closure of fistulas that persist for more than 7 to 10 days is recommended.

Closure of CSF Fistulas

The treatment algorithm for CSF fistulas is presented in Fig. 145-13. In a patient with a fracture of the otic capsule that results in profound sensorineural hearing loss, obliteration of the mastoid and middle ear is recommended.[79,80] The ear canal, the tympanic membrane, the incus and malleus, and the middle ear mucosa are all excised. The external auditory meatus is closed in a two-layer closure, and a complete mastoidectomy is performed. The mucosa of the eustachian tube is inverted, and a muscle plug is inserted. The incus is then inserted as well, wedging the muscle into place. The eustachian tube and the fracture

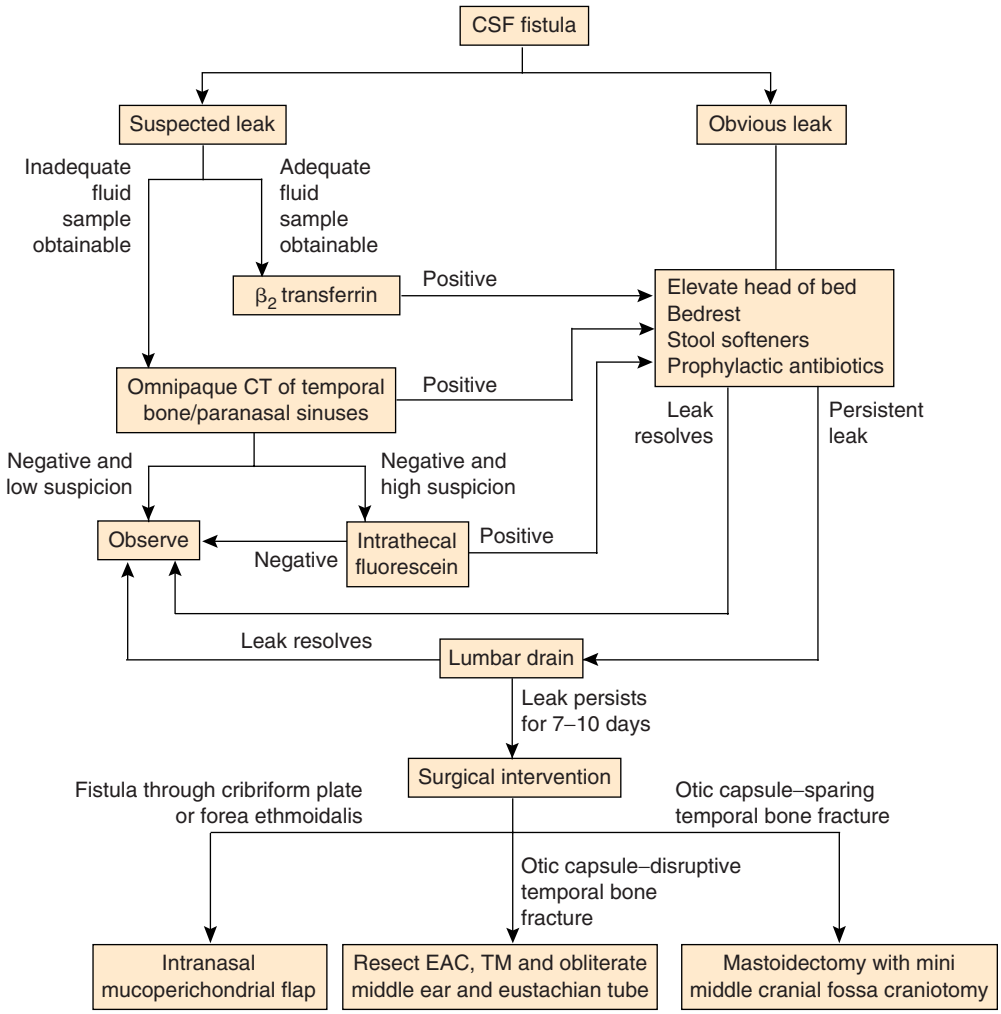

Figure 145-13. Management of traumatic cerebrospinal fluid (CSF) fistula. EAC, external auditory canal; TM, tympanic membrane.

line are covered by temporalis fascia, and the mastoid cavity and middle ear are obliterated with an abdominal fat graft.

The approach for the closure of a fistula that results from an otic capsule–sparing fracture is dictated by the location of the fracture along the floor of the middle cranial fossa, the presence of brain herniation, and the status of the ossicular chain. Fistulas that occur laterally in the middle cranial fossa are accessible through a complete mastoidectomy and can be repaired by sealing the mastoid cavity off from the epitympanum and middle ear by placing a temporalis fascia graft over the antrum, the facial recess, and the retrofacial air cell tracts. A second fascia graft is placed over the fistula, and the mastoid cavity is obliterated with a fat graft. Fistulas that occur more medially along the tegmen tympani or that are associated with brain herniation are addressed with a combined approach. When the temporal lobe herniates through the tegmen, the damaged brain is débrided via the transmastoid approach, and the remaining brain and dura are elevated back up into the middle fossa via the middle fossa craniotomy. Temporalis fascia is placed over the floor of the middle cranial fossa. If a bony defect is present in the tegmen, the craniotomy bone window is split or thinned with a burr and placed along the floor of the middle cranial fossa superior to the fascia to prevent subsequent prolapse. A piece of Gelfilm is inserted through the mastoid cavity and antrum and placed over the top of the ossicles in the epitympanum to avoid adhesions and postoperative conductive hearing loss.

In the case of a fistula through the tegmen tympani in a patient with an ossicular discontinuity and the absence of brain herniation, the fistula can often be closed via a transmastoid approach alone. A tragal cartilage graft is inserted superior to the superior EAC wall and extending to the tympanic portion of the facial nerve. The cartilage graft seals off the epitympanum and prevents the herniation of tissue into the middle ear. The epitympanum is filled with a temporalis fascia graft.

Additional techniques have been advocated by other authors. Glasscock and colleagues[81] have advocated an intradural as opposed to an extradural approach for large defects, arguing that a better closure can be achieved intradurally. Kveton and Goravalingappa[82] reported on the successful closure of 13 cases of CSF leakage using hydroxyapatite cement through a transmastoid approach. This approach is highly successful for closing CSF leaks that follow the translabyrinthine removal of acoustic neuromas, but care must be taken in traumatic CSF leaks, where the field is much more contaminated. Placement of a foreign body in a potentially contaminated wound increases the chance of infection. One of the other potential complications of the closure of tegmen CSF fistula with hydroxyapatite cement is conductive hearing loss, which may occur if any of the cement migrates to the ossicular chain.

There is a high risk of EAC stenosis and cholesteatoma formation when the ear canal is severely traumatized as is seen with gunshot wounds to the temporal bone.[83,84] In this situation, the CSF fistulas are generally closed, with resection of the EAC and tympanic membrane and obliteration of the mastoid and middle ear as described previously. Extreme care is taken to avoid leaving any fragments of epithelium that may subsequently lead to cholesteatoma formation. All mucosa is removed, and the eustachian tube and external meatus are closed as described previously.

Hearing Loss

Temporal bone trauma can cause conductive hearing loss, sensorineural hearing loss, or mixed loss. Otic capsule–sparing fractures extend along the roof of the EAC, often tearing the tympanic membrane in the region of the notch of Rivinus. The fracture proceeds along the tegmen tympani, and, in 20% of patients, disrupts the ossicular chain.[8] The most common injuries to the ossicular chain are separation of the incudostapedial joint (82%), dislocation of the incus (57%), and fracture of the stapes crura (30%) (Fig. 145-14).[85] The majority of stapedial fractures do not occur in isolation but rather are associated with incus dislocations.[8] Fixation of the ossicles in the epitympanum (25%) and fracture of the malleus (11%) occur less frequently.[85] One third of patients have multiple middle ear problems.

Almost universally, patients with temporal bone fractures experience a hemotympanum with associated conductive hearing loss. Over

Figure 145-14. Dislocated incus protruding through the tympanic membrane.

a few days to a few weeks after injury, the middle ear will re-aerate, with resolution of the hearing loss attributable to the middle ear fluid. Factors that increase the duration of the middle ear fluid include endotracheal intubation, associated craniofacial fractures, and the presence of a CSF leak. Eighty percent of cases of conductive hearing loss resolves spontaneously without the need for surgical intervention.[86] Residual conductive hearing loss following resolution of the hemotympanum and healing of the tympanic membrane suggests the possibilities of ossicular fracture or discontinuity. The indication for exploratory tympanotomy and ossicular reconstruction is conductive hearing loss of more than 30 dB that persists for more than 2 months after injury. However, if the conductive hearing loss is in the only hearing ear, then surgery is contraindicated. The audiogram of a mixed hearing loss must be critically assessed to establish the true potential benefit of ossicular reconstruction. If the bone conduction thresholds are more than 30 dB worse than in the contralateral ear, reconstruction—even with an excellent closure of the conductive component of the hearing loss—will provide minimal subjective improvement. In this scenario, the patient would still require a hearing aid to attain usable hearing in the surgical ear. Consequently, unless the mixed loss is profound and the patient cannot benefit preoperatively from a hearing aid, ossicular reconstruction is not recommended.

The most conducive injury for ossicular reconstruction is a dislocation of the incudostapedial joint. In this situation, an Applebaum hydroxyapatite prosthesis is inserted between the long process of the incus and the capitulum of the stapes and generally results in near closure of the air-bone gap. Dislocation of the entire incus requires bridging the gap between the stapes suprastructure and the manubrium of the malleus. A sculpted incus interposition graft is preferred. Partial ossicular replacement prostheses are also available. Incus interposition is accomplished by drilling a cup in the end of the short process of the incus that will fit over the capitulum of the stapes. The long process of the incus is removed and the body sculptured with an articular surface that will fit medial to the manubrium. If, in addition to the incus dislocation, the stapes suprastructure is fractured, then the long process of the incus is left intact, and the body and short process are sculptured. The superior surface of the body of the incus is fashioned to rest under the manubrium, and the long process sits on the footplate. A variety of total ossicular replacement prostheses are also available for this purpose. A more unique problem occurs when the stapes suprastructure is fractured but the incus remains connected to the malleus; these patients are good candidates for a laser stapedotomy.

Ossicular reconstruction for traumatic ossicular disruptions are superior to those performed for chronic otitis media. Hough and

Stuart[85] report closure of the air-bone gap to within 10 dB in 78% of patients and complete closure in 45%.

Otic capsule–disrupting fractures typically result in severe to profound sensorineural hearing loss. Multiple pathogenic mechanisms can contribute to the deafness, including disruption of the membranous labyrinth, avulsion or trauma to the cochlear nerve, interruption of the cochlear blood supply, hemorrhage into the cochlea, and perilymphatic fistulas. Another proposed mechanism is endolymphatic hydrops, which results from the obstruction of the endolymphatic duct by the temporal bone fracture.[87] Acoustic trauma associated with temporal bone fractures and incus dislocations frequently contributes to a sensorineural component to a mixed hearing loss; 50% of patients with traumatic incus dislocations have at least 10 dB of sensorineural hearing loss, and 18% have more than 30 dB of loss.[88] The loss occurs primarily in the 2000- to 4000-Hz range. The prognosis for recovery of function in patients with anacusis or profound deafness is extremely poor; however, patients with moderate to severe loss may have some recovery.[86,89] Patients who are experiencing progressive or fluctuating sensorineural hearing loss, which is suggestive of a possible underlying perilymphatic fistula, may benefit from exploration and patching of the fistula.[90]

Cholesteatoma and External Auditory Canal Stenosis

Cholesteatoma formation may occur many years after a temporal bone fracture.[84,91] There are four pathogenic mechanisms responsible for posttraumatic cholesteatoma formation: (1) epithelial entrapment in the fracture line; (2) ingrowth of epithelium through the unhealed fracture line or a rent in the tympanic membrane; (3) traumatic implantation of tympanic membrane skin into the middle ear; (4) trapping of epithelium medial to a stenosis of the EAC. The typical location for cholesteatoma resulting from epithelium trapped within the fracture line is in the epitympanum and the antrum. The fracture line along the posterior superior canal wall and scutum expands and then closes, thus trapping the canal skin. As the trapped skin grows, it expands into the epitympanum and antrum, thus forming a cholesteatoma; the ingrowth of epithelium through a displaced fracture line may also extend into the same region. Traumatic implantation of tympanic membrane skin results in cholesteatoma formation within the mesotympanum. Blast injuries can result in the displacement of keratinizing stratified squamous epithelium into the mastoid air cells, the mesotympanum, the epitympanum, and even intracranially.[92] The fourth mechanism of cholesteatoma formation in a canal cholesteatoma. Posttraumatic canal cholesteatomas are the most preventable by careful follow-up, débridement, and stenting when narrowing progresses. The ear canal can be dilated with the insertion of increasing numbers of Oto-Wicks (Meditronic Xomed, Jacksonville, FL) that have been saturated with a nonototoxic antibiotic drop and that are replaced every few days. After the canal is adequately dilated, Merocel (Meditronic Xomed) sponge is inserted to maintain the lumen. A large vented custom ear mold is occasionally required to maintain the lumen after severe canal injuries; the mold is used throughout the day for 3 to 6 months. When the stenosis is complete and dilation is not possible, a canaloplasty and, possibly, a tympanoplasty are required. A lateral stenosis of the EAC should not be allowed to persist, even if it is completely benign in appearance, because of the very high probability of cholesteatoma formation.

Post-traumatic cholesteatoma involving the attic, antrum, or mastoid air cells often grows for many years before detection. Until the cholesteatoma involves the ossicular chain (with resultant conductive hearing loss), erodes into the labyrinth (causing vertigo or sensorineural hearing loss), compresses the facial nerve (resulting in facial paresis), or grows into the middle ear and can be visualized on physical examination, the growth goes undetected.

Carotid Artery Injury

Carotid artery injury can occur in up to 1% of severe blunt head trauma. York and colleagues reported a review of 43 patients who underwent cerebral angiograms for suspected carotid injuries following blunt head trauma. Eleven carotid injuries were identified in 10 patients.[93] They used a fracture of the carotid canal identified on CT as a predictive indicator of carotid artery injury and found that it had a 60% sensitivity and 67% specificity. Thirty-five percent of patients with carotid canal fractures suffered a carotid artery injury. The incidence is high in this study when compared with the literature and probably represents the selection criteria of entry into the study (i.e., patients in whom angiograms were obtained because of a high suspicion for a vascular injury). Recommended criteria for obtaining carotid angiography include a neurologic examination not consistent with the brain CT scan; lateralizing neurologic deficits (hemiparesis, transient ischemic attacks, cerebrovascular accident, amaurosis fugax); Horner's syndrome; cervical bruit; or displaced fracture through the carotid canal.[94]

Another potential delayed complication of temporal bone fractures is a carotid cavernous fistula. These arteriovenous fistulas may manifest with pulsatile or nonpulsatile exophthalmos, chemosis, and a bruit detected with auscultation over the affected orbit.[95]

CHAPTER ONE HUNDRED AND FORTY-SIX

Cochlear Transduction and the Molecular Basis of Auditory Pathology

JoAnn McGee

Edward J. Walsh

Key Points

- Animal models have played a key role in the effort to elucidate the role of gene products in peripheral auditory physiology and the molecular basis of deafness.
- Congenital hearing loss generally is inherited, and the phenotypic spectrum produced by mutations in a particular gene can be attributed to the severity of the mutation, allelic heterogeneity, alternative splicing, and the contribution of modifier genes. In addition, some genes interact with the environment (e.g., noise, aminoglycoside antibiotics) to increase susceptibility to hearing loss.
- The physical characteristics of the cochlear partition (i.e., its mass and stiffness) vary from one end of the cochlea to the other, creating a basoapical gradient that results in a mechanical system with resonant properties that are continuously distributed and span the audiometric range of hearing from high to low frequency.
- The tectorial membrane, a gelatinous extracellular matrix overlying the organ of Corti, provides the necessary structure to convert basilar membrane displacement to radial shearing forces, which in turn influence hair bundle deflection and subsequent mechanoelectrical transduction. Defects in genes encoding extracellular matrix proteins that are components of the tectorial membrane (e.g., TECTA, COL11A2, COL9A1) result in hearing deficits.
- Cochlear amplification refers to a physiologically vulnerable mechanism that increases sensitivity to sound, enhances frequency selectivity, and broadens the dynamic operating range. Cochlear amplification is the result of unique voltage-dependent contractile properties of outer hair cells, which rely on the *SLC26A5* gene that encodes the essential motor protein prestin.
- Numerous proteins that are localized to sensory hair cells are critical for the normal development and/or maintenance of the intricate structure and/or function of the hair bundle and when defective are responsible for various forms of deafness. These include motor proteins (e.g., myosin IIIa, VI, VIIa, XVa), cytoskeletal proteins (e.g., espin, γ-actin, TRIOBP, radixin, diaphanous 1), adhesion proteins (e.g., cadherin 23, protocadherin 15, usherin, Vlgr1), scaffolding proteins (e.g., harmonin, SANS, whirlin), and other necessary proteins of unknown function (e.g., TMC1, TMHS, TMIE).
- Hearing impairments categorized as "auditory neuropathy" include those associated with defective inner hair cell ribbon synapse function (e.g., those caused by mutations in the genes *OTOF* and *VGLUT3*), as well as neuropathies involving faulty conduction along auditory nerve fibers, which often occur when components of the Schwann cell myelin sheath are defective (e.g., MPZ, GJB1, PMP22).
- Development of the epithelial barrier forming the endolymphatic compartment within the cochlear duct requires the vital tight junction components claudin-14 and tricellulin. In addition, the gap junction proteins connexin 26, connexin 30, and connexin 31 (encoded by *GJB2*, *GJB6*, and *GJB3*, respectively) are essential for ion homeostasis, as are numerous ion channel subunits (e.g., KCNQ4, BSND, KCNE1, KCNQ1) and ion pumps and transporters (e.g., ATP6B1, SLC26A4 [PDS, pendrin]).
- Many other proteins, including transcription factors and regulators, enzymes, ligands and receptors, and proteins produced by mitochondrial genes, have been associated with human deafness. Moreover, many genes underlying deafness in mouse models have been identified for which human deafness has not yet been established, and vice versa.
- A thorough, comprehensive understanding of the role that distinctive proteins play in normal cochlear development and peripheral auditory function will require a continuing aggressive effort on the part of the scientific community, and the knowledge gained from the use of animal models will help guide clinical diagnoses and provide direction for appropriate treatment strategies.

The work on which this chapter is based was supported in part by NIH Grant NIDCD R01 #DC04566 and NEI R01 #EY016247.

Deafness, in all of its forms, affects an estimated 186 of every 100,000 newborns in the United States[372] and increases in prevalence with advancing age. For example, by the age of 60 years, one of every three people in the United States experiences communication difficulties as a consequence of lost hearing, and by the age of 85 years, one half of the population has some degree of hearing disability. In most cases, peripheral auditory disease involves some form of cochlear abnormality that disrupts sensory transduction, and various etiologic factors have been recognized, including genetic abnormalities, trauma (acoustic and mechanical), ototoxic agents, bacterial and viral infections, and disturbances in other organ systems that influence cochlear physiology indirectly. This chapter describes the physiologic mechanisms underlying cochlear transduction at both the systemic and molecular levels. In addition, basic mechanisms of cochlear transduction are correlated with a subset of inner ear disorders that are representative of various classes of disease.

Significant breakthroughs in the identification of genes and gene products that serve as integral elements of cochlear transduction have been made beginning in the mid to late 1990s. Clearly, pathogenic mutations of many of these genes are implicated in various forms of deafness (Table 146-1). Although numerous cases of inherited deafness had been identified historically on the basis of phenotype, the etiopathogenic mechanisms responsible for deafness remained unknown before technologic advances allowed for the identification and cloning of genes associated with normal hearing. By comparing human genes with orthologous genes that are known to cause deafness in animals, the cell biology and disease associated with particular gene mutations can be studied, leading to an understanding of the role of gene products in sensory transduction. Although a variety of nonhuman species have played indispensable roles in the study of cochlear transduction and sensory pathology, in recent years the mouse model has emerged as particularly useful (Table 146-2; see also Table 146-1). This movement is fueled, in large part, by the highly successful, comprehensive investigation of the murine genome and the ever-expanding availability of tools that allow the targeting and manipulation of specific genes, technologic changes that greatly extend the capability of researchers to examine the role of gene products in the transduction process. However, although much has been learned about the molecular and genetic basis of cochlear function, or malfunction as the case may be, much work remains to be done in the ongoing effort to unravel the intricacies associated with cochlear transduction and deafness.

Approximately 68% of all cases of congenital hearing loss are inherited, and of these, at least 70% are nonsyndromic—that is, auditory disability is the only manifestation of the disorder.[372] Nonsyndromic hearing losses are grouped according to their inheritance mode: DFNA refers to autosomal dominant cases, DFNB to autosomal recessive, and DFN to X-linked or mitochondrial cases; a unique numeral following each acronym has been used to identify each chromosomal locus discovered in chronologic order. As a consequence of a major effort to identify and classify inherited hearing disabilities, it is clear that the nonsyndromic basis of inherited deafness is highly heterogeneous. Many loci known to produce autosomal dominant forms of deafness when mutated have been genetically mapped, although only a subset of the genes responsible for autosomal dominant forms have been identified and cloned. Autosomal recessive forms of inherited hearing loss account for most nonsyndromic abnormalities (approximately 80%). It has become increasingly clear, however, that different mutations in a given gene may be responsible for differences in the severity of hearing loss, different patterns of inheritance, and susceptibility to environmental factors such as noise or aminoglycoside antibiotics, as well as the involvement of other organ systems. For example, mutations in a number of genes (e.g., *COL11A2*, *ESPN*, *GJB2*, *GJB3*, *GJB6*, *MYO6*, *MYO7A*, *PJVK*, *TECTA*, *TMC1*) are responsible for both autosomal dominant and autosomal recessive forms of nonsyndromic deafness. Moreover, mutations in several genes (e.g., *CDH23*, *COL11A2*, *GJB2*, *GJB3*, GJB6, *MYH9*, *MYO7A*, *MYO15A*, *PCDH15*, *SLC26A4*, *USH1C*, *WFS1*, *WHRN*) are responsible for both nonsyndromic and syndromic forms of deafness (see Table 146-1). The phenotypic spectrum produced by mutations in a gene has been attributed to the severity of the mutation, allelic heterogeneity, alternative splicing, and the contribution of modifier genes.[60,136,171,254,336,362,486]

This chapter reviews basic mechanisms underlying sensory transduction associated with hearing and integrates contemporary models of transduction with the latest acquired information regarding the molecular structure and organization of key inner ear systems. Because of the sheer number of factors now known to be necessary for normal inner ear development, maintenance, and function, a comprehensive accounting is not possible here—not all such factors are addressed. Of note, the stated biologic role of most of the proteins discussed here remains speculative, and substantial work is needed to determine their precise role in the inner ear, as well as the nature of their interactions with other proteins. Excellent reviews that are relevant to the subject of this chapter are listed in the Bibliographic References.[29,61,170,187,215,236,310,320,443,453,585,588,631]

Passive Cochlear Mechanics

The cochlea, and the organ of Corti in particular, constitute an evolutionary marvel of biologic engineering as intricate, microscaled mechanical systems. Although the hallmark of peripheral auditory function in mammals may be the evolutionary adaptation of a relatively simple, passive resonant system into an active one that consumes energy and efficiently detects and amplifies vibratory energy, it is useful to note that the fundamental nature of cochlear mechanics is evident even in cadavers, as so elegantly demonstrated by Nobel prize winner Georg von Békésy.[586] Because cochlear mechanics at this level of function are independent of other factors—neither requiring nor consuming adenosine triphosphate (ATP), for example—the sound-driven motion of the organ of Corti observed by von Békésy and others is commonly referred to as passive.

The primary elements of passive cochlear transduction are hydromechanical in character, and the integrated contributions of many structural elements are known to determine the resonant character of cadaveric and therefore mechanically passive cochleae (Fig. 146-1). The cochlear partition is composed of an epithelial sheet known as the tympanic cover layer that supports the fibroelastic basilar membrane, itself the central structure of the end organ both functionally and anatomically. This partition supports, in turn, both the sensory and nonsensory supporting epithelium. The fluid-filled major chambers of the cochlea—specifically, the scala vestibuli and scala tympani, which are filled with perilymph, and the scala media, which is filled with endolymph—also play an important role in transduction. These structural elements, together with the tectorial membrane (an extracellular gelatinous structure secreted by nonsensory inner ear epithelial cells) that extends from the spiral limbus radially over the apical surface of the organ of Corti, comprise the principal elements that give rise to passive mechanical transduction. Although Reissner's membrane separates scala media from scala vestibuli and therefore plays an important homeostatic role in the maintenance of cochlear electrochemistry, it does not seem to play a significant role as an element of passive cochlear mechanics.

Because the focus of this chapter is on cochlear transduction, we will only remind the reader that sound waves collected in the external ear canal produce vibrations of the tympanic membrane, which in turn vibrate middle ear ossicles (Fig. 146-2A). It is, of course, the vibratory motion of the stapedial footplate that transmits the mechanical energy of the ossicular chain directly through the oval window of the cochlea, effectively delivering sound pressure waves to the scala vestibuli and translating mechanical motion into pressure waves that propagate through the virtually incompressible cochlear fluids at a velocity approximating 1.5 km/sec. At this rate of propagation, the spread of the pressure wave throughout the volume of the cochlea is nearly instantaneous. Because the bony walls of the cochlea are rigid and its fluid contents incompressible, the higher pressure (or lower, depending on the direction of motion of the stapedial footplate) in scala vestibuli relative to scala tympani produces a pressure differential across the cochlear partition that creates intracochlear forces that set the partition into motion (see Fig. 146-2D). As described in more detail in a later section, the physical makeup of the organ of Corti, and of the basilar

Gene	Name/Protein	Human Disorder	Murine Disorder	Type of Molecule	Localization
COL4A3	Type IV collagen α3 chain	Alport syndrome[368]	Targeted null[89]	Extracellular matrix component	Basal lamina of cochlear duct and strial blood vessels, kidney
COL4A4	Type IV collagen α4 chain	Alport syndrome[368]		Extracellular matrix component	Basal lamina of cochlear duct and strial blood vessels, kidney
COL4A5	Type IV collagen α5 chain	Alport syndrome, X-linked[36]		Extracellular matrix component	Basal lamina of cochlear duct and strial blood vessels, kidney
COL9A1	Type IX collagen α1 chain	Stickler syndrome[566]	Targeted null[537]	Extracellular matrix component	Tectorial membrane, fibrocytes of spiral ligament
COL11A1	Type XI collagen α1 chain	Stickler, syndrome type II, Marshall, syndrome[198,442]	Chondrodysplasia (*cho*)[74,326]	Extracellular matrix component	Greater epithelial ridge and lateral wall of the cochlea early in development; inner sulcus, Claudius cells, and Boettcher cells during development
COL11A2	Type XI collagen α2 chain	DFNB53, DFNA13, Stickler syndrome type III (nonocular), otospondylomega-epiphyseal dysplasia (OSMED) syndrome[71,361,581]	Targeted null[361]	Extracellular matrix component	Tectorial membrane
CRYM	μ-Crystallin (NADP-regulated thyroid hormone–binding protein)	DFNAi[2]	Targeted null—normal hearing[538]	Involved in K^+ recycling?	Lateral region of spiral ligament and fibrocytes of spiral limbus
DFNA5	Deafness, autosomal dominant 5, ICERE-1	DFNA5[569]	Targeted null—normal hearing[570]		Organ of Corti, limbus, stria (RT-PCR only)
DIAPH1 (*HDIA1*)	Diaphanous homolog 1	DFNA1[346]	Targeted null—hearing not assessed[404]	Cytoplasmic protein regulating actin polymerization	Inner ear (RT-PCR only)
DSPP	Dentin sialophosphoprotein	DFNA39 associated with dentinogenesis imperfecta type 1[620]			
EDN3	Endothelin 3	Waardenburg syndrome type IV, Waardenburg-Hirschsprung disease[138]	Lethal spotting (*ls*)[39]	Ligand	Strial intermediate cells, pigmentation, gut
EDNRB	Endothelin receptor type B	Waardenburg syndrome type IV, Waardenburg-Hirschsprung disease[34]	Piebald (s)[232]	Receptor	Widespread in pigmentation, gut

Table 146-1

Selected Genes Underlying Various Forms of Deafness in Humans—cont'd

Gene	Name/Protein	Human Disorder	Murine Disorder	Type of Molecule	Localization
ESPN	Espin	DFNB36, DFNAi[129,381]	Jerker (*je*)[634]	Actin-bundling protein	Hair cell stereocilia
ESRRB (*NR3B2*)	Estrogen-related receptor β	DFNB35[80]	Targeted conditional null[69]	Orphan nuclear receptor; alters cell fate of strial epithelial cells	Strial marginal cells
EYA1	Eyes-absent 1 homolog (*Drosophila*)	Branchio-oto-renal syndrome type 1[1]	Targeted null, spontaneous mutant[250,621]	Transcriptional coactivator	Neuroepithelia, ganglia, otic capsule and middle ear mesenchyme, kidney, jaw
EYA4	Eyes-absent 4 homolog (*Drosophila*)	DFNA10[599]	Targeted null[116]	Transcriptional coactivator	Eustachian tube and middle ear?
FGFR3	Fibroblast growth factor receptor 3	Craniosynostosis with deafness, Muenke syndrome[125,224]	Targeted null[81]	Growth factor receptor; affects support cell fate	Pillar cells, Deiters cells, hair cells during development, skull
FOXI1 (*FKH10*)	Forkhead box I1	Pendred syndrome[625]	Targeted null[242,243]	Transcriptional activator of SLC26A4	Endolymphatic duct/sac
GATA3	GATA-binding protein 3	Hypoparathyroidism, sensorineural deafness, and renal dysplasia (HDR) syndrome[567]	Targeted null[266,571]	Enhancer-binding protein (for T-cell antigen receptor gene activation); zinc finger transcription factor	Otocyst and periotic mesenchyme; developing sensory epithelia, OHCs, spiral ganglion neurons, olivocochlear efferent neurons
GJB1 (*CMT*) (*CX32*)	Gap junction membrane channel protein β1, connexin 32	Charcot-Marie-Tooth type 1X syndrome (X-linked)[49]		Gap junction component	Schwann cells of auditory nerve and other peripheral nerves
GJB2 (*CX26*)	Gap junction membrane channel protein β2, connexin 26	DFNB1, DFNA3, keratitis-ichthyosis-deafness syndrome, palmoplantar hyperkeratosis, palmoplantar keratoderma[269,439,441]	Targeted, conditional null; dominantnegative transgene[79,305]	Gap junction component	Fibrocytes of the spiral ligament and spiral limbus; nonsensory epithelial cells in the region of the organ of Corti
GJB3 (*CX31*)	Gap junction membrane channel protein β3, connexin 31	DFNA2, DFNBi; erythrokeratodermia variabilis, peripheral neuropathy[340,342,440,618]	Targeted null—no hearing loss[421]	Gap junction component	Fibrocytes of the spiral ligament and spiral limbus; Schwann cells of auditory nerve and other peripheral nerves
GJB6 (*CX30*)	Gap junction membrane channel protein β6, connexin 30	DFNB1, DFNA3, Clouston syndrome[108,197]	Targeted null[544]	Gap junction component	Cells of the spiral limbus, the spiral ligament, the stria vascularis, and in supporting cells of the organ of Corti
KCNE1 (*IsK*, *MinK*)	Potassium voltage-gated channel, IsK-related subfamily, member 1	Jervell and Lange-Nielsen syndrome locus 2[487,561]	Targeted null; spontaneous mutant (*pkr*)[323,580]	K^+ channel β-subunit	Strial marginal cells, heart

Continued

Table 146-1

Selected Genes Underlying Various Forms of Deafness in Humans—cont'd

Gene	Name/Protein	Human Disorder	Murine Disorder	Type of Molecule	Localization
KCNQ1 (*KvLQT1*, *KCNA9*)	Potassium voltage-gated channel, subfamily Q, member 1	Jervell and Lange-Nielsen syndrome locus 1[382]	Targeted null[66,315]	K^+ channel subunit	Strial marginal cells, heart
KCNQ4	Potassium voltage-gated channel, subfamily Q, member 4	DFNA2[304]	Targeted null, targeted knock-in[275]	K^+ channel subunit	Hair cells, spiral ganglion neurons
Kit	Kit proto-oncogene	Piebald syndrome[183]	Dominant spotting (*W*)[180,528]	Transmembrane protein, receptor for tyrosine kinase	Developing melanocytes (including strial intermediate cells)
LRTOMT	Leucine-rich transmembrane *O*-methyltransferase	DFNB63[9]		Fusion gene that gives rise to *LRTOMT1* and *LRTOMT2*	Hair cells and supporting cells
MITF	Microphthalmia transcription factor	Waardenburg syndrome type IIA, Tietz syndrome[20,541]	Microphthalmia (*mi*)[222]	Transcription factor	Strial intermediate cells during development, pigmentation
MPZ (P_0)	Myelin protein zero (P_0)	Charcot-Marie-Tooth syndrome type 1B with sensorineural deafness (auditory neuropathy), Déjérine-Sottas syndrome, congenital hypomyelinating neuropathy[212,213]	Transgenic mouse line[638]	Cell adhesion molecule and main component of compact myelin in peripheral nervous system	Schwann cells of auditory nerve and other peripheral nerves
MYH9	Myosin heavy chain IX, nonmuscle heavy chain IIA (NMHC IIA)	DFNA17, May-Hegglin anomaly, Sebastian, Fechtner, and Epstein syndromes[309,497]	Gene-trapping, homozygotes—embryonic lethal, heterozygotes—normal hearing[400]	Motor protein	Hair cells, spiral ligament, spiral limbus, spiral ganglion
MYH14	Myosin heavy chain XIV, nonmuscle heavy chain IIC (NMHC IIC)	DFNA4[128]		Motor protein	Organ of Corti, stria vascularis, Hensen cells, Claudius cells, external sulcus cells, epithelium of the spiral prominence
MYO1A	Myosin IA	DFNA48[127]	Targeted null—normal startle response[560]	Motor protein	
MYO3A	Myosin IIIA	DFNB30[591]		Motor protein	Hair cells
MYO6	Myosin VI	DFNB37, DFNA22[10,363]	Snell's waltzer (*sv*), tailchaser (*tlc*) (ENU)[35,219]	Motor protein	Hair cells
MYO7A	Myosin VIIA	DFNB2, DFNA11, Usher syndrome type 1B[338,339,600]	Shaker 1 (*sh1*)[182]	Motor protein	Hair cells, retina
MYO15A	Myosin XVa	DFNB3; Smith-Magenis syndrome[330,592]	Shaker 2 (*sh2*)[422]	Motor protein	Hair cells

Table 146-1

Selected Genes Underlying Various Forms of Deafness in Humans—cont'd

Gene	Name/Protein	Human Disorder	Murine Disorder	Type of Molecule	Localization
ND	Norrie disease protein, norrin	Norrie disease[46,72]	Targeted null[47,429]	Extracellular matrix component	Stria, spiral ganglion, eye, brain
OTOA	Otoancorin	DFNB22[640]		Glycosylphosphatidylinositol-linked membrane protein	Apical surface of interdental cells; apical surface of border epithelial cells lying adjacent and medial to IHCs during development
OTOF	Otoferlin	DFNB9[626]	Targeted null[455]	Synaptic vesicle–trafficking protein	IHCs
PAX2	Paired box gene 2	Renal-coloboma syndrome[137]	Targeted null[552]	Transcription factor	
PAX3	Paired box gene 3	Waardenburg syndrome types I, III[234,542]	Splotch (*Sp*)[141,530]	Transcription factor	Developing dorsal neural tube, pigmentation
PCDH15	Protocadherin-15	DFNB23, Usher syndrome types 1F[11,12,15]	Ames waltzer (*av*)[14]	Cell adhesion protein	Hair cells
PJVK	Pejvakin	DFNB59, DFNAi[109,488]	DFNB59 knock-in, sirtaki (ENU)[109,488]		Hair cells, spiral ganglion, brainstem auditory neurons
PMP22	Peripheral myelin protein 22	Charcot-Marie-Tooth syndrome type 1A with sensorineural deafness (auditory neuropathy)[296]	Trembler (*Tr*)[536,638]	Hydrophobic intrinsic membrane protein of myelin sheaths in peripheral nervous system	Schwann cells of auditory nerve and other peripheral nerves
POU3F4 (*BRN4*.0)	POU domain, class 3, transcription factor 4	DFN3 (X-linked)[107]	Targeted null, sex-linked fidget (*slf*)[366,412,414]	Transcription factor	Mesoderm around otic vesicle and lateral wall; spiral ligament, Reissner's membrane
POU4F3 (*BRN3c*)	POU domain, class 4, transcription factor 3	DFNA15[564]	Targeted null, dreidel (*ddl*)[143,619]	Transcription factor	Hair cells
RDX	Radixin	DFNB24[273]	Targeted null[289]	Cross-link actin filaments to plasma membrane	Hair cells
SALL1 (*HSAL1*)	Sal-like 1	Townes-Brocks syndrome[292]	Targeted mutation producing truncated protein[280]	Transcription factor (repressor)	
SANS	Scaffolding protein containing ankyrin repeats and SAM (sterile alpha motif) domain	Usher syndrome type 1G[377,601]	Jackson shaker (*js*)[283]	Scaffold protein	Hair cells
SIX1	Homolog of *Drosophila* sine oculis homeobox 1 gene	Branchio-oto-renal or branchio-otic syndrome type 3[458]	Targeted null[637]	Transcriptional regulator	Embryonic development of ear, kidney, muscle; branchial arch

Continued

Table 146-1

Selected Genes Underlying Various Forms of Deafness in Humans—cont'd

Gene	Name/Protein	Human Disorder	Murine Disorder	Type of Molecule	Localization
SIX5	Homolog of *Drosophila* sine oculis homeobox 5 gene	Branchio-oto-renal syndrome type 2[231]	Targeted null[291,479]	Transcriptional regulator	Embryonic development of ear, kidney; branchial arch
SLC17A8 (*VGLUT3*)	Solute carrier family 17 (sodium phosphate cotransporter), member 8; vesicular glutamate transporter-3	DFNA25[457]	Targeted null[457,490]	Vesicular glutamate transporter	IHCs (synaptic vesicles)
SLC19A2	Solute carrier family 19 (thiamine transporter), member 2; high-affinity thiamine transporter 1 (Thtr1)	Thiamine-responsive megaloblastic anemia syndrome (diabetes mellitus, megaloblastic anemia, sensorineural deafness)[121,158,308]	Targeted null[390]	Thiamine transporter	Hair cells, greater expression in IHCs than in OHCs
SLC26A4 (*PDS*)	Solute carrier family 26, member 4 (pendrin)	DFNB4, Pendred syndrome, enlarged vestibular aqueduct, Mondini dysplasia[151,325]	Targeted null[150]	Anion transporter (pumps bicarbonate into endolymph and maintains pH homeostasis)	Spiral prominence epithelial cells, root cells, endolymphatic duct and sac, thyroid gland
SLC26A5 (*PRES*)	Solute carrier family 26, member 5 (prestin)	DFNB61[337]	Targeted null, targeted knock-in[103,328]	Cl^- translocator/motor protein	OHCs
SLUG, *SNAI2*	Snail homolog 2	Waardenburg syndrome type II[474]	Targeted null[474]	Transcription factor	Embryonic neural crest
SOX2	Sex-determining region of the Y chromosome–related (SRY-related) high-mobility group (HMG) box gene 2	Syndromic: anophthalmia or microphthalmia, sensorineural hearing loss, anterior pituitary hypoplasia, hypogonadism[268]	Light coat and circling (*lcc*); yellow submarine (*ysb*)[130,281]	Transcription factor	Developing CNS and placodes—involved in hypothalamopituitary and reproductive axes; prosensory domain of cochlear epithelium
SOX10	SRY-box containing gene 10	Waardenburg syndrome type IV[419]	Dominant megacolon (*dom*)[217,521]	Transcription factor	Otocyst, pigmentation, gut
STRC	Stereocilin	DFNB16[576]	Targeted null[577]	Transmembrane or extracellular protein?	Hair cells (component of horizontal top connectors between adjacent stereocilia and the tops of the tallest OHC stereocilia that attach to the tectorial membrane)
TBX1	T-box 1	DiGeorge syndrome[73]	Transgene overexpression, targeted null[172,582]	Transcription factor	Otocyst
TCOF1	Treacle	Treacher Collins syndrome[123]	Targeted null heterozygotes[122]	Nucleolar trafficking protein	Neural crest cells

Table 146-1

Selected Genes Underlying Various Forms of Deafness in Humans—cont'd

Gene	Name/Protein	Human Disorder	Murine Disorder	Type of Molecule	Localization
TECTA	α-Tectorin	DFNB21, DFNA8/DFNA12[378,574]	Targeted null, targeted missense[317,318]	Extracellular matrix component	Tectorial membrane; also in inner sulcus and Hensen cells during development
TFCP2L3 (*GRHL2*)	Transcription factor cellular promotor 2-like 3 (grainyhead-like 2)	DFNA28, age-related hearing loss[408,568]		Transcription factor	Organ of Corti, stria vascularis, Reissner's membrane, interdental cells, cells lining the scala media
THRB	Thyroid hormone receptor β	Thyroid hormone resistance[473]	Targeted null[167]	Transcription factor	Cochlear sensory epithelium, Kolliker's organ, spiral ganglion, Hensen cells, stria vascularis
TIMM8A (*DDP1*)	Translocase of mitochondrial inner membrane 8A; DDP1 (deafness dystonia peptide 1)	Mohr-Tranebjaerg syndrome/Jensen syndrome (X-linked)[248,553,554]		Mitochondrial protein	Widespread including muscle
TMC1	Transmembrane channel-like gene 1	DFNB7/DFNB11, DFNA36[306]	Deafness (*dn*); Beethoven (*Bth*)[306,587]	Transmembrane protein	Hair cells
TMHS (*LHFPL5*)	Tetraspan membrane protein of hair cell stereocilia; lipoma HMGIC fusion partner-like 5	DFNB66/DFNB67[263,498]	Hurry-scurry (hscy)[341]	Transmembrane protein	Transient expression in hair cells (especially stereocilia) during development
TMIE	Transmembrane inner ear expressed gene	DFNB6[380]	Spinner (*sr*), circling (*cir*)[75,367]	Transmembrane protein	Hair cells
TMPRSS3 (*ECHOS1*)	Type II transmembrane protease, serine 3	DFNB8/DFNB10[489]		Transmembrane serine protease	Stria vascularis, inner and outer pillar cells, Deiters cells, Hensen cells, epithelial cells lining the inner spiral sulcus, spiral ganglion
TRIC (*MARVELD2*)	Tricellulin (Marvel domain–containing protein 2)	DFNB49[435]		Tight junction membrane protein at tricellular contacts	Tricellular tight junctions in sensory epithelium, including among hair cells and supporting cells, and among strial marginal cells
TRIOBP (*TARA*)	TRIO (triple functioning domain) and filamentous actin [F-actin]–binding protein (TRIO-associated repeat on actin)	DFNB28[436,499]		F-actin–binding protein	Hair cells

Continued

Table 146-1

Selected Genes Underlying Various Forms of Deafness in Humans—cont'd

Gene	Name/Protein	Human Disorder	Murine Disorder	Type of Molecule	Localization
USH1C	Usher 1C, harmonin	DFNB18, Usher syndrome type 1C[13,575]	Deaf circler, (*dfcr*), targeted null, targeted knock-in[252,316,321]	Scaffold protein	Hair cells, photoreceptors
USH2A	Usherin	Usher syndrome type 2A[147]	Targeted null[335]	Transmembrane protein (component of ankle links of hair cell stereocilia)	Hair cells, photoreceptors
USH3A (*CLRN1*)	Clarin-1	Usher syndrome type 3[6,249]	Targeted null (unpublished)	Transmembrane protein	Hair cells, photoreceptors
VLGR1 (*MASS1*; *GPR98*)	Very large G–protein–coupled receptor 1	Usher syndrome type 2C[603]	Targeted mutation producing truncated protein, targeted null, frings, rueda (ENU)[255,359,623]	Transmembrane protein (component of ankle links of hair cell stereocilia)	Hair cells, photoreceptors
WFS1	Wolfram syndrome gene 1, wolframin	DFNA6/DFNA14/ DFNA38, Wolfram syndrome[51,534,629]		Transcellular ion movement (component of endoplasmic reticulum, especially canalicular reticulum)	Hair cells, Deiters cells, Hensen cells, Claudius cells; epithelial cells lining the external spiral sulcus, spiral prominence, spiral ligament; interdental cells; Reissner's membrane
WHRN	Whirlin	DFNB31; Usher syndrome type 2D[136,358]	Whirler (*wi*)[358]	Scaffold protein involved in elongation and maintenance of hair cell stereocilia	Hair cells, photoreceptors

ATPase, adenosine triphosphatase; CNS, central nervous system; EGF, epithelial growth factor; HMGIC, high mobility group I-C proteins; IHC, inner hair cell; NADP, nicotinamide-adenine dinucleotide phosphate; OHC, outer hair cell; RT-PCR, reverse transcriptase–polymerase chain reaction.

Table 146-2

Selected Genes Underlying Murine Deafness for Which Human Deafness Has Not Been Determined

Gene	Name/Protein	Murine Disorder	Type of Molecule	Localization
Bsn	Bassoon	Targeted disruption—Bassoon (*Bsn*) mice exhibit characteristics of auditory neuropathy; anchoring of ribbons in inner hair cells is impaired[277]	Presynaptic scaffolding protein	Hair cells
Cacna1D ($Ca_V1.3$)	Calcium channel, voltage-dependent, L type, α1D subunit	Targeted null mice are deaf[420]	Voltage-sensitive calcium channel	Hair cells
Cdkn2d (*Ink4D*)	Cyclin-dependent kinase inhibitor 2D	Targeted null mice—the postmitotic state of sensory hair cells is disrupted: they reenter the cell cycle and subsequently undergo apoptosis, resulting in progressive hearing loss[70]	Cell cycle regulation	Hair cells
Cldn11	Claudin-11	Targeted null mice are hearing-impaired; endocochlear potential is reduced[195,290]	Tight junction protein	Strial basal cells

Table 146-2

Selected Genes Underlying Murine Deafness for Which Human Deafness Has Not Been Determined—cont'd

Gene	Name/Protein	Murine Disorder	Type of Molecule	Localization
Clic5	Chloride intracellular channel 5	Jitterbug (*jbg*) mice are hearing-impaired; hearing loss is progressive[175]	May associate with radixin and stabilize connection between actin core of stereocilia and plasma membrane	Hair cells
Gfi1	Growth factor–independent 1	Targeted null mice lack an acoustic startle reflex; outer hair cells degenerate[218,590] Humans with a missense mutation show no evidence of hearing loss[407]	Transcriptional repressor oncoprotein; regulated by POU4F3	Hair cells, spiral ganglion cells
Itga8	Integrin $\alpha 8\beta 1$	Targeted null mice die soon after birth; utricular hair cells lack stereocilia or have malformed stereocilia[334]	Cell surface glycoprotein that mediates cell-cell and cell–extracellular matrix interactions (signaling molecule)	Apical hair cell surface where stereocilia form
Kcnj10 (*Kir4.1*)	Potassium channel, inwardly rectifying, subfamily J, member 10	Targeted null mice are deaf (absent endocochlear potential; reduced endolymph volume and K^+ concentration)[353]	K^+ channel	Strial intermediate cells
Math1 (*Atoh1*)	Mouse homolog of atonal 1	Targeted null mice are deaf (hair cells do not develop)[50]	Basic helix-loop-helix transcription factor	Hair cells
Otog	Otogelin	Twister (*twt*), targeted null mice are hearing-impaired[508,509]	Extracellular matrix component	Tectorial membrane
Otos	Otospiralin	Targeted null mice are moderately hearing-impaired; type II and IV fibrocytes degenerate[112]		Fibrocytes of the spiral limbus and spiral ligament
Ptprq	Protein tyrosine phosphatase receptor Q	Transgenic mice are hearing-impaired and have progressive hair cell loss in the base of the cochlea[190]	Receptor-like protein tyrosine phosphatase	Hair cells
Slc4a7 (*Nbc3*)	Solute carrier family 4 (sodium bicarbonate cotransporter), member 7; Nbc3	Targeted null mice develop hearing impairment[57]	Sodium bicarbonate cotransporter (Nbc); pH regulation	Type I and II fibrocytes
Slc12a2 (*Nkcc1*)	Solute carrier family 12 (sodium-potassium-chloride transporter), member 2	Shaker-without-syndactylism (*sy-ns*)[124]; Targeted null mice are deaf[110,157]	Na^+-K^+-$2Cl^-$ cotransporter	Strial marginal cells, distal nephron
Slc12a6 (*Kcc3*)	Solute carrier family 12 (potassium-chloride cotransporter), member 6; Kcc3	Targeted null mice develop a slowly progressive hearing loss[56]	K^+-Cl^- cotransporter	Supporting cells of hair cells, epithelial cells of organ of Corti, type I and III fibrocytes, neurons, renal proximal tubule
Slc12a7 (*Kcc4*)	Solute carrier family 12 (potassium-chloride cotransporter), member 7; Kcc4	Targeted null mice are deaf, develop renal tubular acidosis[55]	K^+-Cl^- cotransporter	Deiters cells, supporting cells of inner hair cells

Continued

Table 146-2

Selected Genes Underlying Murine Deafness for Which Human Deafness Has Not Been Determined—cont'd

Gene	Name/Protein	Murine Disorder	Type of Molecule	Localization
Spnb4	β-Spectrin 4	Quivering (*qv*) mice have moderate to severe abnormalities in ABR wave I; later peaks generally are absent[401]	Ion channel localization in myelinated nerves	Spiral ganglion neurons (axons)
Tbx18	T-box transcription factor 18	Transgenic mice are deaf; endocochlear potential is absent; stria vascularis is disrupted[555]	Transcription factor	Otic mesenchyme that differentiates into fibrocytes
Tectb	β-Tectorin	Targeted null mice have significantly elevated thresholds below 20 kHz and sharper tuning at high frequencies[462]	Extracellular matrix component	Tectorial membrane
Tmprss1 (*Hpn*)	Transmembrane protease serine 1 (hepsin)	Targeted null mice exhibit profound hearing loss[201]	Transmembrane serine protease	Inner ear
Trpml3 (*Mcoln3*)	Transient receptor potential cation channel, mucolipin subfamily member 3	Varitint-waddler (*Va*) mice are deaf, have reduced endocochlear potential and pigmentation defects[65,119]	Transmembrane protein; ion channel protein of intracellular endosomes and lysosomes	Hair cells (cytoplasmic vesicles, stereocilia, plasma membrane), strial intermediate cells

ABR, auditory brainstem response.

membrane in particular, establishes a space-frequency map that determines the limits of hearing and the capacity of the subject to resolve frequency differences among vibrations that contain energy in the audible range.

Physical Dimensions

At the basal end of the cochlea near the round window, the width of the basilar membrane, as measured between the tympanic lip of the spiral limbus and the basilar crest of the spiral ligament, is narrow relative to dimensions representing more apical locations (Fig. 146-3). In fact, the width of the basilar membrane progressively increases along a base-to-apex gradient in mammals, such that in humans, for example (see Fig. 146-3 E), the width at the base is approximately 100 µm and approaches 500 µm near the apex.[604] In association with graded basilar membrane width, the number of mesothelial cells, or tympanic border cells, lining the basilar membrane increases along the basoapical length of the end organ, as does the length of outer hair cells (OHCs) and associated stereocilia. Conversely, the thickness of the basilar membrane and the density of radial filaments embedded in the homogenous ground matrix of the partition decrease progressively from base to apex (see Fig. 146-3C). It is notable that radial filaments are composed primarily of collagen type II,[132,545,558] whereas the ground matrix of the partition itself is composed primarily of fibronectin, tenascin, proteoglycans containing keratin sulfate and chondroitin sulfate, and emilin-2 (*e*lastin *m*icrofibril *i*nterface-*l*ocated prote*in*-2).[21,375,475,539,611] Consequently, the basilar membrane and organ of Corti complex is stiffer and less massive at the base than at the apex (see Fig. 146-3F). The result is an end organ with resonant properties that are continuously distributed from base to apex that supports a mechanical system that separates, or filters, complex fluid waves into sinusoidal constituents. As a result, high-frequency acoustic events are preferentially transduced in the base (see Fig. 146-3G), because it is stiff and less massive. The inverse is true in the case of low-frequency acoustic events.

Another physical characteristic of the cochlea that exerts influence over the mechanics of transduction is the relative volume of perilymphatic fluid compartments that are larger at the base than at the apex (see Fig. 146-1). Consequently, there is a clear difference in fluid-mass loading of basilar membrane motion along the length of the end organ. The magnitude of the intracochlear fluid load is thought to dominate longitudinal coupling along the length of the cochlea. Of note, very little coupling occurs otherwise between adjacent regions of the basilar membrane—beyond, that is, simple stretching and compression forces.[204,394,395,583] At rest, therefore, the basilar membrane seems to be under very little tension, and without direct mechanical coupling, the traveling wave cannot propagate further apically after reaching its resonant peak, or place. Moreover, the viscous friction between the basilar membrane and cochlear fluids produces a damping effect that limits its displacement.

The Traveling Wave

The hydromechanical consequences of introducing a pressure pulse, or wave, into perilymphatic fluids is a traveling wave that propagates along the organ of Corti from the base to the apex (see Fig. 146-2). The traveling wave propagates basoapically, because the stiffness of the cochlear partition decreases longitudinally from the base to the apex (see Fig. 146-3F) as its mass increases. The motion and direction of the wave that travels along the basilar membrane are independent of the location of the vibratory source. von Békésy[586] observed this feature of cochlear mechanics by introducing a pressure pulse through an artificial window carved into the bony labyrinth near the cochlear apex. Traveling waves created under these conditions are essentially indistinguishable from traveling waves triggered by ossicular vibration. The basoapical propagation of the traveling wave is an outcome of the end organ's physical makeup, with the stiffer and less massive elements forming the base of the organ of Corti being set into motion by an instantaneous pressure difference between the major scalae before the more compliant and massive sections of the apical cochlea. The resultant traveling wave reflects the more or less independent, yet orderly, sequential movement of loosely coupled basilar membrane segments that form a frequency decomposition system generally thought of as the *space-frequency* or *tonotopic map* (see Fig. 146-3G).

As the traveling wave propagates toward the apex, traveling initially at a high rate of speed, the velocity of the wave decreases, with production of progressively shorter wavelengths for any given input frequency as a consequence (see Fig. 146-2E). As the amplitude of the propagating wave steadily increases as it passes toward the apex,

Figure 146-1. **A,** Midmodiolar section through a human cochlea showing the basal *(lower)*, middle, and apical *(upper)* turns. The modiolus is the central core of the cochlea and houses spiral ganglion neurons. The cochlear duct, otherwise known as the scala media (SM), contains endolymph and is separated from the perilymphatic fluid chambers, scala tympani (ST), and scala vestibuli (SV) by the cochlear partition and Reissner's membrane, respectively. At the cochlear apex, the fluids of the ST and SV mix through an opening called the helicotrema. **B,** Higher-magnification image of a modiolar section through the basal turn of the cochlea of a Rhesus monkey. The organ of Corti rests on the cochlear partition, a structure that includes the basilar membrane (BM) and a layer of mesothelial cells lining the BM and facing the ST. The stria vascularis (StV) and spiral ligament (SLig) form the lateral boundary of SM. **C,** Cross section of the organ of Corti from the middle turn of a cat cochlea. The triangular-shaped tunnel of Corti (TC), formed by the inner and outer pillar cells, separates the inner hair cell (IHC) from the outer hair cells (OHCs). The tectorial membrane (TM) can be seen pulled away from the sensory cells. **D,** Representation of the organ of Corti, showing the one row of IHCs and three rows of OHCs. Note the fluid spaces surrounding the OHCs, and that the tallest stereocilia of OHCs are embedded in the tectorial membrane, whereas the stereocilia of IHCs do not reach the tectorial membrane. *(**A,** Courtesy of Dr. William B. partition displacement reaches a maximum value at its characteristic place—where intrinsic resonance meets, and nearly matches, the vibratory frequency of the triggering acoustic event (see Fig. 146-2F). As pointed out previously, the stiffness of the basilar membrane decreases exponentially with distance from the stapes,[205,394,395,586] so it is not surprising that the resonant frequency also decreases exponentially as a function of distance from the stapes, because the characteristic place is determined by the stiffness of the cochlear partition. Thus, the aforementioned space-frequency, or tonotopic, map is created, whereby the peak in vibration amplitude is located at the base of the cochlea for high frequencies and at progressively apical regions for lower frequencies.

Just as stiffness dominates the physics of the traveling wave as it travels toward its characteristic place, basilar membrane motion at and just above the characteristic place is dominated by the mass of the system. It is important to point out that the actual peak of the traveling wave occurs at a location just basal to the true resonant place, characterized by a match between intrinsic resonance and the triggering vibratory energy. At the place of peak displacement, the traveling wave slows to an essential standstill (i.e., it stalls) before remaining energy is completely dissipated, and the partition is completely and rapidly restored to its resting position slightly apical to the resonant place. Near the characteristic place for a given stimulus frequency, the pressure wave returns to the basal end of the cochlea through the fluids of the scala tympani, where the flexible round window membrane is displaced in an equal but opposite direction to that of the volume displacement of the stapes footplate.

At the apical end of the cochlea, the endolymphatic space terminates just short of the bony labyrinthine wall and maintains a firm physical boundary between endolymph and perilymph, allowing the fluids in the scala vestibuli and scala tympani to communicate directly by way of a small duct called the helicotrema (see Fig. 146-3B). The helicotrema acts as an acoustic shunt across the cochlear partition that reduces the pressure difference between the scalae produced by very-low-frequency stimulation.[96] The size of the helicotrema is thought to determine the low frequency cutoff of the system; that is, large

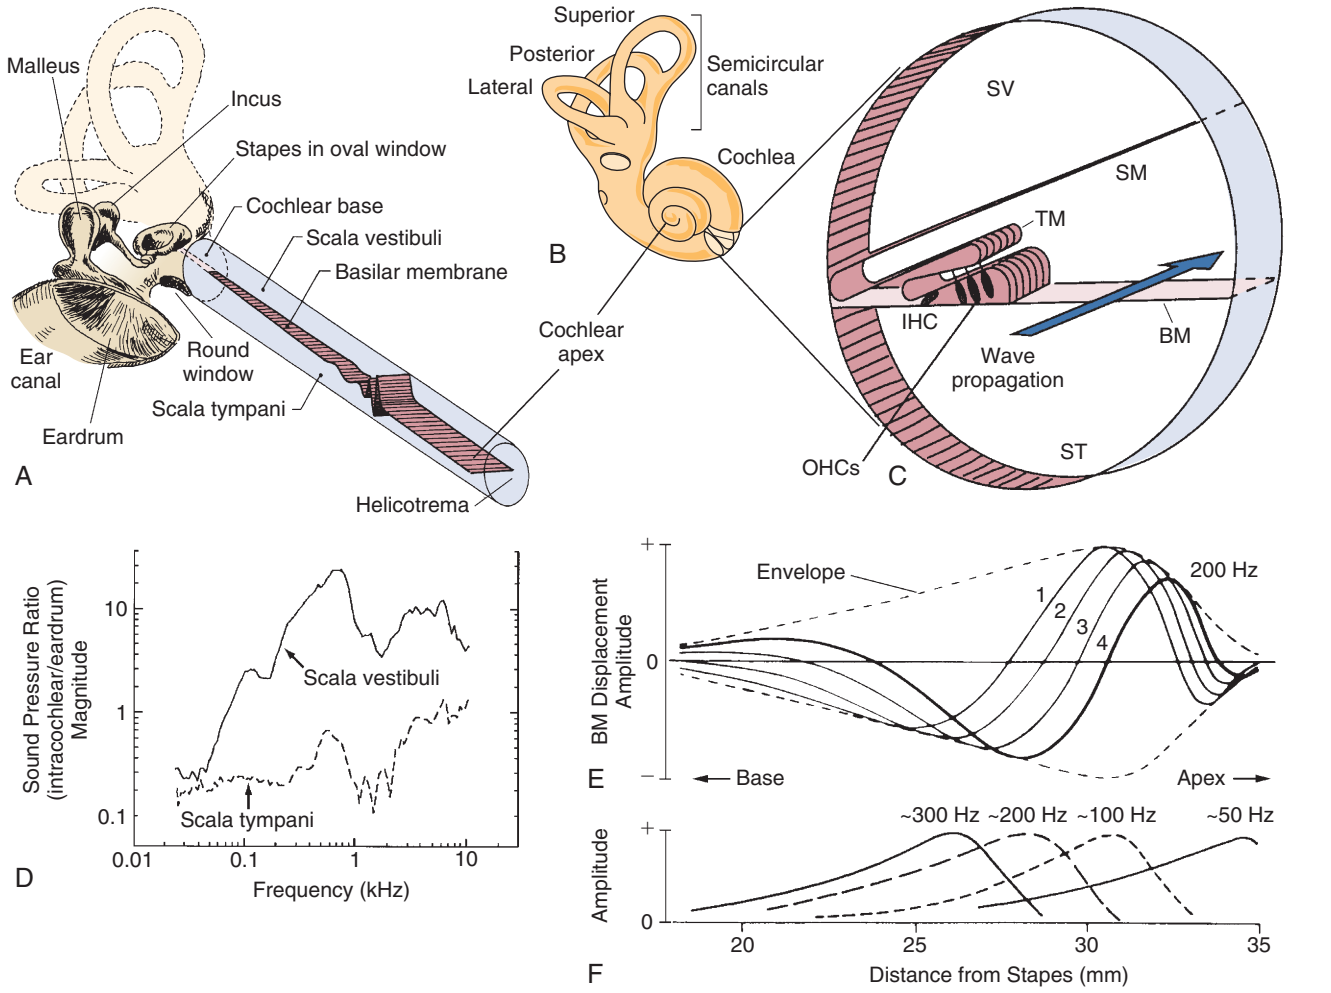

Figure 146-2. **A,** Schematic illustration of the inner ear with the cochlea uncoiled revealing the basilar membrane (BM) and a traveling wave at one instant in time in response to a pure tone. The eardrum (tympanic membrane) and middle ear ossicles also are shown in relation to the semicircular canals. The oval window opens into scala vestibuli (SV) and the round window to scala tympani (ST). **B,** Drawing of the inner ear with a segment of a cochlear turn extracted to expose the scalae. **C,** Diagram of a section through the cochlea showing the location of inner and outer hair cells (IHC and OHCs, respectively) in relation to the BM and TM and the direction of wave propagation. SM, scala media. **D,** The ratio of pressures measured within the SV and ST to the pressure at the eardrum produced in response to tone bursts are plotted as a function of stimulus frequency; responses were recorded from a cat. The difference between SV and ST pressures is responsible for displacement of the basilar membrane. **E,** BM displacements produced in a cadaveric human cochlea in response to 200 Hz at four separate points in time. The envelope of the traveling wave also is indicated. **F,** Envelopes of traveling waves measured along the BM in a cadaveric human cochlea in response to four stimulus frequencies, showing the relationship between the location of peak displacement and frequency (higher frequencies produce peaks at locations progressively closer to the base). *(**A,** From Dallos P, Fakler B.* Nat Rev Md Cell Biol. *2002;3:104; **B,** from Holme RH, Steel KP. openings shunt pressure waves extending to higher frequencies than those associated with small helicotrema. The shunting effect of helicotrema reduces the pressure differential across the cochlear partition, and it is this aspect of cochlear design that is thought to decrease damage to the cochlea produced by intense low-frequency pressure fluctuations.[403]

Active Cochlear Mechanics

Von Békésy recognized more than half a century ago that the envelope of the traveling wave measured in cochleae from human cadavers is broadly tuned—so broadly tuned as to be inconsistent with a living person's ability to discriminate closely spaced frequencies. Numerous groups of investigators have since confirmed the findings of von Békésy and have shown with clarity that sharp tuning and high sensitivity are lost in physiologically compromised cochleae or cochleae from cadavers.[432,494] Only after mechanical measurements were made in vivo with nonhuman species did it become clear that the peak of the traveling wave in living animals is, in fact, very sharply tuned at low levels of stimulation and exhibits nonlinear growth as sound levels increase.[274,314,433,454,494] The seminal study of Rhode,[433] which showed the amplitude of basilar membrane vibration relative to stapes displacement to be as much as two to three orders of magnitude greater under low-stimulus-level conditions than at higher levels in normal animals, led most directly to the contemporary understanding of cochlear mechanics as a nonlinear phenomenon (i.e., high sensitivity to changes in stimulus pressure at low levels, marked compression in the midlevel range, and linear growth at high levels) (Fig. 146-4).

Active mechanics associated with basilar membrane amplification is a metabolically labile, energy-consuming process that is, consequently, physiologically vulnerable. It is of particular importance to

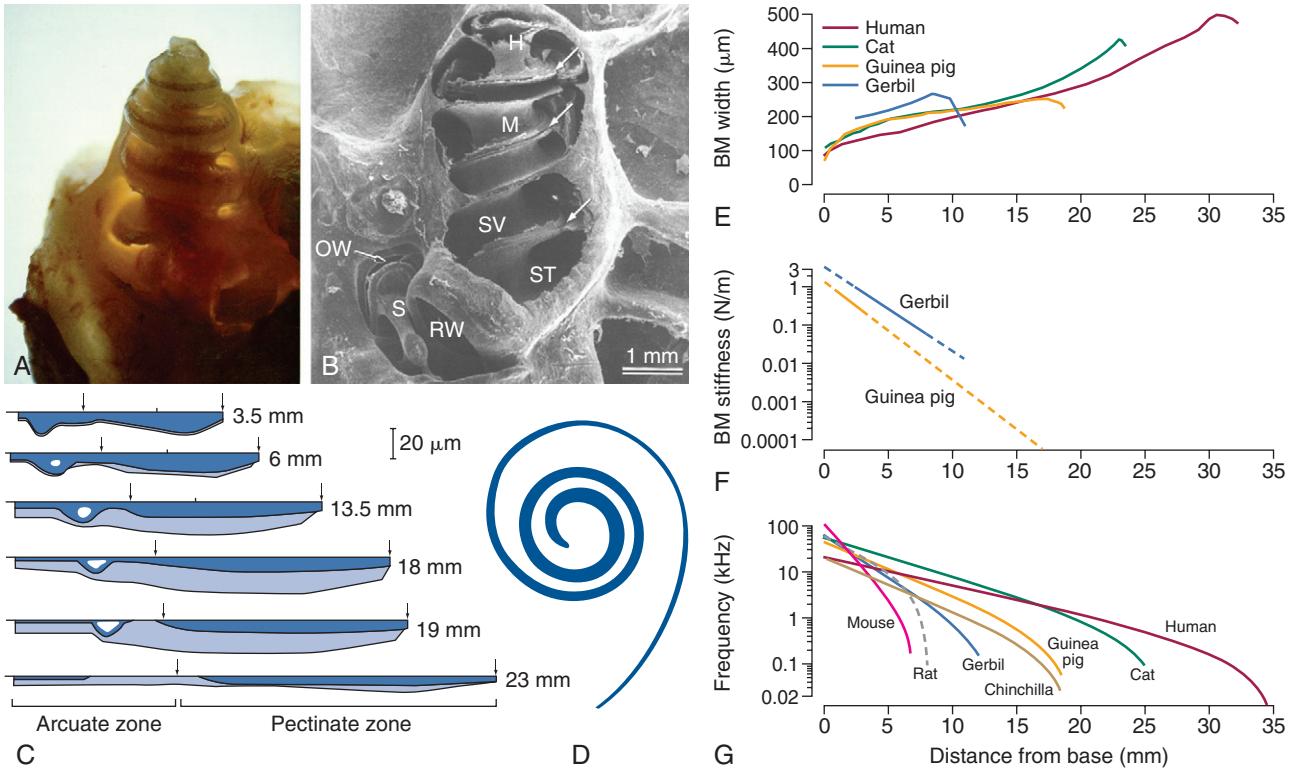

Figure 146-3. **A,** Photograph of the cochlea of a guinea pig after the outer bony shell has been thinned. **B,** Scanning electron micrograph (SEM) of a chinchilla cochlea after the bone on one side has been removed. The bony modiolus (M) is shown in the center, and the fluid-filled scala tympani (ST) and scala vestibuli (SV) are indicated in the basal turn. The helicotrema (H) is shown at the apex, and the *arrows* indicate the osseous spiral lamina to which the cochlear partition is attached at its medial extent. The round window (RW) and the stapes (S) are indicated, and the footplate of the stapes has been pulled away slightly, exposing the oval window (OW). **C,** Schematic illustration of the variation in thickness of the basilar membrane *(dark blue area)* and the associated mesothelial layer *(light blue area)* and the width of the basilar membrane *(horizontal axis)* at six locations along the cochlear spiral of the cat; specified locations are relative to the base. The demarcation between the arcuate and pectinate zones is indicated by the *left arrow* at each location; the arcuate zone (pars tecta) extends from the lip of the osseous spiral lamina to the foot of the outer pillar cell (OPC) and the pectinate zone from the OPC to the basilar crest of the spiral ligament *(right arrows)*. **D,** Scaled representation of the ribbon-like nature of the human basilar membrane indicating its width relative to its length. **E,** Quantitative relationship between the width of the basilar membrane (BM) and the distance from the base for the human,[604] cat,[64] guinea pig,[154] and gerbil.[445] **F,** Estimates of the stiffness of the basilar membrane in the guinea pig[205] and gerbil[139] as a function of location. **G,** Maps of the characteristic frequency (CF) of a cochlear location (i.e., peak of the envelope of the traveling wave) as a function of position along the basilar membrane for several species. Note that the lengths of the basilar membrane for each species can be estimated by the distance that each curve occupies along the x-axis. Frequency-position maps were based on a formulation developed by Greenwood[196] using empirical fits to data for the species shown here, except for rat, which was developed by Muller.[374] *(**A,** From Wasterstrom SA. recognize that the active mechanical event underlying amplification is highly localized. That is, the principle of active mechanics applies to a circumscribed portion of the cochlear partition that is limited to the immediate vicinity of the characteristic place for a given stimulus frequency (see Fig. 146-4A and B). At frequencies removed from the characteristic place, the properties of cochlear partition vibration in a living animal follow linear rules of growth, as in cadaverous tissue (Fig. 146-5).[179] Another important point is that the traveling wave peaks at increasingly apical regions of the cochlear partition with increasing stimulus level, shifting the cochlear place-frequency map toward lower frequencies at any given place.

Role of Outer Hair Cells in Active Mechanics

Many early studies indicated that OHCs play a fundamental role in active cochlear mechanics, as indicated by estimates of diminished cochlear sensitivity and frequency selectivity and loss of nonlinear operating properties when OHCs are missing from the end organ (see Fig. 146-4). The identification of specializations that distinguish inner hair cells (IHCs) from OHCs of the mammalian cochlea offered early clues that the contribution of OHCs to the transduction process is unique (Fig. 146-6). For example, only approximately 5% of all auditory nerve fibers innervate OHCs,[371,525,524] yet there are at least three times as many OHCs as IHCs (Fig. 146-7). These findings suggested that the transmission of sensory information to the central nervous system (CNS) probably is not the primary function of OHCs. In studies of acute preparations, investigators noted that the cochlea, and OHCs in particular, are highly vulnerable to hypoxia or other forms of insult.[76,148,293,432,433,448,449,494] In animal models of chronic damage, OHCs were found to be more susceptible to noise-induced or aminoglycoside-induced damage than IHCs, and when OHCs were lost, with IHCs appearing unaffected, cochlear sensitivity was significantly reduced, as was frequency selectivity, and input-output curves acquired a more linear character in the region of OHC damage.[77,97,101,149,208,278,279,329,450,465] In addition, other cochlear nonlinearities, such as two-tone suppression (i.e., the reduction in the response to one tone elicited by the presence of another) and distortion tones (i.e., the appearance of additional tones not present in the stimulus produced by the interaction of two or more primary tones, such as $2f_1$-f_2 or f_2-f_1, where f_1 and f_2 represent the

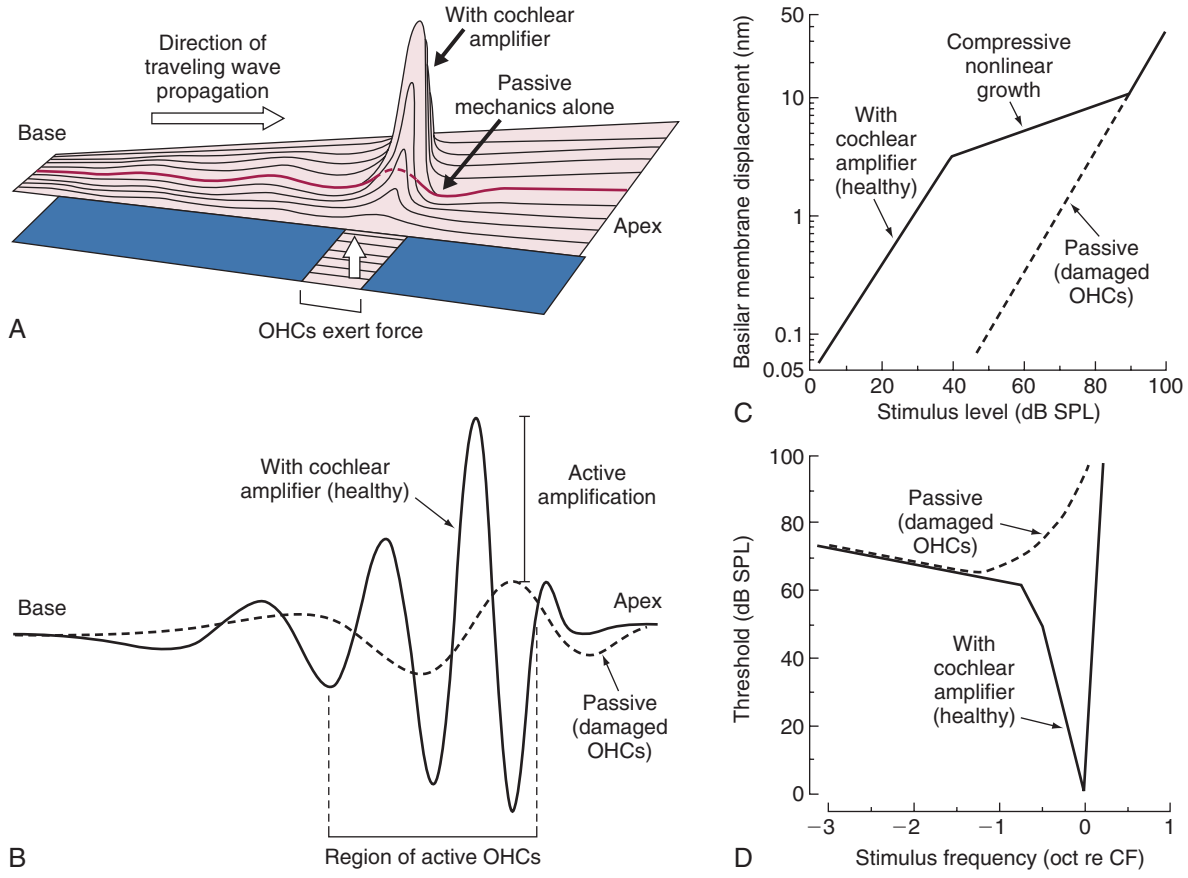

Figure 146-4. **A,** Schematic representation of traveling waves propagating along the basilar membrane (BM) in response to a pure tone. When the cochlear amplifier is functioning, outer hair cells (OHCs) within a restricted region of the traveling wave peak exert a force that enhances BM motion relative to that observed during passive mechanics alone for low-level stimuli. **B,** Similar to **A,** except note that the peak of the traveling wave produced with cochlear amplification is much narrower than the peak produced during passive mechanics alone, which is important for frequency discrimination. Also note that during active amplification, the peak of the traveling wave occurs slightly more basal than that produced during passive mechanics. **C,** Schematic relationship between stimulus level and BM displacement. When OHCs are normal, stimulus level increments of less than 40 dB sound pressure level (SPL) produce a linear increase in BM displacement. Between approximately 40 and 80 dB SPL, OHC responses saturate, producing a compressed response and nonlinear growth. Above 80 dB SPL, growth becomes linear again. When OHCs are damaged, displacements occur only to higher level stimuli and exhibit linear growth. **D,** The relationship between stimulus frequency (measured in octaves relative to the characteristic frequency [oct re CF] at that location) and the level required to elicit a criterion or "threshold" response at a given point along the BM (e.g., tuning curves). When the cochlear amplifier is operational, thresholds may be 40 to 60 dB lower and frequency selectivity greatly enhanced compared with a passive cochlea. *(**A,** From Ashmore JF, Kolston PJ. Cochlear amplification and its pathology: emphasis on the role of the tectorial membrane.* Ear Nose Throat J. *1997;76:151.)*

primary tones, with f_1 less than f_2), are either lost or diminished when OHCs are traumatized.[102,480] The discovery of sound-evoked otoacoustic emissions, sounds that are generated by the end organ during transduction and are measured in the external ear canal,[270] along with spontaneous otoacoustic emissions,[608] and their dependence on OHCs provided additional evidence that an active, OHC-driven mechanism operates within the cochlea, which is capable of producing energy and propagating it in the reverse direction. The influence of OHCs on cochlear mechanics was further suggested on the basis of observations made after stimulating the crossed olivocochlear bundle (OCB), a brainstem pathway populated by large, myelinated fibers that arise among neurons located in the medial region of the superior olivary complex that cross the brainstem at the floor of the fourth ventricle and terminate in calyx-like presynaptic terminals on OHCs.[200,287,427,428,518,597,598] Specifically, OCB activation altered cochlear output,[118,155,156,176,605] as well as otoacoustic emissions[373,505] and basilar membrane displacement,[376] supporting the notion that OHCs directly influence cochlear mechanics. Further support for the view that OHCs play an essential role in active mechanics comes from the work of Mammano and Ashmore,[349] who demonstrated that outer hair cell motility induced by electrical stimulation of the excised cochlea displaced both the reticular lamina and the basilar membrane.

Prestin (SLC26A5) Is Essential for Outer Hair Cell Motility and Active Transduction

The finding that OHCs contract or elongate at very high rates (up to at least 70 kHz) along the length of their longitudinal axes when depolarized or hyperpolarized, respectively,[30,62,63,98,99,168,177,261,478,630] led to the suggestion that OHCs may amplify the displacement of the basilar membrane if forces generated by their motility are produced on a cycle-by-cycle basis and precisely timed relative to passive mechanical events (see Fig. 146-6E). Somatic length changes of up to 5% of the total length of OHCs are determined directly by the magnitude of the transmembrane voltage and not by ionic currents. In addition, the voltage-motility relationship observed among OHCs is highly nonlinear (Fig. 146-8B). Unlike in IHCs, the lateral wall of OHCs is densely packed with particles that are integral components of the plasma membrane,[165,202,264,470] and these particles are thought to be oligomers of the protein recently identified as the molecular motor underlying fast somatic motility (see Fig. 146-6C and E).

Figure 146-5. The discovery that OHC motility is accompanied by gating currents that reflect a nonlinear capacitance led to the suggestion that it was the movement of charged particles within the domain of the plasma membrane that operates as the motive force of contractility.[31,476] The voltage-sensitive motor protein underlying the process was identified in 2000 and given the name prestin (SLC26A5). Prestin (Fig. 146-8A) is a modified anion-transporter protein belonging to the solute carrier 26 (SLC) family of proteins.[633] Antibodies to prestin have been localized in OHC membranes, and developmental changes in the expression of prestin immunoreactivity follow a temporal profile that overlaps the development of electromotility, providing further support for the view that prestin is the motor protein.[42] Although the precise location of the voltage sensor remains unknown, and although it may be an integral component of the prestin molecule itself, findings from recent studies suggest that intracellular Cl^- ions act as extrinsic charged voltage sensors (see Fig. 146-8B, inset). In this model, Cl^- ions occupy a position in the intracellular domain of the membrane-bound prestin protein and move along an inward electrical gradient away from the extracellular domain during depolarization. This charge movement produces, in turn, a conformational change in the protein that reduces its surface area and shortens the cell; the opposite action occurs during hyperpolarization, when Cl^- ions move toward the extracellular space within the domain of the protein (although the anion is never translocated to the extracellular space), causing an increase in surface area and lengthening of the cell.[100,391] Salicylates, which are known to cause temporary hearing loss when administered at high doses,[535] are permeable to the plasma membrane and act as competitive antagonists of Cl^-, thereby reducing electromotility and, presumably, diminishing sensitivity.[391] The role of prestin in transduction was studied directly in a mouse strain in which prestin was deleted. The knockout mouse exhibited a loss of OHC electromotility in homozygous mutant animals (see Fig. 146-8D), a 40- to 60-dB loss in sensitivity, and loss of OHCs in the base of the cochlea (see Fig. 146-8C).[328] In addition, the frequency selectivity of individual auditory nerve fibers is diminished in knockout mice.[68] Although the length and stiffness of OHCs are reduced in the knockout mouse, these findings collectively suggest that active transduction is a direct product of OHC somatic motility. Confirmation of prestin's role in cochlear amplification was recently established in a study of a "knock-in" mouse model, in which the protein's function was diminished but OHCs exhibited normal length and stiffness.[103] Natural mutations of the prestin gene have been identified in humans, and the resulting condition is transmitted as a recessive, nonsyndromic form of congenital deafness. In this case, however, hearing loss is in the severe to profound category (i.e., on the order of 90 dB or greater) and exists as a bilateral form of deafness among persons who are homozygous for the trait. The degree of hearing loss is more variable among heterozygotes, ranging from normal in one case to mild (40 dB) and even moderate to profound (60 dB) in others, suggesting the semidominance of the abnormal allele through haploinsufficiency.[337]

Conversion of Basilar Membrane Displacement to Radial Shearing Forces

All existing models of transduction center on the idea that displacement of the basilar membrane results in a radial shearing motion between

the reticular lamina and the tectorial membrane, a motion that serves as the mechanical trigger of transduction currents. The reticular lamina consists of the interdigitating heads of the inner and outer pillar cells, the apical surfaces of the phalangeal processes of Deiters cells, and the apical surfaces of the hair cells through which the stereocilia project (see Fig. 146-6D). The apical surfaces of the supporting cells are flattened and are composed of microtubules and actin microfilaments, lending support to the idea that the reticular lamina is a relatively rigid structure that moves in concert with basilar membrane motion. The tectorial membrane is firmly attached to the spiral limbus and overlies the reticular lamina, with its tip or marginal zone connected to Hensen cells. The tallest row of stereocilia protrude from the apical surface of each outer hair cell and embed within the inferior surface of the tectorial membrane along the entire length of the cochlear spiral.[288,333] Bundles of radially oriented filaments, consisting of type II, V, IX, and XI collagens, are embedded within the gelatinous matrix of the mammalian tectorial membrane (see Fig. 146-10A and B).[209,361,444,514,515,545,546] The presence of collagen enhances the rigidity of the structure, making it less compressible and less elastic, particularly in the radial dimension.[3,199,446] These features support a system in which the shearing motion between the reticular lamina and the tectorial membrane causes stereocilia to bend in the direction of the modiolus or the spiral limbus, depending on whether the basilar membrane is displaced toward the scala tympani or scala vestibuli, respectively.

In contrast with OHCs, the stereocilia of IHCs do not appear to firmly contact the tectorial membrane (see Fig. 146-1D). Therefore,

Figure 146-7. during basilar membrane vibration, the relevant mechanical stimulus to IHC stereocilia is thought to be the flow of endolymph within the subtectorial space, the narrow channel between the reticular lamina and tectorial membrane into which the stereocilia protrude.[387] Fluid coupling is then thought to lead directly to the displacement of IHC stereocilia in proportion to basilar membrane velocity at low frequencies (less than 500 Hz) and to basilar membrane displacement at higher frequencies; sustained displacements of the basilar membrane, or very-low-frequency displacements, do not effectively bend IHC stereocilia.[403]

Radial Displacement Patterns of the Basilar Membrane

The dynamics of basilar membrane displacement at the characteristic frequency place are more complex when examined radially. Inner and outer pillar cells that form the fluid-filled tunnel of Corti are packed with bundles of microtubules and actin microfilaments arranged in parallel that are cross-linked and are thought to produce structural rigidity within the cochlear partition.[25,140,244] The foot of the inner pillar cell lies near the bony spiral lamina, whereas the foot of the outer pillar cell lies over the basilar membrane and is not supported by bone (Fig. 146-9). Therefore, when the basilar membrane is displaced in a passive cochlea, movement occurs maximally near the foot of the outer pillar cell, with the basilar membrane pivoting at the foot of the inner pillar cell.[104] When OHCs contract, the reticular lamina pivots at the apex of the tunnel of Corti, and the basilar membrane and reticular lamina are pulled together, enhancing overall basilar membrane displacement.[168,349,350,383] Furthermore, unlike in passive mechanical events, in which the full width of the basilar membrane moves uniformly (synchronously), during active mechanics, the magnitude and phase of displacement vary in the radial dimension.[83,383,388,395,396,431,495,563,609,622] Although differences among studies from different laboratories are significant regarding the precise pattern of basilar membrane movement in the radial direction after displacement, many workers suggest that the position of greatest motion is in the domain of the OHC, and that motion in the OHC region is out of phase relative to the foot of the outer pillar cell. This finding has significant implications in the ongoing effort to understand the relationship between inner and outer hair cell responses during the transduction process.

Tectorial Membrane Pathophysiology

The tectorial membrane is composed of two primary matrix elements: a group of radially oriented collagen fibrils and a striated sheet matrix that is made up of tightly packed, small-diameter filaments that are interlinked by cross-bridges to give it a striated appearance.[209,288,300,333,559] In addition to the variety of collagens making up the core structure, a collection of glycoproteins—α-tectorin, β-tectorin, and otogelin—also are constituent elements of the tectorial membrane.[78,193,285,319,444] Otogelin, a glycoprotein that is found in essentially all of the acellular membranes of the inner ear, is associated with the large collagen fibrils, whereas α-tectorin and β-tectorin are components of the striated sheet matrix.

The mass and stiffness of the tectorial membrane are important variables that together determine the resonant properties of the structure that, in turn, affects its displacement pattern during acoustic stimulation. Much like dimensional changes that have been measured along the length of the basilar membrane, the cross-sectional area of the tectorial membrane has been shown to increase from the base to the apex as indicated by morphometric measurements of fully hydrated tissue specimens (Fig. 146-10C).[445] Moreover, base-to-apex stiffness gradients in both the transverse and radial axes of the tectorial membrane have been observed,[199,446] and they are similar to those reported for basilar membrane stiffness gradients (see Fig. 146-10C).[139,205] Taken together, basoapical gradients in the physical properties of the tectorial membrane suggest the possibility that the structure may support longitudinally propagating traveling waves,[181] giving rise to a second cochlear frequency-place map. Some investigators have suggested that the resonant frequency of the tectorial membrane lies approximately one-half octave below that of the basilar membrane's characteristic or resonant frequency at any given position along the cochlear spiral.[17,18,203,641] However, until the opportunity to study mutant mice in which the tectorial membrane is completely detached from the spiral limbus and the surface of the organ of Corti[317] presented itself, direct evidence regarding the precise role of the tectorial membrane as an element of transduction was largely unavailable.

Targeted disruption of the gene that encodes α-tectorin (*Tecta*) in mice ($Tecta^{\Delta ENT/\Delta ENT}$) leads to loss of not only α-tectorin but also β-tectorin and otogelin.[317] In addition, the striated sheet matrix is absent, and collagen fibrils are disorganized in the tectorial membranes of mice that are homozygous for the deletion, not to mention that the structure is detached from the spiral limbus and floats freely in scala media. Like the IHC stereocilia of normal animals, the stereocilia of OHCs in α-tectorin–mutant mice are fluid-coupled to end organ motion, and mice exhibit elevated thresholds that reflect that condition (i.e., generally elevated neural thresholds decrease at a rate of approximately 6 dB/octave with increasing frequency). Mechanical input-output curves constructed from responses to tone bursts presented at characteristic frequency also are more linear (although approximately 35 dB less sensitive), and frequency selectivity is normal, or at least

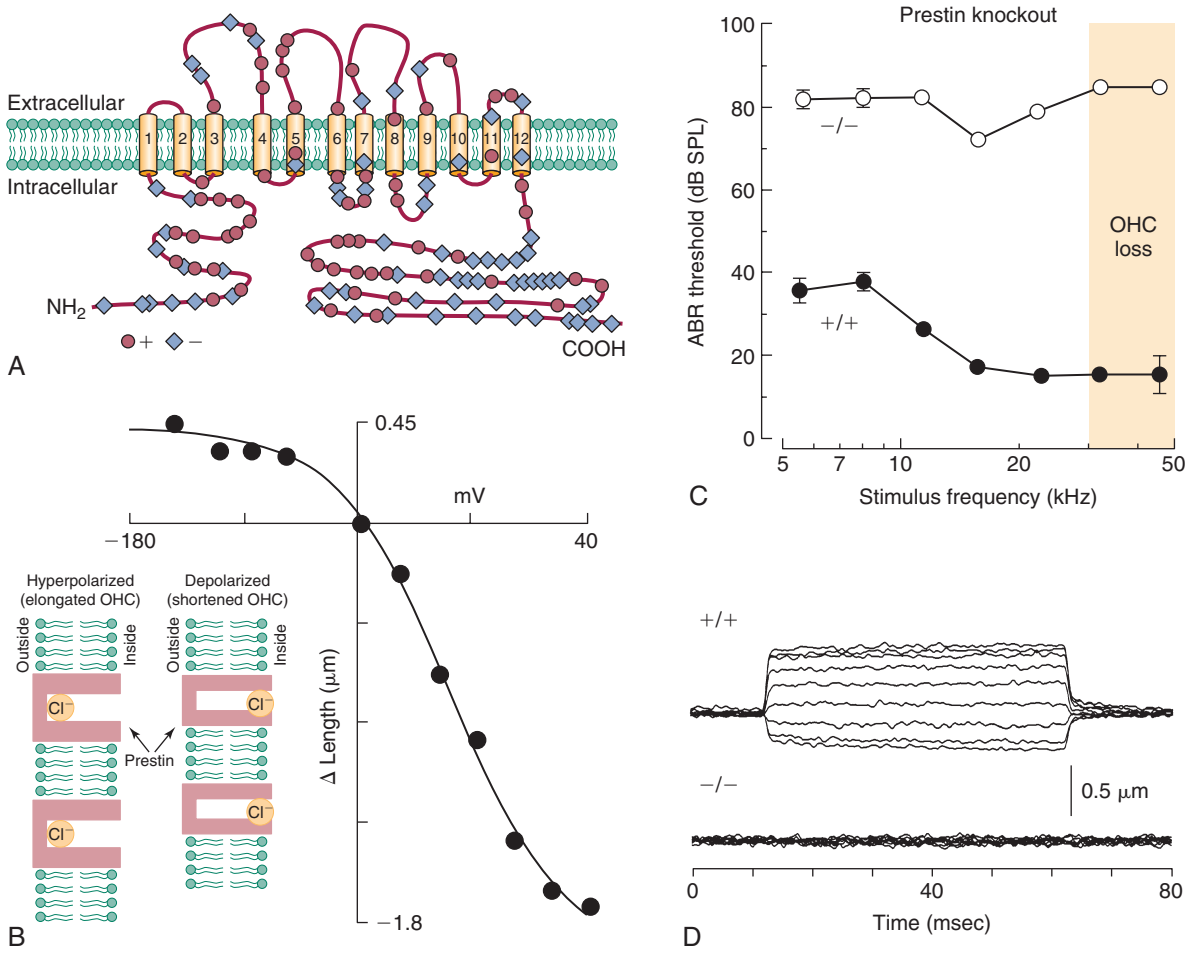

Figure 146-8. **A,** Schematic representation of the membrane topology of prestin (SLC26A5). Prestin consists of 744 amino acids and is predicted to have 12 transmembrane domains and intracellular amino-terminal (NH_2) and carboxyl-terminal (COOH) ends. *Circles* and *diamonds* represent positively and negatively charged amino acids, respectively. **B,** Change in the length of an isolated outer hair cell (OHC) as a function of voltage stepped from a holding potential of –68.4 mV. The *inset* is an illustration of single prestin molecules located in the plasma membrane that can toggle between two conformational states, depending on transmembrane voltage. The larger the depolarization, the greater likelihood that the shorter state will be adopted, and vice versa. The nonlinear capacitance associated with length changes may be due to the translocation of anions, such as Cl^- *(yellow circles)*, that move closer to the extracellular side during hyperpolarization and toward the intracellular side during depolarization. **C,** Targeted disruption of prestin results in severely elevated auditory brainstem response (ABR) thresholds in homozygous mice, and somatic motility is absent in isolated OHCs (**D**). *(**A,** From Dallos P, Fakler B. Prestin, a new type of motor protein.* Nat Rev Mol Cell Biol. *2002;3:104; Reprinted by permission from Macmillan Publishers Ltd. **B,** from Santos-Sacchi J. Walsh; **C,** and **D,** adapted from Liberman MC, Gao J, He DZ, et al. Prestin is required for electromotility of the outer hair cell and for the cochlear amplifier.* Nature. *2002;419:300.)*

nearly so. Of interest, a second region of sensitivity in basilar membrane tuning curves that is approximately 0.5 octave below the best frequency in normal mice is not observed in α-tectorin mutant mice, suggesting that the tectorial membrane may be responsible for that second resonance.

These findings suggest that the tectorial membrane is required for OHCs to amplify displacement of the basilar membrane at low stimulus levels. In humans, mutations in the *TECTA* gene are responsible for both recessive and dominant forms of deafness—DFNB21, DFNA8, and DFNA12.[378,574] In patients with DFNA8 or DFNA12, hearing loss is congenital and nonprogressive[574] and can be more severe in the midfrequency than other frequency ranges, whereas patients with DFNB21 experience severe-to-profound deafness, and the onset can be either prelingual or postlingual.[378]

Further insight into the tectorial membrane's role in transduction can be found by studying a strain of mice in which the *Tecta* gene is disrupted at the same location (Y1870C)[318] as a mutation found in patients with autosomal dominant hearing loss associated with a missense mutation in the *TECTA* gene.[574] The tectorial membrane is detached and individuals exhibit a phenotype similar to that observed in $Tecta^{\Delta ENT/\Delta ENT}$ mice in the case of homozygotes, whereas the tectorial membrane remains attached in heterozygous mice, although the striated sheet matrix is disrupted, Hensen's stripe is lost, and the subtectorial space in the region of IHCs is enlarged. Although basilar membrane thresholds are minimally elevated (approximately 10 dB) in heterozygotes, neural thresholds are elevated by approximately 55 dB, suggesting that the precise spatial relationship between the tectorial membrane and reticular lamina in the region of the IHCs is a critical factor associated with fluid coupling between IHCs and OHCs.

As with mice expressing an abnormal *Tecta* gene, loss of β-tectorin in the tectorial membrane is associated with the loss of the striated sheet matrix and Hensen's stripe, although the tectorial membrane itself remains attached to the spiral limbus.[462] Both α-tectorin and otogelin have been detected in the tectorial membrane of mutant animals, and imprints of the tallest row of outer hair cell stereocilia have been observed on the underside of the membrane. Although basilar membrane sensitivity is just slightly diminished at the base of the cochlea in affected animals (i.e., tuning curve tips are elevated approximately 10 dB), tuning curve sharpness is enhanced, and the second resonance normally observed below the best frequency is lost. In contrast with

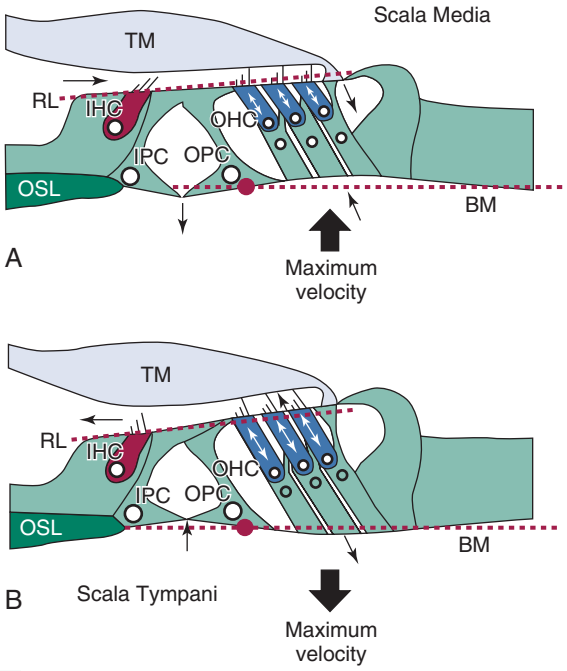

Figure 146-9. Model of basilar membrane (BM) vibration across the radial extent of the membrane. **A,** As the BM moves toward scala vestibuli, at the point of maximum BM velocity, the shearing motion between the BM and tectorial membrane (TM) causes the stereocilia to bend in the excitatory direction, producing depolarization and contraction or shortening of the outer hair cells (OHCs), pulling the reticular lamina (RL) toward the BM. IHC, inner hair cell; IPL, inner pillar cell; OPC, outer pillar cell; OSL, osseus spiral lamina. **B,** As the BM moves toward the scala tympani, and at the point of maximum BM velocity, hair bundles are deflected in the inhibitory direction, causing hyperpolarization and elongation of the OHCs. *Dotted lines* indicate the positions of the BM and RL at rest. Note that the *large red dot* along the BM located at the foot of the OPC represents a pivot point, which allows the displacement of the BM beneath the tunnel of Corti to be out of phase with the displacement that occurs under the OHCs. *(Redrawn from Nilsen KE, Russell IJ. Figure 146-10. **A** and **B,** Schematic representation of the organ of Corti from the apical (**A**) and basal turns (**B**) of the cochlea showing the location of the tectorial membrane (TM) in relation to the surface of the organ of Corti. Major proteins of the TM include types II, V, IX, and XI collagen, α- and β-tectorin, and otogelin. Note the differences in basilar membrane (BM) width and thickness and outer hair cell lengths at the two locations. **C,** The cross-sectional area of the TM[445] and its stiffness,[446] measured in both the transverse and radial directions, are shown as a function of distance from the base of the cochlea for the gerbil. Stiffness of the gerbil's basilar membrane[139] is plotted for comparison. *(**A** and **B,** Adapted from Spoendlin H. Innervation densities of the cochlea.* Acta Otolaryngol. *1972;73:235.)*

findings observed in the base, neural sensitivities were elevated by 40 to 50 dB at frequencies below 20 kHz. The enhanced frequency selectivity observed in the base of the cochlea in β-tectorin–deficient mice may be a consequence of the loss of the striated sheet matrix in that region and the concomitant reduction of longitudinal elastic coupling that reduces, in turn, the spread of excitation, although this explanation remains speculative.

Mice with a targeted disruption of the gene that encodes otogelin (Otog) exhibit abnormalities in the tectorial membrane, primarily in the region near the spiral limbus. The tectorial membrane of these animals lacked normal fibrils, and anomalous rodlike structures within the limbal zone of the tectorial membrane were observed in the apex of the cochlea in some cases and along its entire length in others.[508] The degree of hearing loss in otogelin-null mutants is highly variable, even within individual mice. Some animals seemed to experience mild, frequency-independent deficits, whereas others seemed to be profoundly deaf and have a progressive loss of hearing. Heterozygous mice, on the other hand, had normal phenotypes. Although mutations in the human otogelin gene have not been reported, results from mouse studies suggest that abnormalities in otogelin mutants may increase susceptibility of the tectorial membrane to mechanical stress.

Absence of the α2 chain of collagen type XI (Col11a2) also produces defects in the tectorial membrane, as well as moderate to severe hearing loss.[361] In mutant mice, the tectorial membrane is slightly thicker than normal, and collagen fibrils seem to be less densely and evenly packed and more disorganized than in control animals. Col11a2 is thought to play an important role in the maintenance of the tectorial membrane by influencing the spacing of interfibrillar distances among type II fibrils, which are present in large numbers. It is interesting that phenotypic differences are observed between heterozygous mice and wild-type mice. In patients expressing *COL11A2* mutations, a continuum of defects is observed, the mildest form being an autosomal dominant, nonsyndromic form of deafness (DFNA13),[361] whereas autosomal recessive, nonsyndromic deafness (DFNB53),[71] Stickler's syndrome locus 3 (without eye involvement), and autosomal dominant or autosomal recessive otospondylomegaepiphyseal dysplasia (OSMED) syndrome[418,510,581] represent the most severe forms. Hearing loss in patients with DFNA13 occurs prelingually, is nonprogressive, and primarily affects the midfrequency range of hearing[361]; hearing loss in patients with DFNB53 is prelingual, nonprogressive, and profound.[71]

It is noteworthy that type IX collagen forms heterotypic fibrils with type II collagen in the tectorial membrane.[514] In this regard, a mutation in the *COL9A1* gene has been identified that causes Stickler's syndrome.[566] The condition is inherited as an autosomal recessive trait and is characterized by moderate to severe hearing loss, with greater insensitivity in the high-frequency domain. Although type IX collagen has been detected in fibrocytes of the spiral ligament, abnormalities, including disorganized collagen fibril patterns, are limited to the tectorial membrane of *Col9a1*-targeted null mice. However, auditory brainstem response (ABR) thresholds are elevated on P30, and sensitivity is progressively diminished with age in this mouse strain.[537]

Hair Cell Transduction

Although hydromechanical events produce organ of Corti vibration patterns that serve as the effective sensory stimulus for hearing and form the basis of the relationship between cochlear place and characteristic frequency (i.e., tonotopy), the hair cell is the central element of sensory transduction because it is the receptor cell, a mechanoreceptor that converts mechanical to electrical energy. In the human cochlea there are approximately 3500 IHCs and 12,000 OHCs, with densities corresponding to approximately 86 IHCs/mm and 343 OHCs/mm, although considerable variability exists within the population generally.[562,614] The lengths of OHCs increase continuously from the base of the cochlea to the apex, whereas the lengths of IHCs remain fairly consistent (Fig. 146-11C). Unlike some sensory systems (e.g., olfactory and somatosensory systems), in which primary afferent fibers display specialized peripheral endings designed to sense external stimuli and transmit that information directly to the CNS, the statoacoustic system, as well as the visual and gustatory systems, senses its environment by means of specialized epithelial cells, the receptor cells, that are housed in specialized peripheral organs (e.g., the cochlea, the semicircular canals, the otolith organs). Furthermore, receptor cells serving the statoacoustic system are innervated by primary afferents and do not enter the CNS directly.

Hair Cell Stereocilia

To understand the dynamics of transduction, it is necessary to look carefully at the apical surface of statoacoustic receptor cells (see Fig. 146-11A and B). In doing so, it is immediately apparent that they are highly differentiated. Numerous shaft-like protrusions, referred to individually as "hairs" and collectively as "hair bundles" by early anatomists, project from each receptor cell. These apical extensions came to be known as stereocilia, even though they clearly are not true cilia (i.e., they do not conform to the well-defined organizational plan of true cilia, in which two central tubules are surrounded by nine doublet microtubules) and are more appropriately thought of as specialized

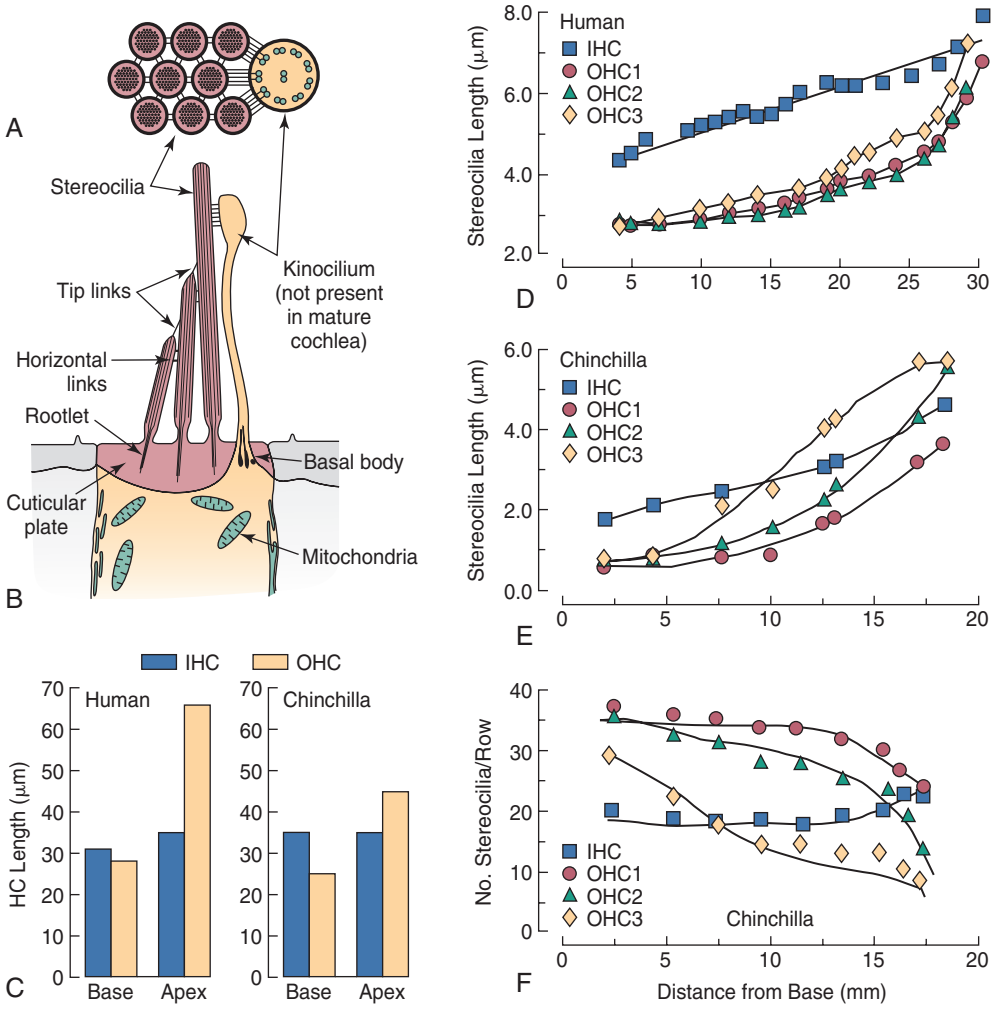

Figure 146-11. **A,** Drawing of a cross section through hair cell stereocilia and the kinocilium, which is present on auditory hair cells only during early development, showing the dense, regular packing of actin filaments that constitute the central core of each stereocilium and the single doublet surrounded by nine pairs of microtubules that make up kinocilia. **B,** Representation of the apical region of hair cells, illustrating tip links that connect the tips of shorter stereocilia with the adjacent taller stereocilia and horizontal links that cross-link all adjacent stereocilia, as well as the kinocilium (also shown in **A**). **C,** The lengths of inner hair cells (IHCs) populating the base and apex are similar, as are IHCs from humans and chinchilla, whereas outer hair cell (OHC) lengths increase from base to apex—quite dramatically in the case of human OHCs. Data for human hair cells are from Nadol[379] and those for chinchillas are from Lim.[331] **D** and **E,** The length of the stereocilia in the tallest row of a hair bundle increases progressively from base to apex in humans (**D**) and chinchillas (**E**). Data for humans were obtained by Wright,[612] and those for chinchillas by Lim.[332] **F,** The number of stereocilia per row as a function of distance along the cochlear partition. Data from Lim.[332] (***A,*** *From Thurm U, et al. Studies of mechanoelectric transduction in concentric hair bundles of invertebrates. microvilli. All vestibular hair cells and all auditory hair cells of lower vertebrates are equipped with a single kinocilium, a true cilium that protrudes from the apical surface of each receptor cell. The functional role of kinocilia is uncertain, in no small measure owing to the observation that hair cell transduction remains unchanged after its microsurgical ablation.[241] It also is interesting that kinocilia project from the surface of immature auditory hair cells of mammals but are lost during the final stages of differentiation.

Approximately 50 to 70 stereocilia protrude from each IHC and approximately 150 from each OHC, although toward the apex of the cochlea, the number of stereocilia on OHCs decreases to less than half of the number found on OHCs populating the basal turn of the cochlea in humans,[613] as in other mammals (see Fig. 146-11F). Stereociliary lengths for both IHCs and OHCs progressively increase from the base to the apex of the cochlea (see Fig. 146-11D and E). The orientation and pattern of stereocilia within a bundle are highly stereotypical, and the overall configuration for auditory hair cells is conserved among mammals. Individual hair bundles are organized into approximately three rows of stereocilia that are arranged according to a nearly linear motif in the case of IHCs and in the form of a W in the case of OHCs, with the base of the W facing the lateral wall of the cochlea (Fig. 146-12). Stereocilia within each row are approximately the same height, and the longest row is located on the side of the cell that is proximal to the spiral ligament and adjacent to the kinocilium, or the basal body in the case of mature auditory hair cells. The length of stereocilia decreases in an orderly manner in rows that are located progressively proximal to the modiolus, producing what is commonly described as a stairstep configuration. As a result of this arrangement, the hair bundle has a plane of bilateral symmetry, providing the foundation for directional sensitivity (see the following).

The stereocilium tapers near its point of insertion into the surface of the receptor cell (see Figs. 146-11B and 146-12C), and only a small fraction of the total number of actin filaments penetrate the cuticular plate, itself a dense network of randomly oriented, interconnected actin filaments packed into the apical fraction of the receptor cell body.[117,160,220,549] The rootlets of actin filaments projecting from the base of stereocilia are anchored firmly within the cuticular plate and are linked to the actin filaments within the plate, enhancing the rigidity of the structure. The protein spectrin is a major actin linkage element within the overall assembly,[133] and along with fimbrin, α-actinin (which attaches to the ends of the actin filaments), tropomyosin, profilin (a protein that regulates actin polymerization and sequesters actin monomers), myosin, calmodulin, and calbindin, these compounds are the major proteinaceous components of the cuticular plate.[513,516,517,627] The stereociliary neck produced by the constriction of the stereocilium at its insertion point allows the structure to pivot, as opposed to flexing, near the surface of the receptor cell, acting like a stiff lever when mechanically distorted.

Much of what is known about the receptor cell trigger mechanism, an event characterized by the deformation or bending of stereocilia, comes from studies in which stereocilia are physically displaced throughout their dynamic range. In that context, it is remarkable to note that the deflection of a hair bundle by 30 to 60 nm generates a receptor potential equal to approximately 90% of a receptor cell's dynamic range,[463] reflecting a very steep and very sensitive deflection-response relationship. This deflection is less than the typical diameter of a single stereocilium (i.e., approximately 200 nm). It is in this dimension that we can begin to appreciate the intrinsic value of the elaborate design of the cochlea. The ability to detect acoustic events as faint as 0 dB sound pressure level (SPL) clearly requires the sensory cell to perform optimally, and optimization is achieved by placing the cell in a highly stable environment (a fluid-filled bony labyrinth) and supporting it within a rigid but flexible infrastructure (the organ of Corti). The need for such architectural sophistication becomes apparent with the recognition that the sensitivity of hearing is ultimately limited by the Brownian motion of hair bundles, estimated to be on the order of 1 nm[52] but reduced to approximately 0.1 nm as a consequence of inherent mechanical filtering.[95] It is relatively easy to gain perspective on this matter by considering the observation that the absolute threshold of hearing requires a displacement of the basilar membrane of a mere 0.1 nm,[494] a motion that would be reduced to approximately 0.001 nm were it not for the basilar membrane amplification provided by actively motile OHCs. The amplified motion of the basilar membrane at threshold translates into displacement of hair cell stereocilia of approximately 1 nm and sensitivities on the order of 30 mV per degree of rotation, corresponding to approximately 0.4 mV per nm of displacement at the tip of a 3- to 4-μm-long bundle.[463]

Hair Bundle Deflections and Receptor Potentials

Statoacoustic receptor cell potentials, like receptor cells in sensory systems in general, are graded in response to stimulation, and the displacement-voltage curve associated with the movement of a stereociliary bundle throughout its dynamic range generally is sigmoidal.[91,240,460,463] The nature of this relationship is consistent with the observation that the magnitude of the receptor potential is proportional to the degree of stereociliary deflection in the most sensitive region of its operating range but saturates with larger deflections in either direction (see Fig. 146-12G). When the bundle is deflected toward the tallest stereocilia, the hair cell depolarizes, and deflections of the bundle in the direction opposite the tallest stereocilia hyperpolarize the cell (see Fig. 146-12G, inset). These findings support the view that hair bundle polarity is an essential element of normal hair cell function.[343] In addition, the displacement-voltage curve is highly asymmetrical relative to its resting state, such that responses saturate with smaller deflections directed away from the taller stereocilia than in the excitatory or depolarizing direction, and that deflection of the hair bundle in a direction perpendicular to this axis produces no response. Furthermore, displacement along an intermediate or oblique axis elicits a response that is proportional to its vectorial projection along the axis of symmetry.[159,503]

Hair Cell Transduction Channels

Conductance changes in hair cells associated with mechanically evoked responses indicate that when stereocilia are deflected in the excitatory direction, transduction channels in the membrane open, producing current flow leading to membrane depolarization, whereas movement of the stereocilia in the inhibitory direction causes the closure of transduction channels.[240] The latency of hair cell responses to bundle displacement is remarkably fast, on the order of 40 μsec at 22° C,[86] and kinetic analyses of the receptor current have shown that it takes approximately 100 μsec to reach steady-state currents at 4° C in response to large bundle displacements.[85] Activation time is inversely related to the magnitude of bundle displacement and is temperature-dependent, and fast offset times associated with receptor current follow positive voltage steps.[85] Because enzymatic systems or second messengers would be too slow to underlie the transducer response, these data suggest that transducer channel activation is directly coupled to displacement of the stereocilia.[85] Additional studies support a two-state model, whereby transduction channels operate in either an open or a closed state, with the probability of being in one or the other state depending on the degree of hair bundle deflection.[90,230,389] Moreover, the concept of an elastic mechanical linkage, or gating spring, associated with the transduction channel was established on the basis of the observation that the offset dynamic of transducer currents after a positive prepulse is independent of bundle position for negative stereociliary bundle displacements beyond a certain critical limit. According to this model, these linkages relax at negative displacements and therefore do not influence the state of the channel.[85]

On the basis of this model, the asymmetrical displacement-voltage curve described previously is explained by the fact that a small population of transduction channels, roughly 10% to 15%, is in the open state at rest. When stereocilia are bent toward the tallest stereocilia, the probability that channels will open increases, driving membrane resistance to lower values. Conversely, during maximal deflection of stereocilia in the inhibitory direction, transduction channels that were open at rest close and hyperpolarize the cell. The proportion of time spent in the open or the closed state is a function of the degree of mechanical displacement of stereocilia. Moreover, it is known that the stiffness of the hair bundle is at its minimum at the point of maximum sensitivity of the displacement-receptor potential curve

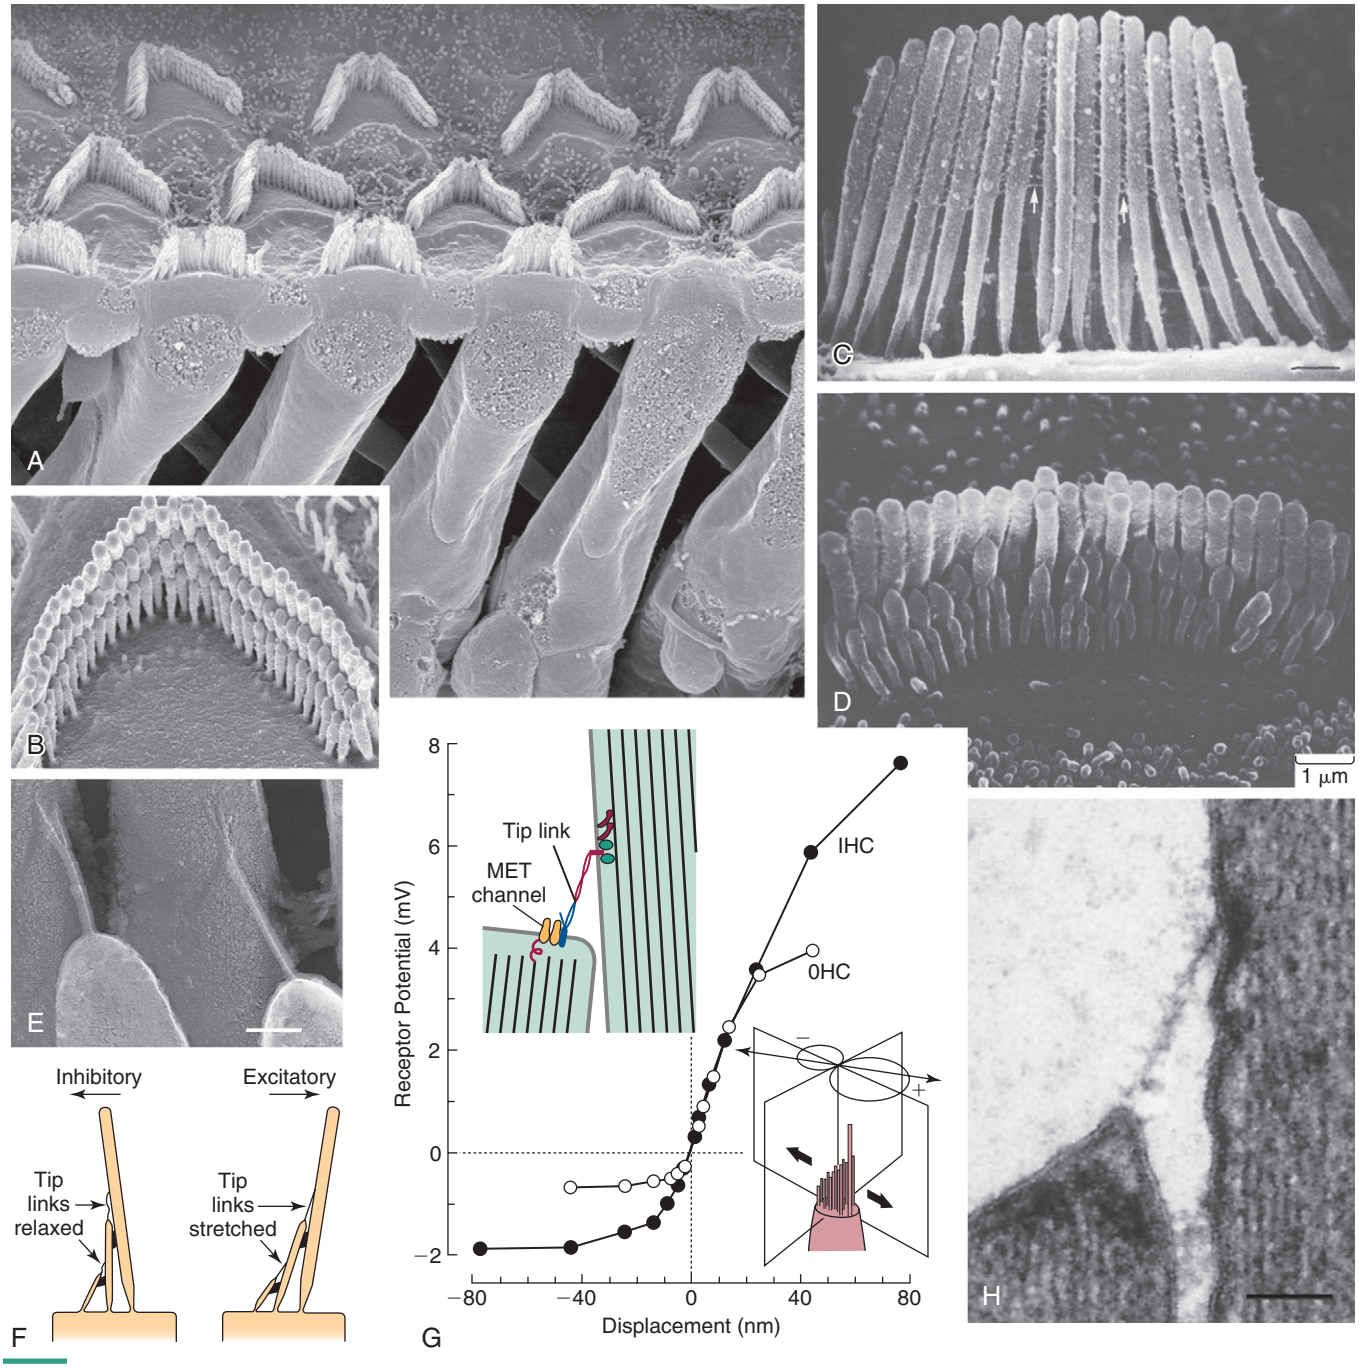

Figure 146-12. **A,** Scanning electron micrograph (SEM) of the outer hair cell (OHC) region of a mouse cochlea after the tectorial membrane and pillar cells have been removed, showing the large intercellular chamber that OHCs occupy in situ. **B,** Higher magnification of an SEM showing the highly ordered hair bundle of a single OHC. **C,** SEM of the tallest row of stereocilia of an inner hair cell (IHC) from a guinea pig cochlea. when approximately 50% of the channels are open, a finding that supports the gating spring model.[238,461]

Focal measurements of extracellular potentials at various locations in the vicinity of hair bundles during the activation phase of transduction,[239] along with studies designed to block transduction by the local application of an aminoglycoside antibiotic[299] at different sites around the hair bundle,[246] revealed that the transduction channels are situated near the tips of the stereocilia. Additional support for this view has been advanced through imaging studies in which calcium was identified in the tips of stereocilia initially after bundle deflection and later in the base of the structure,[113] a finding that supports the view that Ca^{2+} enters the stereocilia through a transduction channel located at the tip.

Estimates indicate that the number of transduction channels per cell corresponds roughly to the number of stereocilia in a hair bundle (see Fig. 146-11F),[230,238,460] and transduction channels seem to be present in stereocilia of all heights within a bundle.[113]

Because of the small number of transduction channels present on hair cells, the effort to identify their molecular composition has been difficult at best.[84,94] However, results from invertebrate studies in *Drosophila melanogaster* and from studies of nonmammalian vertebrates (zebrafish) suggest that the best candidates for the transduction channel gene in mammalian hair cells belong to the transient receptor potential (TRP) gene family.[286,504] Nonetheless, it remains clear that additional studies are necessary to answer the question.

Transduction Channel Ion Selectivity

Hair cell transduction channels are permeable to a large number of monovalent and divalent cations, including small organic cations, such as choline and tetramethylammonium, suggesting that the internal diameter of the channel is relatively large, on the order of 0.7 nm, and the channel is relatively nonselective.[87,389] It is known that K^+ carries the major portion of the receptor current in vivo, as indicated by three observations: (1) the high concentration of K^+ in endolymph[27,259,519]; (2) the reversal potential of the transducer current is the same as the endocochlear potential[459]; and (3) that the concentration of K^+ found in perilymph increases after stimulation.[257] As a result of the combined positive endocochlear potential (+80 mV) and the negative intracellular potential of hair cells (−40 to −60 mV), a large potential gradient (greater than 120 mV) is established across the apical hair cell membrane (Figure 146-13). When hair bundles are deflected and transduction channels open, K^+ ions in the endolymph are flushed down a large electrochemical gradient through stereociliary transduction channels. This inward transducer current flows across the basolateral membrane, producing the receptor potential, and voltage-gated Ca^{2+} channels are activated, resulting in an influx of Ca^{2+} and release of neurotransmitter from the base of the hair cell.

Gating of Transduction Channels

Anatomic support for the presence of mechanical linkages that gate the opening and closing of transduction channels was acquired with the

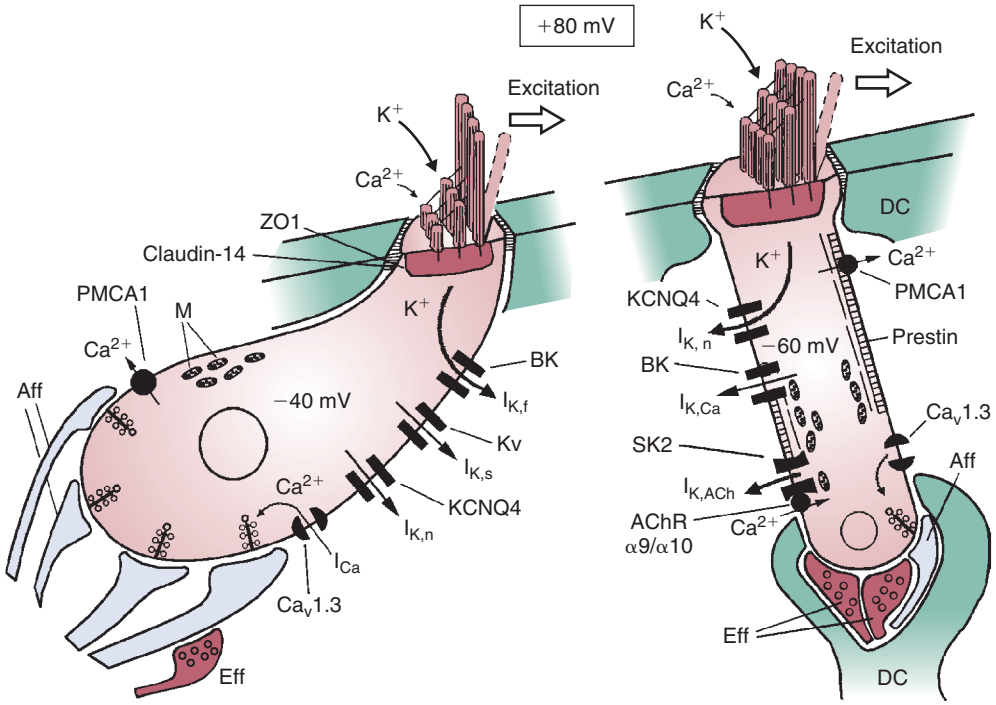

Figure 146-13. Drawing of an inner hair cell (IHC) *(left)* and an outer hair cell (OHC) *(right),* illustrating some of the basolateral membrane ion channels, pumps, and contacts by nerve endings. Three potassium currents in the IHC are shown: The K^+ current with fast kinetics, $I_{K,f}$, is carried by the large-conductance Ca^{2+}-dependent and voltage-dependent K^+ channel, BK; the $I_{K,s}$ current with slow kinetics is carried by a voltage-gated potassium channel (Kv). Both of these are outwardly rectifying. A slow delayed rectifier activated at negative potentials, $I_{K,n}$, carried by KCNQ4 channels also is shown. In OHCs, the major basolateral membrane K^+ current is $I_{K,n}$, which is active at negative potentials and carried by voltage-dependent KCNQ4 channels. A smaller voltage-dependent and Ca^{2+}-dependent current, $I_{K,Ca}$, carried by BK channels also is present. In addition, acetylcholine (ACh) released by efferent nerve terminals binds to acetylcholine receptors (AChR α9/α10) on OHCs that activate Ca^{2+}-permeable excitatory channels, which evoke a hyperpolarizing potassium current ($I_{K,ACh}$) mediated by a small-conductance Ca^{2+}-activated potassium channel (SK2). Both IHCs and OHCs have voltage-gated Ca^{2+} currents (I_{Ca}) mediated by L-type Ca^{2+} channels ($Ca_V1.3$) that open during depolarization, causing Ca^{2+} to enter the cell and trigger neurotransmitter release. Ca^{2+} is extruded from both hair cell types through plasma membrane Ca^{2+}-ATPase isoform 1 (PMCA1) pumps, and PMCA3 is localized to the cuticular plate region of IHCs (PMCA2a is concentrated in the stereocilia). Note that most channels are actually located in the basal portion of the membrane. In addition, claudin-14 is localized to the tight junctions near the apical membrane, and zona occludens-1 (ZO-1) is located near the tight junctions and cuticular plate of both hair cell types, as well as supporting cells. Prestin is present along the lateral cytoplasmic membrane of OHCs. Aff, afferent nerve ending; Eff, efferent nerve ending; DC, Deiters cell; M, mitochondria. *(Modified from Geisler CD.* From Sound to Synapse: Physiology of the Mammalian Ear. *New York: Oxford University Press; 1998.)*

discovery of tip links that stretch between shorter stereocilia and adjacent taller stereocilia (see Fig. 146-11B), connecting the distal tip of each stereocilium with the side of the longer adjacent stereocilium (Fig.e 146-12).[415] Tip links are aligned parallel to the axis of polarization of the hair bundle[82] and therefore play a role in the mechanism that determines the sensitivity of hair bundles to direction of displacement. When the bundle is deflected toward the taller stereocilia, tip links are stretched, which physically opens transduction channels, causing excitation (see Fig. 146-12G). When the bundle is deflected away from the taller stereocilia, tip links relax, causing the channel to close. Movement of the bundle perpendicular to the axis of symmetry produces little or no response, because the tension on tip links does not change. Orthogonal displacement of stereociliary bundles, on the other hand, produces reduced responses that are proportional to the exerted force.

The presence of tip links also may account for the rapid response of the transduction channel, and elastic linkages, like those considered previously, also may explain why transduction channels can be pulled open but not pushed shut. Moreover, the arrangement of tip links may explain why the number of transduction channels per hair cell is so small. Finally, although still an outstanding question, some studies suggest that transduction channels may be located at each end of the tip link,[113] as depicted schematically in Figure 146-12G.

The chemical composition of tip links is glycoproteinaceous, and glycoproteins seem to organize as two intertwined helical filaments that bifurcate and attach at two points on the side of the taller stereocilium (see Fig. 146-12E) by way of an electron-dense insertional plaque (see Fig. 146-12H) and at the level of an electron-dense region at the tip of the shorter stereocilium by way of three anchor filaments.[262] The molecular integrity of the tip link depends on the presence of calcium, as demonstrated by treating preparations with the Ca^{2+} chelator BAPTA (1,2-bis(*o*-aminophenoxy)ethane-*N*,*N*,*N*′,*N*′-tetraacetic acid), which breaks tip links and eliminates mechanoelectrical transduction.[33] Acoustic overstimulation can also cause tip link breakage.[416,540] Zhao and colleagues[632] made the important observation that tip links broken as a result of exposure to BAPTA regenerate within 24 hours, restoring mechanoelectrical transduction in the process. Perhaps a similar dynamic is operative in the case of recovery from temporary threshold shifts associated with acoustic overstimulation.

Recent studies have shown that tip links are composed of the extracellular domains of two proteins belonging to the cadherin superfamily of proteins, which generally mediate adhesion between cells—cadherin 23 (CDH23) and protocadherin 15 (PCDH15).[8,507,520] Tip links appear to form as an asymmetrical complex, consisting of homodimers of CDH23 localized to the upper segment of the tip link and homodimers of PCDH15 localized to the lower segment, with the two proteins interacting in the trans configuration at their NH_2 termini (see Fig. 146-15C).[267]

The gene that encodes cadherin 23 is defective in both patients with DFNB12[60] and persons with Usher syndrome type 1D,[58,60] as well as the waltzer (*v*) mouse[120,589,610] and the mutant zebrafish sputnik.[520] Usher syndrome type 1D is characterized by a constellation of signs and symptoms, including congenital sensorineural hearing loss, retinitis pigmentosa, and vestibular dysfunction.[58] Persons in the DFNB12 category exhibit profound, prelingual sensorineural hearing impairment.[67] Stereociliary abnormalities observed in waltzer mice during the late embryonic and early postnatal period include misplacement of the kinocilium and the presence of multiple stereociliary bundle islets on individual hair cells.[120,589,610] Although stereocilia are properly oriented early in development among waltzer mice, the characteristic polarization found in normal stereociliary bundles is lost, and orientation becomes chaotic as they degenerate. ABRs to intense acoustic stimuli cannot be detected in homozygous $Cdh23^{v\text{-}2J}$- or $Cdh23^{v\text{-}6J}$-mutant animals at the age of 3 to 4 weeks[120] and have not been detected at any age in yet another allelic variant of a waltzer mutant, $Cdh23^{v\text{-}Bus}$.[628]

Genetic complementation tests have shown that the locus for age-related hearing loss (AHL), a common characteristic of inbred mouse strains,[144,251,253,607,636] is allelic with Cdh23.[384] In addition, a predisposition to noise-induced hearing loss has been linked to this locus.[105,226,635] Thus, although certain mutations of Cdh23 are directly associated with deafness, others may enhance susceptibility to hearing loss associated with aging, environmental factors such as acoustic trauma, or other genetic factors, possibly as a consequence of altered binding capacity or decreased stability of Cdh23.

Defects in the gene that encodes protocadherin 15 cause deafness in patients with Usher syndrome type 1F,[12,15] in DFNB23,[11] and in the Ames waltzer (*av*) mouse.[14] In addition to congenital deafness, persons affected by Usher syndrome type 1F exhibit signs of vestibular dysfunction and suffer the consequences of retinitis pigmentosa.[12,15] The stereociliary bundles of hair cells in various mutant strains of Ames waltzer mice consistently display abnormal morphology followed by hair cell death and degeneration of the organ of Corti.[12,15,16,207,398,426] Stereocilia of both IHCs and OHCs become disorganized early in postnatal life, with loss of the stereotypical staircase profile of normal hair bundles as the clearest expression of stereociliary abnormality. Similar pathology has been observed in vestibular hair cells.[426] Acoustic stimuli fail to elicit responses in mice that are homozygous for several of the alleles that have been studied,[16,398,426] although mice that are homozygous for the $Pcdh15^{av\text{-}Jfb}$ allele appear to respond to high-level acoustic stimulation.[207] Of note, some of the hair cell abnormalities observed in Cdh23- and Pcdh15-mutant mice may be the result of other roles played by these proteins (see later on).

Composition of Stereocilia

As mentioned previously, stereocilia are not true cilia—they are microvillous extensions of the apical plasma membrane of hair cells. These extensions are tightly packed with microfilaments that run the length of each specialized villus.[163] Like microvilli of other epithelial cells (e.g., the brush border of intestinal epithelial cells), the longitudinally arrayed microfilaments of stereocilia are composed of hexagonally organized, tightly compacted actin filament bundles. Filamentous actin monomers are polar molecules, and individual filaments within a bundle are arranged in parallel and exhibit common polarity (Fig. 146-14A).[161,548] This organizational scheme provides a framework for the renewal of stereocilia, because actin monomers are incorporated into actin filaments at the tips of stereocilia as older components of actin filaments cycle toward the cell body at a rate of approximately 2.5 μm/day.[467,482] These data suggest that the actin core of the tallest stereocilia turns over completely every 2 days, approximately, in the base and every 3 days in the apex of the human cochlea. These rates are considerably slower than the overall turnover rates for shorter, conventional microvilli, like those found on Hensen cells and outer phalangeal cells.[194] The continuous renewal of actin filaments within stereocilia appears to play an important role in repair and recovery from acoustic overstimulation, and the failure of this system to operate properly may have significant otopathologic consequences.

The hexagonal pattern of actin bundles comprising the stereociliary core is maintained by actin-bundling proteins, including plastin/fimbrin and espin that form cross-linkages and fasten together individual actin filaments (see Fig. 146-14B). These bridging proteins occur at frequent and uniform intervals along the shafts of actin filaments[133,160,501,548,551] and, in keeping with the stereotypical association with crossover points of the α-helical subunits, are highly organized and coaligned.[548] The extensive cross-linking among adjacent actin filaments imparts a high degree of stiffness to each stereocilium (see Fig. 146-14C)[533] and consequently minimizes independent movement of actin elements during deflection such that an individual stereocilium moves as a rigid rod, one that will fracture much like glass if excessively deflected.[162] Moreover, actin filaments are neither stretched nor compressed during bundle deflection but appear to slide past one another as a result of the flexibility of the bond between the actin cross-linking proteins and the actin filaments.[549,584] It is noteworthy that cross-bridges between stereociliary actin filaments are reduced in number after acoustic overstimulation resulting in temporary threshold elevation, a condition that reduces stereocilia stiffness as a consequence.[550]

Defects in Cytoskeletal Proteins Lead to Deafness

Cytoskeletal actin exists in one of two highly conserved forms, either the β- or the γ-form, and the proteins differ from one another by a mere four amino acids located at the NH_2-terminal ends of the

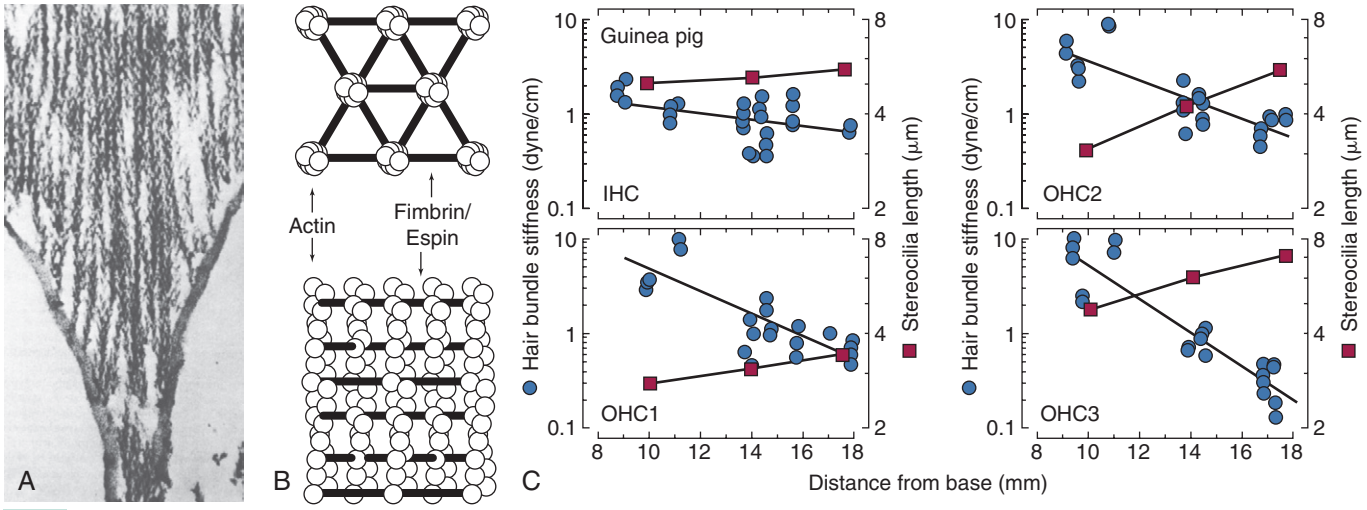

Figure 146-14. **A,** The uniform polarity of actin filaments within the stereocilium is demonstrated in a lizard cochlea by incubating preparations with the S1 fragment of myosin, thereby marking the polarity of the filament. The arrowhead-like appearance of actin filaments indicates that their pointed ends are located proximal to the hair cell body and that the barbed ends of actin filaments are located at the stereocilia tips. **B,** Paracrystalline array of actin filaments depicted in the longitudinal orientation *(bottom)* and in cross section *(top)*, showing the cross-linkages composed of fimbrin and espin. **C,** Stiffness of hair bundles of guinea pig hair cells as a function of distance along the cochlear partition *(circles)*. molecule.[142] Both forms generally are coexpressed in mammalian nonmuscle cells[272]; however, unlike in most nonmuscle cells, in which β-actin is expressed as the principal form, in auditory hair cells γ-actin is the principal variant of the protein, and it is distributed ubiquitously within the cell.[223] β-Actin expression, on the other hand, is restricted to stereocilia.[482] Mutations in the γ-actin gene (*ACTG1*) lead to autosomal dominant progressive hearing loss (DFNA20/26)[572,639] that presumably is the consequence of a diminished ability to repair the actin cytoskeleton (Fig. 146-15) among affected persons. A mouse model expressing a functional null mutation in the gene encoding γ-actin is available, and animals from this strain acquire normal hearing during the early postnatal period.[41] However, this relatively brief period of normalcy gives way to progressive hearing loss, as indicated by ABR and distortion product otoacoustic emission (DPOAE) recordings.[406] The first morphologic sign of pathology appears in the form of hair bundle disruption and is followed shortly thereafter by the loss of hair and supporting cells. These data suggest that whereas β-actin is sufficient for the normal development of stereociliary bundles, γ-actin is required for their normal maintenance. Insight into the role that γ-actin may play in maintenance can be gleaned from noise exposure studies. It turns out that occasional gaps appear in phalloidin-stained F-actin filaments forming the core of stereocilia after noise exposure, and that these gaps are labeled by an antibody to γ-actin. These findings suggest, naturally enough, that γ-actin may be required to repair traumatized hair bundles. Similar gaps have been observed in mature actin filaments associated with *Actg1*$^{-/-}$ mice, again suggesting that γ-actin is a necessary player in the maintenance of stereociliary structural integrity.[41]

An essential role for the actin-bundling protein espin in the maintenance of stereociliary infrastructure also has been identified in deaf mice that are homozygous for the jerker (*je*) mutation,[634] a finding that led to the identification of mutations in the *ESPN* gene in autosomal recessive, prelingual and profound hearing loss (DFNB36) in humans.[381] The jerker trait arose spontaneously, and homozygous mutant animals exhibit stereociliary abnormalities, hair cell degeneration, deafness, and vestibular system dysfunction.[26,115,511,512,529] Although stereocilia seem to develop normally, they are shorter than normal as a rule, and degenerative changes occur during the early postnatal period. Homozygous mutant animals are unresponsive to acoustic stimuli throughout life. Of interest, overexpression of espin in hair cells results in abnormally long stereocilia, suggesting that the level of espin expression is critical for normal stereocilia development.[466] Espin is expressed primarily in hair bundles and is distributed along the entire stereociliary length (see Fig. 146-15),[634] although light espin staining has been observed in the cuticular plate and soma in chicks.[324] Although fimbrin also plays a role cross-linking actin filaments, in contrast with espin, its activity is inhibited by Ca^{2+}.[38] Thus, in the absence of espin, Ca^{2+} entry into stereocilia may destabilize the actin core and serve to trigger pathologic changes as a consequence.[634] Also of note is that espin binds to actin with higher affinity than does fimbrin and may play a role as an important stabilizing factor after formation,[38] although data from studies in the chick suggest that espin is expressed early on when stereocilia first begin to elongate.[324] Autosomal dominant forms of hearing loss resulting from mutations in ESPN in humans also have been identified.[129]

In the context of linkage proteins that have a clear role in peripheral auditory function, a gene family of integral membrane proteins that appear to link the actin cytoskeleton to the plasma membrane and are essential elements of audition have been identified, and include proteins in the ezrin-radixin-moesin family. The highest concentration of the protein radixin is found at the base of hair cell stereocilia in a variety of species, including frog, chicken, zebrafish, and mouse (see Fig. 146-15A). Radixin appears to anchor the pointed ends of actin filaments to the plasma membrane in the region of the stereocilium taper.[402] In the absence of radixin, mice are profoundly deaf, and both IHC and OHC stereocilia become progressively disarrayed and hair cells subsequently degenerate, even though the system appears to develop normally.[289] Of interest, whereas radixin alone is detectable in cochlear hair cells from normal adult mice, both radixin and, to a lesser extent, ezrin are found in adult vestibular hair cells. In radixin-null mice, ezrin appears to compensate for radixin, promoting development of both cochlear and vestibular hair cell stereociliary bundles. However, unlike vestibular hair cells, cochlear hair cells require radixin for continued maintenance beyond early postnatal life. As in the mouse, radixin is required for normal hearing in humans as well, with pathogenic mutations producing prelingual, bilateral, and profound hearing loss that is inherited as an autosomal recessive trait (DFNB24).[273] Moreover, immunoreactiv-

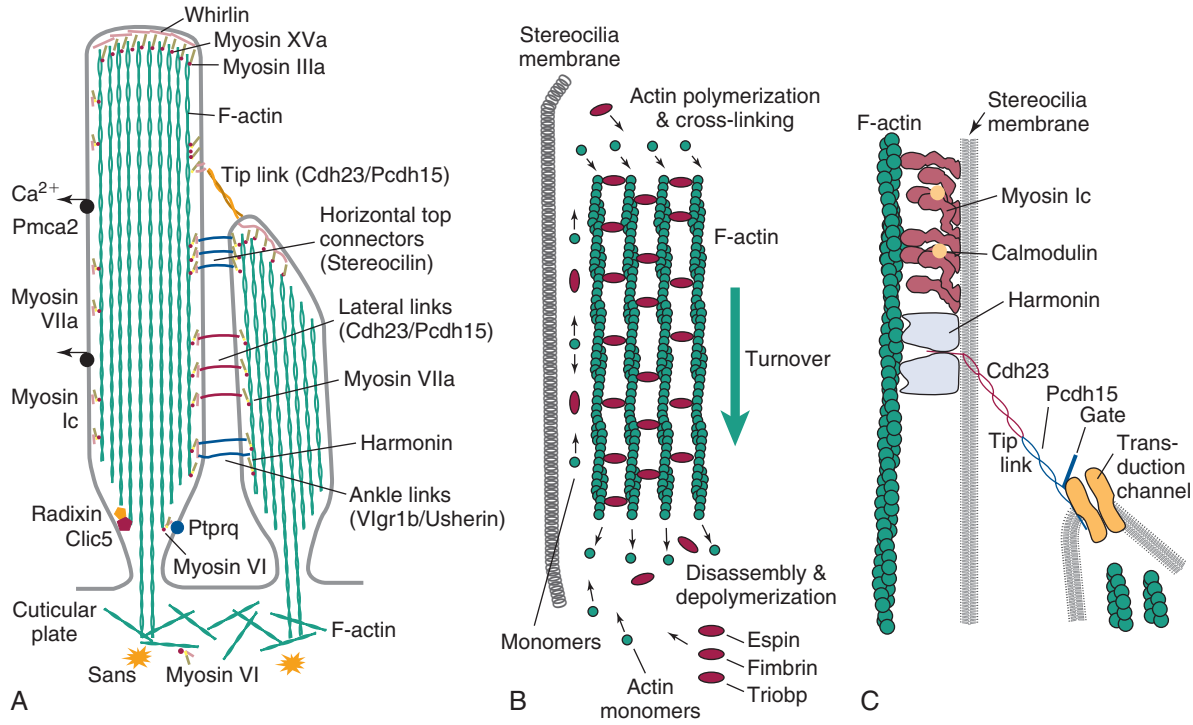

Figure 146-15. A, Schematic illustration of a longitudinal section through two stereocilia located in adjacent rows, connected by a tip link, and other linkages. Note that lateral links and ankle links are found only in developing cochlear hair cells. Unconventional myosins found in the mature hair cell include myosin XVa and myosin IIIa, which concentrate at stereocilia tips; myosin VIIa and myosin 1c, which are are found along the shafts of stereocilia; and myosin VI, the only known member of the myosin superfamily that moves toward the pointed end of actin filaments, found at the base of stereocilia and in the cuticular plate. Whirlin also concentrates at tips of stereocilia, whereas radixin, Clic5, and Ptprq concentrate near the base of stereocilia. Transmembrane proteins with long extracellular domains include cadherin 23, protocadherin 15, Vlgr1b, and usherin, which appear to be components of specific interstereociliary linkages, along with stereocilin, which may be an extracellular protein. The intracellular scaffolding protein, harmonin, may serve to anchor the transmembrane proteins with long extracellular domains to the F-actin core. **B,** The treadmill model of actin turnover within a stereocilium depicting actin polymerization and cross-linking occurring at the barbed ends of actin filaments located at the tips of stereocilia, and disassembly and depolymerization of actin filaments occurring at the base of stereocilia. **C,** Schematic illustration of the transduction channel, including the tip link complex, myosin motors for adaptation, and harmonin. *(**A** and **B,** Adapted from Rzadzinska AK, Schneider ME, Davies C, et al. ity to radixin is reduced in mice carrying the spontaneous mutation Jitterbug, responsible for a mutation in Clic5, an intracellular chloride channel that is expressed in normal hair cell stereocilia, particularly at the stereociliary base.[175] Stereocilia of mice deficient in Clic5 develop normally but show progressive degeneration after the onset of hearing. Studies suggest that Clic5 may associate with a radixin-actin cytoskeletal complex that appears to be necessary for stereocilia maintenance.

Other proteins associated with actin and that are critical for hearing include TRIOBP and diaphanous 1. Mutations in a long isoform of TRIOBP have been shown to cause autosomal recessive deafness (DFNB28),[436,499] whereas mutations in DIAPH1 are associated with autosomal dominant hearing loss.[346] TRIOBP is associated with filamentous actin, is relatively resistant to the F-actin destabilizer latrunculin B, and is thought to regulate the organization of the actin cytoskeleton.[492] Numerous isoforms of TRIOBP are present in the cochlea, in both IHCs and OHCs, and the protein colocalizes with F-actin along the length of stereocilia (see Fig. 146-15B).[436,499] Diaphanous belongs to the formin family of proteins, which are known to interact with the growing, or barbed, end of actin and recently have been shown to act as effectors for Rho GTPases, key regulators of actin dynamics. Although its role remains unproved, diaphanous is thought to participate in the regulation of cytoskeletal actin turnover, but the protein also may be involved in endosome motility.[397] Diaphanous has been identified within the cochlea by use of a reverse transcription–polymerase chain reaction (RT-PCR) approach,[346] but its precise localization remains unknown. As with many other proteins, the role of both TRIOBP and diaphanous 1 in transduction requires additional investigation.

Dynamic Regulation of Stereocilia Length

In addition to *Espn*, other genes that are required for the development of normal stereocilia height include *Myo15a* and *Whrn* (see Fig. 146-15A). *Myo15a* encodes myosin XVa, an unconventional myosin that is localized near the site of actin polymerization at the tip of each stereocilium in both auditory and vestibular hair cells.[43] *MYO15A* is indispensable for hearing, and pathogenic mutations result in a form of nonsyndromic deafness, DFNB3, in humans,[592] and persons who are homozygous for the mutation are congenitally deaf. The shaker 2 (*sh2*) mutant mouse strain also carries a defect in *Myo15*.[422] The condition is inherited as an autosomal recessive trait, and 1-month-old homozygous mutant mice are unresponsive to acoustic stimulation.[327] Although hair cells are present at this age and stereociliary bundles are present, stereocilia of both IHCs and OHCs are notably shorter than normal, and the normal gradation in stereociliary height is less prominent among adjacent hair cell rows.[422] The stereocilia of vestibular hair cells in both otolith organs and semicircular canals also are abnormally short in mutant mice.[22] It is noteworthy that myosin XVa immunoreactivity is first detected in mice at about the time that stereocilia begin to grow differentially and establish the row-dependent stereociliary bundle height gradation that is characteristic of normal mammals.[43] Labeling also is more intense in the tallest stereocilia, suggesting that formation of the graded stereociliary row pattern requires the presence of myosin XVa.[43,467] Thus, although normal development of the hair bundle is arrested in the absence of functional myosin XVa, the precise mechanism of its action will be the subject of continued investigation.

Whrn encodes a putative scaffolding protein known as whirlin, and genetic abnormalities of the gene, *WHRN*, are the source of deafness in persons with DFNB31; likewise, *Whrn* abnormalities are responsible for deafness in mice designated whirler mutants.[358] DFNB31 is characterized by profound, prelingual sensorineural hearing loss, and mutant whirler (*wi*) mice also exhibit profound deafness, as well as vestibular abnormalities. Hair bundles associated with both IHCs and OHCs in homozygous mutant whirler mice are abnormal.[225] Specifically, IHC stereocilia are significantly shorter than normal as early as embryonic day 18.5. However, stereociliary shaft lengths do continue to increase until approximately 1 day after birth, when the process actually reverses and individual stereociliary lengths begin to decrease. During this period, the organization of stereocilia within hair bundles remains normal, and although relative height gradations are normal, height differences between rows are clearly less prominent than in normal mice. Likewise, overall stereociliary height along the length of the cochlear spiral, a morphologic feature that normally is characterized as a gradient in which height increases continuously from base to apex, is notably reduced in mutant mice.

As with IHCs, OHC stereociliary lengths generally are smaller than normal in whirler mutants, although OHC defects appear slightly later than in IHCs in affected animals. However, an interesting variation in the pattern of stereociliary anomaly has been described in whirler-mutant mice: Specifically, abnormally short stereocilia are located on the edges of each row, although the number of rows appears normal, and stereociliary rows are graded in height. Also of note is that hair bundles do not conform to the classic V- or W-shape observed in normal hair cells. Instead, bundle patterns exhibit a more curvilinear profile. Hair cell degeneration, starting with OHCs, is first observed at approximately the 60th postnatal day and is followed by IHC degeneration,[225] and extensive degeneration generally occurs by the 90th postnatal day, particularly in the basal and middle turns of the cochlea.[358]

In addition to the independent roles played by whirlin and myosin XVa, normal hair bundle development appears to depend on their interaction. Indirect evidence supporting this view suggests that myosin XVa may guide whirlin to stereociliary tips, thereby promoting length enhancement. The rationale for this scenario, speculative as it is, is driven by the observation that the amount of whirlin measured at stereociliary tips is directly proportional to the amount of myosin XVa measured at the same location.[44,111,282] Of interest in this regard is that whirlin expression is down-regulated after stereociliary maturation, whereas myosin XVa expression continues throughout life.[282] In addition to whirlin and myosin XVa, differences in hair bundle morphology between *sh2* and *wi* mice, reviewed earlier,[370] suggest that other interacting proteins are likely to be involved in the development and maintenance of stereocilia.[357] One such protein may be myosin VIIa (see later). Specifically, Prosser and colleagues made the observation that stereocilia grow abnormally long in the absence of myosin VIIa and that whirlin expression persists at the tips of mature stereocilia, rather than undergoing naturally programmed down-regulation. In addition, when either whirlin or myosin XVa is absent from hair cells, myosin VIIa is expressed at the tips of the abnormally short stereocilia, suggesting that myosin VIIa is critically important in regulating the dynamics of stereocilia elongation during maturation.[423]

Another unconventional myosin that is expressed in stereociliary tips is myosin IIIa. This myosin variant appears to concentrate around the tips of stereocilia in a "thimble-like" pattern, in contrast with the "caplike" pattern of myosin XVa expression.[483] Although myosin IIIa does not appear to play a role in development, it has been shown to cause bilateral, autosomal recessive nonsyndromic hearing impairment that begins in the second decade of life. The pattern of hearing loss associated with this condition is such that high-frequency sensitivity is affected initially, with losses occurring progressively in the case of middle- and low-frequency sensitivity.[591]

Interstereociliary Linkages

Like actin-binding proteins, which cross-link actin filaments and help form the core of individual stereocilia, stereocilia are themselves interconnected by way of a complex array of extracellular fibrous cross-linkages (see Fig. 146-15A). At the most fundamental level of organization, filamentous links bind stereocilia within a bundle into a mechanical unit by connecting a stereocilium with neighboring stereocilia on all sides.[173,399,415,434] In adult animals, these proteinaceous links run parallel to the apical surface of the cell connecting different rows of stereocilia, as well as stereocilia of the same row (see Fig. 146-11A), and are thought to contribute to the overall cohesiveness and stiffness of the hair bundle.

Numerous morphologically and biochemically distinct* interstereociliary linkages are recognized; however, some are permanent features of the system, whereas others appear transiently during development.[173,189,191,192,193,415,417,434,547,556,557] For example, although horizontal top connectors are present in both IHCs and OHCs of adults, shaft connectors, located beneath the top connectors in roughly the middle section of the shaft, are found in inner hair cells throughout life but are expressed in outer hair cells only during development. Lateral links, which are located along stereocilia sides, and ankle links, which are located at the stereociliary base, are expressed transiently in both IHCs and OHCs during hair bundle development. Linkages between the kinocilium and two to three adjacent stereocilia from the tallest row are present during the developmental period when kinocilia are a feature of IHCs and OHCs.

Like tip links, kinocilial links are sensitive to BAPTA and resistant to the protease subtilisin. These linkage proteins appear to be composed of both Cdh23 and Pcdh15.[8,192,365] Of interest, transient lateral links also appear to be composed of Cdh23; however, in sharp contrast with tip links, these lateral linkages are insensitive to BAPTA and sensitive to subtilisin.[365] Links resistant to both BAPTA and subtilisin treatment include horizontal top connectors. Stereocilin (STRC) appears to be a primary constituent of top connectors, as well as being present in the attachments between the tallest row of OHC stereocilia and the tectorial membrane.[576,577] Mutations in STRC are associated with nonsyndromic autosomal recessive deafness (DFNB16),[576] and stereocilin-null mice show progressive hearing loss, suggesting that horizontal top connectors are an essential hair bundle feature.[577] The formation of shaft connectors, which are resistant to BAPTA but sensitive to subtilisin, requires protein tyrosine phosphatase receptor Q (Ptprq), and when the *Ptprq* gene is disrupted in mice, stereocilia of hair cells located in the base of the cochlea become disorganized during the early postnatal period and are sporadically lost—an event that leads to hair cell death.[190] Finally, ankle links, which are sensitive to both BAPTA and subtilisin, appear to be composed of both Vlgr1 (*v*ery *l*arge *G*-protein–coupled *r*eceptor 1) and usherin.[4,359] Gene mutations affecting these proteins in humans result in Usher syndrome type 2C and type 2A, respectively.[147,603] Mice carrying functional null alleles for Vlgr1 are profoundly hearing impaired by the age of 3 weeks and lack ankle links at the base of hair cell stereocilia, with progressive disorganization of hair bundles, eventually leading to hair cell loss.[359] By contrast, auditory deficits in usherin-null mice are mild and limited to high frequencies and are not progressive.[335]

Usher syndrome is a genetically heterogeneous disease and the leading cause of combined deafness and blindness around the world. No fewer than 10 forms of the syndrome are recognized, many of which are associated with well-characterized gene defects that produce a group of abnormal gene products collectively referred to as the Usher proteins. Included in that collection is the unconventional myosin VIIa (Usher syndrome type IB [USHIB]),[600] the scaffold protein harmonin (USH1C),[13] the novel cytoplasmic protein sans (USH1G),[377,601] and the transmembrane protein clarin-1 (USH3).[6,249] Spontaneous mutations in orthologous murine genes also have been identified and include shaker-1 (*sh1*),[182] deaf circler (*dfcr*),[252] and Jackson shaker (*js*),[283] representing mutations in *Myo7a, Ush1c,* and *Sans,* respectively. Persons affected by Usher syndrome type I exhibit severe to profound congenital hearing loss, vestibular system dysfunction, and early-onset, progressive retinitis pigmentosa, whereas those affected by Usher syndrome type II have moderate to severe high-frequency hearing impairment, normal vestibular function, and progressive retinitis pigmentosa.

*Differing sensitivities to the Ca^{2+}-chelating agent BAPTA and the protease subtilisin are commonly used to distinguish biochemical differences among interstereociliary linkages being considered in this chapter.

The clinical phenotypes of patients suffering with Usher syndrome type III are highly variable, often leading to misdiagnosis of the disorder as either type I or type II.[405]

Like mice exhibiting abnormalities Cdh23, Pcdh15, or Vlgr1, mice with defective genes encoding myosin VIIa, harmonin, or Sans also are deaf, and hair bundle abnormalities that appear during development constitute a common feature in all three animal models.[182,252,283] The common morphologic phenotype shared by affected animals suggests that these proteins interact with one another, each satisfying a unique role with respect to hair bundle development. Furthermore, the proteins in question do not appear to compensate for one another; pathology ensues when any one of the group is lost or is defective.

Predictably, in keeping with the close functional association of the Usher proteins, numerous interprotein interactions have been identified in recent years. For example, harmonin has been shown to bind with both Cdh23 and Pcdh15, as well as actin filaments, and on the basis of the molecular characteristics of Cdh23 and Pcdh15, some investigators have suggested that harmonin anchors Cdh23 and Pcdh15 to the actin core of stereocilia.[5,54,506] Harmonin also binds to myosin VIIa, and it is especially informative that harmonin cannot be found in the hair bundles of *sh1*-mutant mice, animals exhibiting an abnormal version of Myo7a. This finding suggests that myosin VIIa transports harmonin from the cytoplasmic compartment of the cell body to the stereocilia.[54] Likewise, protocadherin 15 binds to myosin VIIa, and neither protein is "correctly" localized when one of the partners is lost or disrupted, a finding that supports a model in which the two proteins interact critically to ensure the proper spatial maintenance of the protein complex as the hair bundle matures.[496]

Harmonin also binds with both Vlgr1 and usherin,[4,430] as does whirlin,[4,573] and myosin VIIa binds with Vlgr1, usherin, and whirlin.[111,364] Vezatin, a transmembrane protein that also is localized to the basal region of stereocilia,[307] binds to usherin and may be a constituent of the ankle link complex,[364] an idea that is supported by the finding that vezatin, in addition to usherin and whirlin, cannot be detected in the stereocilium of *Vlgr1*-null animals.[364] In an especially revealing study, Vlgr1, usherin, and whirlin, as well as vezatin, cannot be detected in hair cell stereocilia in animals without functional myosin VIIa. This observation suggests that proteins associated with the ankle links are transported to the stereocilia by myosin VIIa,[364] an actin-based motor that is capable of transporting cargo toward the plus, or barbed, ends of actin filaments (i.e., toward stereocilia tips).[565] These findings—that is, the absence of usherin, vezatin, and Vlgr1 in stereocilia of whirler-mutant animals—implicate whirlin as a scaffold protein supporting the ankle link complex.[364] The protein Sans is unusual among the Usher proteins in that it is localized not in stereocilia but in the region beneath the cuticular plate.[5] Sans interacts with harmonin,[5,601] as well as myosin VIIa, and it may regulate the trafficking of at least some of the Usher proteins to the stereocilium, as supported by its location at the interface of the cell body and the hair bundle.[5] Finally, it has been shown that harmonin, Vlgr1b, and usherin are found together in the synapse between hair cells and afferent or efferent fibers in adult cochleae. This observation suggests that Usher proteins may play yet another functional role in mammals, one that influences neural processing within the auditory pathway.[430]

Myosin VI

Numerous unconventional myosins are essential for normal hair cell function, including myosin VI. Mutations in the *MYO6* gene are responsible for autosomal dominant hearing loss, DFNA22[363]; autosomal recessive deafness, DFNB37[10]; and the phenotype observed in Snell's waltzer (*sv*) and tailchaser (*tlc*) mice,[35,219] as well as mutant satellite zebrafish.[491] People affected with DFNB37 have profound congenital sensorineural hearing loss with complementary vestibular dysfunction, whereas hearing deficits in persons affected with DFNA22 are sensorineural in nature, but the onset of the condition is postlingual, and the anomaly develops progressively, unlike in the case of DFNB37-mediated deafness. The degree of hearing loss in these patients ranges from moderate to profound, and affected persons show no signs of vestibular dysfunction.

Like other myosin proteins, myosin VI is a molecular motor that binds to actin filaments or microtubules; however, it is unique as the only myosin thus far identified that moves backward toward the pointed end of actin filaments.[210,602] Of interest, the phenotype of the myosin VI mutant is limited to hair cell dysfunction.

Myosin VI is localized at the base of the stereocilia,[35,211] where the pointed ends of core stereociliary actin filaments project into the cuticular plate and rootlets of stereociliary actin filaments terminate (see Fig. 146-15A). More specifically, myosin VI is located in the circumferential region surrounding the lateral margins of the cuticular plate, an area that is rich in cytoplasmic vesicles, a finding that is particularly evident in amphibian hair cells. More recent localization studies suggest that myosin VI may be found along the length of stereocilia.[219] Unlike with the mutations in mice causing an Usher-like phenotype, the basal aspect of adjacent stereociliary membranes in *Myo6*-mutant animal models appears to fuse, reducing the numbers of individual stereocilia and leading to the formation of "giant" stereocilia that are both longer and wider than normal and often display swollen or bulbous tips, and branching of stereocilia also is observed occasionally. Sequentially, giant stereocilia collapse onto the apical surface of the organ of Corti and appear to fuse with the apical membranes of hair cells and supporting cells, and the organ of Corti undergoes degeneration. During the period of stereocilia fusion, stereocilia branching also is observed, and the apical surfaces of hair cells appear to bulge outward. Ultrastructural examination indicates the presence of extraneous material within the fused stereocilia, possibly components normally found in the apical cytoplasm of hair cells.[219,472,491,493]

Although numerous hypotheses have been advanced to explain hair cell abnormalities observed in *Myo6*-mutant animals, recent studies suggest that the protein may serve to tether Ptprq to the actin cytoskeleton at the base of the stereocilia, maintaining the stereocilia taper and preventing fusion between adjacent stereocilia.[472] In that regard, unlike with the focal localization of Ptprq in the stereociliary base of normal animals, the protein is distributed throughout the stereocilium in Snell's waltzer mice, suggesting that the proteins normally interact with one another directly.[472] Moreover, as an inositol lipid phosphatase, Ptprq would be in a key position to regulate the phosphoinositide phospholipid content of the hair cell membrane.[190] The reciprocal distribution of phosphatidylinositol 4,5-bisphosphate (PIP_2) and Ptprq in stereocilia[221] suggests that Ptprq may play a role in the regulation of actin and membrane turnover, a process that is disrupted in the absence of functional myosin VI.[472]

Adaptation of Mechanoelectrical Transduction Currents

It is well known that receptor currents adapt after sustained deflection of hair bundles (Fig. 146-16A). Adaptation is associated with a horizontal shift in input-output curves after bundle displacement (see Fig. 146-16B), without a change in the slope of the steepest portion of the curve. Shifts in the horizontal position of input-output curves, like those described here, reflect the actions of a dynamic system in which the central operating point is restored after sustained depolarization, re-establishing the sensitivity of the system. The prevailing model used most often to explain adaptation entails a reduction in tip link tension when the bundle is deflected in the excitatory direction and an increase in tension for deflections in the inhibitory direction.[85,88,135,227,502]

Two mechanisms of adaptation have been described: one that underlies rapid adaptation, a phenomenon characterized by a time constant of less than a few milliseconds, and another with a time constant greater than 10 msec, which can achieve values as high as several hundred milliseconds under some circumstances. In the case of *rapid* adaptation, Ca^{2+} ions entering the cell through transduction channels bind directly to an intracellular site that is part of the transduction channel itself (see Fig. 146-16D), which in turn modifies the relationship between tension and the probability that the channel is in the open state.[90,438] In the case of *slow* adaptation, an active motor is thought to slide the transduction channel associated with the taller stereocilium down the actin filament core of the stereocilium (see Fig. 146-16C), thereby reducing tension on the tip link and decreasing the probability that the channel will be in the open state.[32,184,237] Conversely, moving

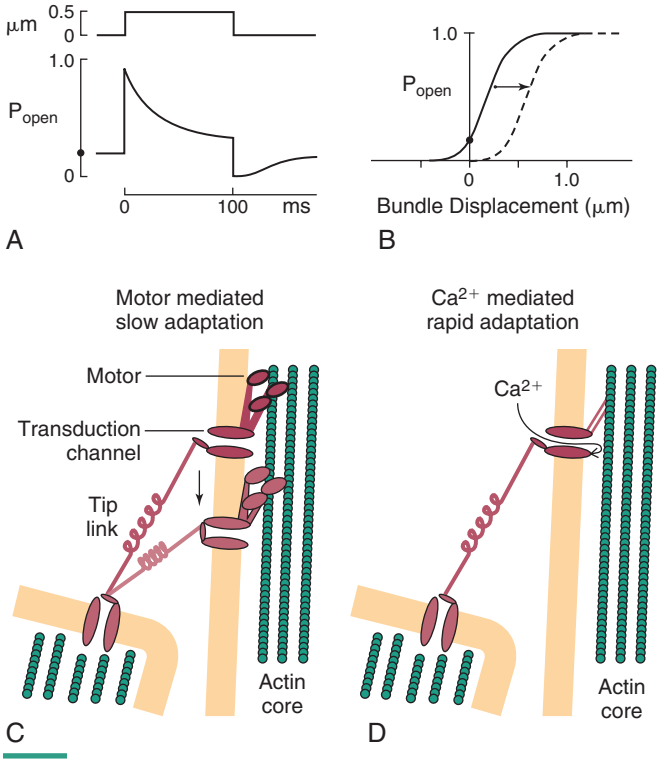

Figure 146-16. **A,** Diagram depicting positive (depolarizing) deflection of a hair bundle and the resulting adaptation observed as a decrease in the probability (*P*) of transduction channel opening over time during sustained bundle deflection. **B,** During the adapted state, the bundle displacement–versus–open probability curve is shifted horizontally along the x-axis, such that still larger bundle displacements are required to evoke a response comparable to that observed at the onset of stimulation. Two models have been proposed to account for adaptation: a motor-mediated slower process that requires resetting tip link tension by slippage of the entire transduction channel along the actin filaments (**C**) and a direct Ca^{2+}-mediated adaptation (**D**) that results from Ca^{2+} entry through the transduction channel and binding to an intracellular site of the channel, altering it to prefer the closed state. *(**A** and **B,** From Pickles JO, Corey DP. Mechanoelectrical transduction by hair cells.* Trends Neurosci. *1992;15:254; **C** and **D,** adapted from Holt JR, Corey DP. Two mechanisms for transducer adaptation in vertebrate hair cells.* Proc Natl Acad Sci U S A. *2000;97:11730.)*

the hair bundle in the inhibitory direction is thought to cause tip links to relax and close channels that were open at rest. During the adaptation phase, transduction channels are thought to climb along the actin core, resetting the operating point and increasing the probability of channel opening. In addition to Ca^{2+}, the latter mechanism requires an active motor, presumably an unconventional myosin that interacts directly with the actin core. Although both forms of adaptation exist in individual hair cells, rapid adaptation is much faster in mammalian IHCs and OHCs than in nonmammalian hair cells.[214,247,271,303,526]

Myosin 1c (myosin 1β) may be the best candidate for the adaptation motor associated with slow adaptation (see Fig. 146-15C).[184,185,228] This view is supported by the observation that slow adaptation profiles are altered when myosin 1c mutations occur.[228] Recent studies suggest that myosin 1c also may influence fast adaptation profiles.[527] In addition, binding between the tip link–associated protein cadherin 23 and myosin 1c has been reported,[507] and the binding character is modulated by calmodulin and is sensitive to calcium chelators, which are known to break tip links.[411] Furthermore, although myosin 1c is detected in stereocilia from mice with abnormal copies of cadherin 23 or myosin VIIa, only in *Cdh23*-mutant mice is its stereociliary binding profile disrupted, suggesting that myosin 1c regulates the gating characteristics of the transduction channel by interacting with cadherin 23.[411] Finally, myosin 1c associates with PIP_2, which normally concentrated in the upper two thirds of the stereocilia, and agents that deplete or sequester PIP_2 significantly reduce the rates of fast and slow adaptation, suggesting that the complex has a role in the regulation of the adaptation process.[221]

Although in early studies it was determined that myosin 1c was localized in the tips of stereocilia, or near each end of the tip link in vestibular hair cells,[178,185,211,531] more recent studies of mammalian auditory hair cells suggest that myosin 1c is distributed throughout the entire stereocilium, and not at the very tip.[483] Accordingly, the protein may play different or additional roles in hair cells of the mammalian auditory system. In that regard, abnormal adaptation profiles have been observed in auditory hair cells of *Myo7a*-mutant mice, indicating that myosin VIIa may anchor or play a role in anchoring transduction channels to the actin core.[302] Moreover, as indicated by the observation that myosin IIIa is localized in the lower insertion site of the tip link, this protein may influence adaptation indirectly by exerting tension at the tip of the stereociliary membrane.[483] Further experimentation is clearly needed to identify the motor of adaptation and to determine the precise role(s) of myosin 1c in auditory hair cells.

Effects of Deficiencies of Other Hair Cell Channels on Hearing

Numerous K^+ channels have been identified in the basolateral membrane of vertebrate hair cells (Fig. 146-13), including BK (large-conductance, Ca^{2+}-activated K^+ channels), SK2 (small conductance Ca^{2+}-activated K^+ channels), and KCNQ4. It is notable that mutations in the gene that encodes KCNQ4 result in the autosomal dominant (DFNA2) form of deafness,[304] a finding that implicates the channel as a particularly important factor in inner ear potassium homeostasis. Persons carrying the mutant allele gradually acquire hearing loss, first in the high-frequency portion of the audible spectrum and slowly progressing to include lower frequencies, suggesting that the mutation leads to slow degeneration of hair cells. KCNQ4 is strongly expressed in OHCs but also has been detected in IHCs.[40,276,392] It appears that the protein is an essential component of the channel that carries the major K^+ current in OHCs, the outwardly rectifying $I_{K,n}$ current,[229,235,275,351] because targeted mutations of *Kcnq4* result in loss of $I_{K,n}$ in OHCs, both in vivo[275] and in organotypic cultures of transfected hair cells.[229] Although response thresholds of mutant mice improve during the first 3 postnatal weeks of life, normal sensitivity is never achieved, and thresholds progressively deteriorate thereafter, reaching a plateau loss of approximately 60 dB, the rate of loss being dependent on which specific mutation is expressed.[275] Hair cell degeneration is the expected histologic correlate of the hearing loss in mutant animals, and the process starts in the base of the cochlear spiral and progresses apically. IHCs are preserved throughout the cochlea and OHCs are preserved in the apical turn. Whereas IHCs from mutant animals are slightly more depolarized at rest when compared with control subjects, OHCs from mutant animals are more significantly depolarized at rest, suggesting that the hearing loss of DFNA2 is the consequence of chronic OHC depolarization resulting from loss of the ability to extrude K^+, which leads in turn to OHC degeneration.[275]

The principal K^+ current in IHCs, on the other hand, is the fast, voltage- and Ca^{2+}-activated current, $I_{K,f}$, which is carried by BK channels[301] composed of α-, β1-, and β4-subunit.[311] Of interest, cochlear thresholds in mice lacking the BKβ1- or the BKβ4-subunit, or both, are normal, strongly suggesting that neither subunit is critical for hearing.[424,464] Nevertheless, an early report suggested that OHCs do indeed degenerate in *BKα*-deficient mice, a condition leading to high-frequency hearing loss[464]; other studies suggest that cochlear thresholds and frequency selectivity are normal in mutant animals.[393,424] However, although IHCs from *BKα*-deficient mice are slightly depolarized at rest, maximum driven discharge rates are reduced, and timing, measured as both increased jitter in first-spike latency and reduced phase-locking, is impaired in many auditory nerve fiber responses. These findings clearly indicate that BK channels play a key role in the temporal processing of acoustic signals.[393]

Although the impact of SK2 channel abnormalities per se on hearing has not been studied, affected animals exhibit Preyer's reflex,

and voltage-gated ionic currents (other than those produced by SK2) in hair cells generally are unaffected.[256,294] However, SK2 channels are known to play an essential role in the maintenance of repetitive spiking activity of immature IHCs,[256] which may have a long-term influence on the normal maturation of the end organ. Of interest, efferent-mediated synaptic currents are absent in OHCs of SK2 mutants, as well as in immature IHCs, which are known to receive a transient cholinergic innervation during maturation.[294] In addition, the absence of SK2 leads to a significant reduction in the efferent innervation of OHCs, and OHC responses to cholinergic agents are absent, suggesting that the SK2 channel regulates or maintains the functional status of acetylcholine receptors.[294] Olivocochlear innervation also is disrupted in mice with deficiencies in the α9- or α10-subunit of nicotinic acetylcholine receptors, although these subunits are not necessary for the development of normal cochlear thresholds.[578,579]

Because the transduction channel is highly permeable to Ca^{2+},[87,113,345,389,437] a mechanism must exist for its extrusion after depolarization. This generally is accomplished by means of the action of plasma membrane Ca^{2+}-ATPases.[344] Pmca2 (also known as Atp2b2) is the primary Ca^{2+}-ATPase isoform expressed in hair bundles,[93,134] where it is found in high concentrations, with estimates reaching approximately 2000 molecules/μm^2 of stereocilia membrane.[28,93,532,624] Mutations in the *Pmca2* gene produce the phenotype observed in deafwaddler (*dfw*) mice, and the consequences of targeted deletion of the gene are deafness and vestibular abnormality.[298,532] In addition, heterozygous $Pmca2^{+/-}$ mice are more susceptible to noise-induced hearing loss,[297] and the severity of age-related hearing loss in mice carrying the mutant *ahl* allele of *Cdh23* (i.e., modifier of deafwaddler [*mdfw*]) is increased by heterozygosity for dysfunctional Pmca2.[384,385] A similar exacerbation in the severity of autosomal recessive hearing loss associated with a missense mutation in *CDH23* by a hypofunctional variant of PMCA2 is observed in humans and underlines the importance of Ca^{2+} homeostasis in the inner ear.[486]

Finally, mice that are deficient in voltage-gated L-type Ca^{2+} channels ($Ca_V1.3$, Cacna1D, or D-LTCC), which are responsible for most of the voltage-gated Ca^{2+} entry into IHCs by way of the basolateral membrane, are congenitally deaf.[420] It generally is thought that the current carried by these L-type Ca^{2+} channels control neurotransmitter release. Degenerative changes in both IHCs and OHCs, as well as spiral ganglion cells, have been observed early in postnatal life,[188] suggesting that this channel is indispensable for normal hearing.

Defects in Hair Cell–Afferent Dendrite Synapses Lead to Deafness

In addition to the requirement for calcium entry into IHCs for normal synaptic transmission, an event that is dependent on the Ca^{2+} channels composed of $Ca_V1.3$ subunits reviewed earlier, the hair cell–afferent dendrite synapse is distinct from other synapses in several ways. First, and perhaps foremost, the synapse in question is characterized by a large presynaptic dense body commonly referred to as a "ribbon." Each afferent dendrite receives input from a single "ribbon synapse" (Fig. 146-17A). The physical arrangement of vesicles attached to the ribbon is thought to provide a readily and continuously available pool of synaptic vesicles that can support a highly efficient and coordinated process of vesicular exocytosis that leads in turn to the synchronous release of neurotransmitter when hair cell depolarization occurs. Such a system is optimally designed to support fine temporal coding of acoustic stimuli.[386] IHC–afferent ribbon synapses also exhibit molecular specializations that differ in some ways from conventional synapses, as well as ribbon synapses found in association with other pathways. For example, IHC ribbon synapses lack synaptophysin, synapsin, and synaptotagmins I and II,[322] and they contain the proteins Ribeye and Piccolo, as well as the presynaptic scaffolding protein Bassoon (see Fig. 146-17B). It is thought that Bassoon is required to anchor the ribbon to the presynaptic membrane.[277] Mice deficient in Bassoon exhibit abnormal ABRs, elevated thresholds, a reduced rate of "fast" exocytosis, and normal DPOAEs—a constellation of characteristics that satisfy the definition of auditory neuropathy.[277]

When depolarized, $Ca_V1.3$ channels open and allow calcium to rapidly enter the cell, and intracellular Ca^{2+} activates the protein otoferlin, which in turn triggers the fusion of synaptic vesicles with the presynaptic membrane and subsequent vesicular exocytosis at the hair

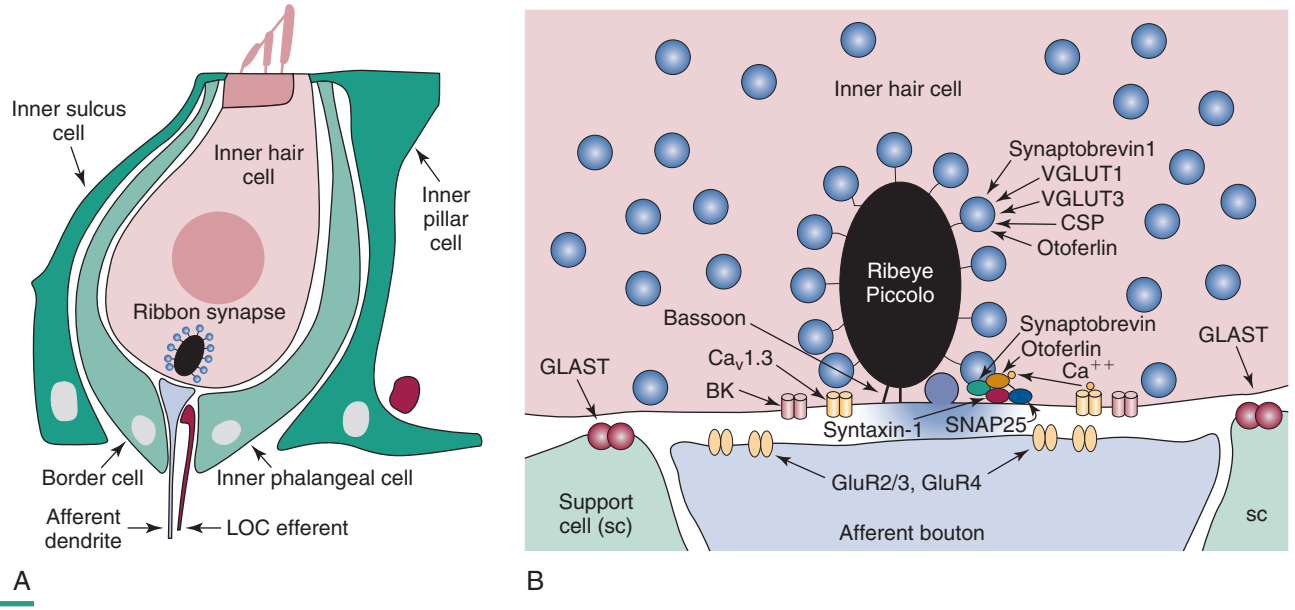

Figure 146-17. **A,** Schematic illustration of an inner hair cell (IHC) and a ribbon synapse with a type I radial afferent dendrite. Supporting cells shown include a border cell located adjacent to the modiolar side of the IHC and an inner phalangeal cell located on the opposite side; an inner sulcus cell and inner pillar cell also are illustrated. A lateral olivocochlear efferent fiber (LOC) is depicted making an axodendritic contact with the radial afferent fiber. **B,** Drawing of a single IHC ribbon synapse and proteins associated with the synapse. The synaptic ribbon is an electron dense body, holding numerous synaptic vesicles *(blue spheres)*, anchored to the presynaptic membrane. BK, large-conductance Ca^{2+}-activated K^+ channel; CSP, cystein-string protein; GluR, glutamate receptor; GLAST, glutamate-aspartate transporter; SNAP-25, synaptosomal-associated protein 25kDa; VGLUT, vesicular glutamate transporter. *(**A,** Adapted from Ruel J, Wang J, Rebillard G, et al. cell–afferent bouton synapse. Like synaptotagmin in conventional synapses, otoferlin acts as a Ca^{2+} sensor and interacts, in a calcium-dependent manner, with the t-SNARE proteins syntaxin-1 and SNAP-25, which are integrated into the presynaptic plasma membrane. The v-SNARE protein synaptobrevin (the vesicle-associated membrane protein [VAMP]) is located within the synaptic vesicle[468] and when activated initiates fusion of the exocytic vesicle with the presynaptic plasma membrane and subsequent release of neurotransmitter into the synaptic cleft. Mutations in otoferlin result in autosomal recessive, prelingual deafness (DFNB9) in humans,[626] and otoferlin-deficient mice also are congenitally deaf.[455] Although ABRs cannot be elicited from targeted null mice, presumably a consequence of failed vesicular exocytosis, ribbon synapses appear intact from a histologic perspective, and DPOAEs are normal; a clear case of auditory neuropathy. Interestingly, however, ABRs can be elicited electrically in null mice, suggesting that DFNB9 patients may be prime candidates for cochlear implants.

Other vesicular proteins of interest include the cysteine-string protein (CSP) is also found in hair cell vesicles[153] and is thought to act as a co-chaperone and protect tonically active synapses from neurodegeneration.[481] The vesicular glutamate transporters VGLUT1[174] and VLGUT3, the latter an unconventional but essential transporter, are located in the synaptic vesicle membrane and are responsible for loading L-glutamate into synaptic vesicles. Mutations in VGLUT3 (SLC17A8) lead to progressive deafness (DFNA25) in humans,[457] as well as in targeted null mice.[457,490] The glutamate-aspartate transporter (GLAST), or excitatory amino acid transporter 1 (EAAT1), is located on adjacent support cells (border and inner phalangeal cells) and is responsible for uptake and recycling of glutamate.[174,186] GLAST-deficient mice accumulate excess glutamate in the perilymph and are more susceptible than normal to acoustic overstimulation. This finding is consistent with the view that GLAST has a significant role to play in the clearance of glutamate from the extracellular milieu and, in doing so, protecting dendrites from glutamate neurotoxity.[206] Neurotransmitter-induced activation of the ionotropic AMPA-type receptors GluR2/3 and GluR4, located in postsynaptic afferent boutons,[355] leads to depolarization of the primary afferent dendrite and transmission of encoded acoustic information to the central nervous system.

Auditory Neuropathy

Auditory neuropathy–type pathologic conditions have been associated with a number of mutated genes that encode proteins located in the presynaptic compartment of the IHC–afferent dendrite synapse, as shown in the previous section. Perhaps those pathologic conditions should be thought of as auditory "synaptopathy"–type pathologic processes because of their locus of origin. These proteins prominently include the $Ca_V1.3$ subunit, Bassoon, otoferlin, and VGLUT3 (SLC71A8). In the following discussion, pathologic conditions associated with synaptic protein abnormalities are differentiated from those that fit more neatly into the "true" auditory neuropathy category—those that are associated with the nerve fiber itself. A good representative of a true auditory neuropathy model is the spontaneous mutant mouse *quivering*, in which defects in the protein β-spectrin 4 (Spnb4) lead to the abnormal distribution of ion channels in spiral ganglion axons, as well as axons of other peripheral and central neurons.[401] In mutant mice, the voltage-gated potassium channel Kcna1 is abnormally distributed along the length of auditory nerve axons, rather than being localized in a juxtaparanodal cluster as in normal animals. β-Spectrin 4 normally is detected in axonal initial segments and the nodes of Ranvier of nerve fibers, and it is generally suspected that the protein may serve to anchor ion channels to the juxtaparanodal region in myelinated nerve fibers and thereby influence saltatory nerve fiber conduction. Response amplitudes and latencies of ABR wave I are distinctly abnormal in β-spectrin 4–mutant mice, and later occurring peaks generally are absent from the response waveform. Likewise, disruption of the myelin sheath of the auditory nerve due to defects in peripheral myelin protein 22 (PMP22) or myelin protein zero (MPZ), also denoted P_0, as observed in Charcot-Marie-Tooth syndrome types 1A[296] and 1B,[212] respectively, leads to true auditory neuropathy in both humans and mice.[638] As in the case of β-spectrin 4–mutant mice, ion channel distributions in auditory nerve fiber axons are disrupted in these animal models as well.[233,593]

Perilymphatic-Endolymphatic Barrier

Normal mechanoelectrical transduction requires the separation of the endolymphatic and perilymphatic inner ear compartments, and the barrier that divides the major perilymph filled scalae from scala media is fashioned by tight junctions that form at the boundaries between cells that limit the endolymphatic space (Fig. 146-18A). These barriers, naturally, prevent the passage of water, ions, and molecules through intercellular spaces (see Fig. 146-18B), thereby maintaining a unique endocochlear milieu and separating the environment of the hair cells' apical surface from the basolateral plasma membrane of the cell by virtue of tight junctions formed between cells that make up the reticular lamina. To maintain this separate endolymphatic compartment, tight junctions are found in all epithelial cells lining the boundaries of the scala media, including the sensory epithelium, supporting cells within the sensory epithelium, cells lining the inner and outer sulci and the spiral limbus, marginal cells of the stria vascularis, and cells of Reissner's membrane. In addition, tight junctions are found in basal cells of the stria vascularis, forming an intrastrial compartment that is separate from both endolymph and perilymph.

Proteins of the claudin family (see Fig. 146-18C) are essential tight junction elements that form connections with the actin cytoskeleton by way of the protein zona occludens 1 (ZO-1), which has been identified as a component of the reticular lamina,[425] the scaffold protein shroom2, and myosin VIIa (see Fig. 146-18D).[146] Mutations in the gene (*CLDN14*) that encodes claudin 14, which is localized in the sensory epithelium, are responsible for an autosomal recessive form of deafness known as DFNB29.[606] Targeted deletion of *Cldn14* in the mouse leads to deafness associated with OHC degeneration that is followed by IHC degeneration. It generally is presumed that cellular death observed under these conditions is due to the increased permeability of cations through cells composing the paracellular pathway of the reticular lamina.[45] Although the endocochlear potential is normal in affected animals, claudin 14 is nonetheless required for the maintenance of the endolymphatic-perilymphatic ionic barrier, which breaks down in its absence. By contrast, tight junctions between strial basal cells are composed of claudin 11, and animals with null mutations in the encoding gene have reduced endocochlear potentials and elevated thresholds, although potassium recycling appears to be normal.[195,290] Moreover, specialized tight junctions connecting tricellular contact points composed of the protein tricellulin (see Fig. 146-18E) are essential for hearing and are responsible for autosomal recessive deafness (DFNB49) when dysfunctional.[435] Mutations associated with other components of tight junction–adherens junction complexes will almost certainly prove to be responsible for as yet unknown statoacoustic abnormalities in both human and nonhuman animals.

Endolymph Homeostasis

Homeostatic mechanisms involving the maintenance of separate endolymphatic and perilymphatic compartments, as well as preservation of the normal ionic environments within each scala, are essential for normal auditory function. Numerous genes, including several genes encoding gap junction proteins (Fig. 146-19), that alter homeostasis and are responsible for hereditary hearing impairments when mutated have been identified. The functions of a subset of these proteins are described in the following paragraphs.

It generally is understood that extrusion and recycling of K^+ after the depolarization of sensory cells are necessary components of mechanoelectrical transduction (Fig. 146-20). As described earlier, after entering hair cells through transduction channels, K^+ ions are extruded through channels located in the basolateral membrane, and enter the extracellular perilymphatic space. Once extruded, the K^+-Cl^- cotransporters Kcc3 and Kcc4, proteins that are encoded by *Slc12a6* and *Slc12a7*, respectively, take K^+ up by way of Deiters cells, which are situated underneath OHCs, and phalangeal cells that surround IHCs.[55,56] Kcc3 also is found in other epithelial cells of the organ of Corti, as well as type I and type III fibrocytes of the spiral ligament.[56] Absence of either protein produces a progressive form of deafness

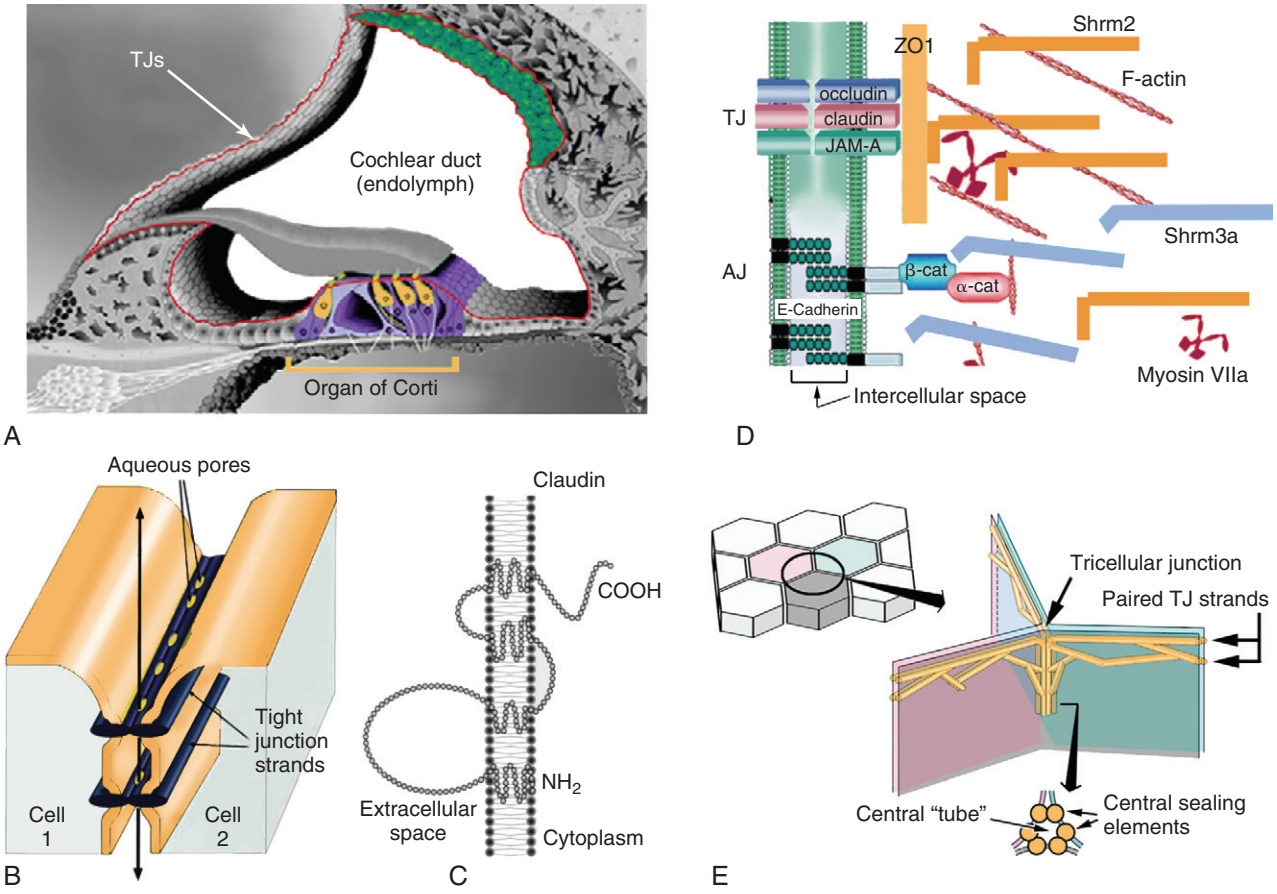

Figure 146-18. **A,** Schematic representation of the location of tight junctions (TJs), composed of claudin-14 within the epithelial barrier forming the cochlear duct, and those composed of claudin-11 between strial intermediate cells forming the barrier between intrastrial fluid and perilymph. **B,** Representation of bicellular TJ strands connecting the most apical region of the lateral membrane of two adjacent cells. TJs function as barriers to establish distinct fluid compartments separating the apical surface of the epithelial cells from the basolateral compartment by preventing admixture of molecules located above the apical surface of the cells from those surrounding the lateral membranes. TJ strands associate laterally with those in apposing membranes, forming paired strands. The aqueous pores regulate the passive paracellular passage *(arrow)* of ions, water, and various molecules, and these vary among epithelial cells in terms of size and charge selectivity. **C,** Proteins in the claudin family are integrally responsible for the formation of TJ strands and have four transmembrane domains and two extracellular loops, and both the amino and carboxyl termini are located on the intracellular side of the membrane. **D,** Claudins located on adjacent cells can form homotypic as well as heterotypic associations, resulting in intercellular adhesion, and they connect to the actin cytoskeleton by means of the scaffolding protein zona occludens 1 (ZO-1), as well as other members of the ZO family. Occludin and the junctional adhesion molecule (JAM-A) also are transmembrane components of TJs, sealing the paracellular space. Shroom 2 and 3a (Shrm2, Shrm3a) are proteins associated with TJs and adherens junctions (AJs), respectively, that may form a network between the actin cytoskeleton and unconventional myosins, such as myosin VIIa, which also is located at the site of TJs. **E,** Schematic illustration of the organization of tricellular TJs, composed of the essential protein tricellulin, as well as occludin. TJs between two adjacent cells become discontinuous at tricellular contact zones and extend basolaterally, forming a central tube; the tricellular TJs become vertically oriented and are composed of three pairs of TJ strands called "central sealing elements," forming a paracellular barrier at tricellular contacts. *(**A** and **D,** Adapted with permission from Etournay R, Zwaenepoel I, Perfettini I, et al. Shroom2, a myosin-VIIa- and actin-binding protein, directly interacts with ZO-1 at tight junctions.* J Cell Sci. *2007;120:2838; **B** and **C,** adapted from Tsukita S, Furuse ML. Tricellulin constitutes a novel barrier at tricellular contacts of epithelial cells.* J Cell Biol. *2005;171:939.)*

in mice beginning near the onset of hearing. Pathology progresses faster in the case of Kcc4 null mice. Hair cell loss is observed in affected animals, and loss of Kcc4 also is associated with renal tubular acidosis.

K^+ taken up by support cells then diffuses through gap junctions to other epithelial cells of the outer sulcus that include Hensen and Claudius cells and into root cells of the spiral ligament,[245,284,477] where the ion is extruded into the extracellular space within the connective tissue of the spiral ligament. Type II fibrocytes, which express Na^+,K^+-ATPase (ATPA1 and ATPB1) and the Na^+-K^+-$2Cl^-$ (Slc12a2, Nkcc1) transporter,[92,484,485,522] take up K^+, which then passes through gap junctions to type I fibrocytes and into basal cells and intermediate cells of the stria vascularis. Intermediate cells that contain KCNJ10 channels extrude K^+ into the intrastrial space,[23,353] where it is taken up by the basolateral membranes of marginal cells, through Na^+-K^+-$2Cl^-$ (Slc12a2, Nkcc1) transporters[295,354,594] and Na^+-K^+-ATPase, including the ATP1A1, ATP1B1, and ATP1B2 subunits.[360,409,484,485,543] In addition, the marginal cell basolateral membrane contains Cl^- channels that associate with a protein called Barttin, encoded by *BSND* (*B*artter syndrome with *s*ensori*n*eural *d*eafness, or Bartter syndrome type IV), which forms the β-subunit required to transport ClC-Ka and ClC-Kb channels to the plasma membrane.[24,53,145,216,469] These channels are responsible for passive diffusion of Cl^- into the intrastrial space. Marginal cells secrete K^+ from their apical membrane by way of heteromeric K^+ channels composed of KCNQ1 (KvLQT1) and KCNE1 (IsK) subunits into scala media.[352,471,500,594,596]

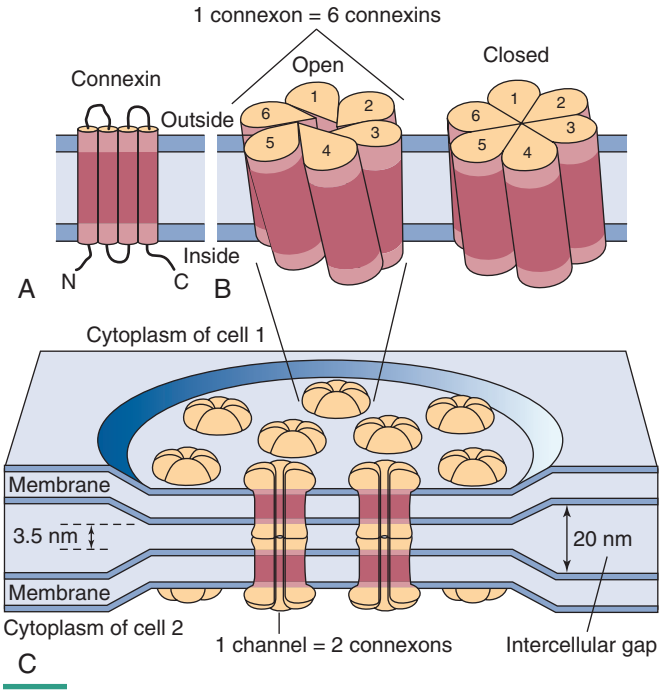

Figure 146-19. A, Gap junctions, which allow the direct passage of low-molecular-weight ions, second messengers, and metabolites (less than 1 kDa in size) between the cytoplasm of adjacent cells, are formed by the connexin family of proteins. Each connexin molecule has four transmembrane α-helical domains, and the amino and carboxyl termini are located intracellularly. Six connexins assemble to form a connexon or hemichannel (**B**). Connexons of adjacent cells form apposing partners to form a gap junction (**C**). Different types of channels can be formed, depending upon the combination of connexin proteins assembling to form the connexon, and depending upon the combination of connexons forming the channel. The channel pore can be regulated by protein kinase C, Ca^{2+}, calmodulin, cyclic adenosine monophosphate (cAMP), and pH, as well as other factors. Aggregates of gap junctions form large semicrystalline arrays where the apposing plasma membranes are in close proximity (3.5 nm) compared with the typical extracellular distance between cells (20 nm). (***A*** *to* ***C,*** *Modified from Kandel ER, Siegelbaum SA, Schwartz JH. Synaptic transmission. In: Kandel ER, Schwartz JH, Jessel TM, eds.* Principles in Neural Science. *New York: Elsevier; 1991:123.)*

Numerous proteins that are components of gap junctions have been identified in the cochlea, including the connexins CX26 (GJB2), CX30 (GJB6), and CX31 (GJB3). These proteins are particularly evident in supporting cells, interdental cells of the spiral limbus, root cells, and fibrocytes, as well as in basal and intermediate cells of the stria vascularis.[164,166,169,258,284,312,313,615-617] Mutations of the *GJB2* gene cause autosomal recessive and autosomal dominant forms of deafness (DFNB1, DFNA3), in addition to syndromic conditions that include deafness.[114,269,439,441] Mutations of *GJB6* also are responsible for autosomal recessive (DFNB1)[108] and autosomal dominant (DFNA3)[197] forms of deafness, and mutations in *GJB3* are associated with autosomal dominant (DFNA2)[618] and autosomal recessive forms of hearing loss.[340]

Similarly, genetically targeted ablation or mutation of CX26[79,305] or CX30[544] in mice results in hearing impairment, with associated degeneration of supporting cells in the organ of Corti, initially in the region of IHCs, followed by hair cell loss. These findings suggest that both CX26 and CX30 play a particularly important role in organ of Corti homeostasis. Similar degeneration of the sensorineural epithelium was observed in a human temporal bone associated with CX26-related hearing loss.[260]

Mutations in KCNQ1 (KVLQT1) or KCNE1 cause deafness associated with Jervell and Lange-Nielsen syndrome, as well as cardiac manifestations including a prolonged QT interval.[382,487,561] In addition, the endolymphatic compartment of transgenic mice lacking Kcnq1[66,315] or KCNE1,[580] or mice carrying spontaneous mutations of *Kcne1*,[323] is collapsed, and affected animals are deaf. Mutations in *BSND* cause Bartter syndrome, which is associated with sensorineural deafness and kidney failure,[53] suggesting that Cl^- extrusion from marginal cells into the intrastrial fluid space is essential for hearing. Similarly, mice with targeted disruption of *Bsnd* in the inner ear exhibit congenitally elevated thresholds as a result of a reduction in endocochlear potential, although the K^+ concentration in endolymph remains normal.[447] Of interest, mice lacking the ClC-Ka subunit are not deaf,[356] suggesting that the channel formed by the ClC-Kb subunit is sufficient for hearing. Targeted deletion of the *Nkcc1* (Slc12a2) gene that encodes the Na^+-K^+-$2Cl^-$ transporter protein in mice leads to deafness,[110,157] and a spontaneously occurring mutation in the gene is responsible for deafness in the mouse mutant called no syndactylism (*sy-ns*), which is transmitted as an autosomal recessive trait.[124] These findings suggest that abnormalities of this protein may cause human deafness as a consequence of defective endolymph secretion. In transgenic mice lacking the KCNJ10 (Kir4.1) channel, the endocochlear potential is eliminated, endolymphatic K^+ concentration is reduced, and Reissner's membrane is partially collapsed, producing deafness as assessed by absent Preyer's reflexes,[353] and sensory cells degenerate early in the postnatal period,[456] suggesting that KCNJ10 is necessary for providing the force for endocochlear potential generation.

Ablation of the *Pou3f4* gene, located on the X chromosome and known to encode a POU transcription factor expressed in fibrocytes of the spiral ligament, results in a reduced endocochlear potential and profound deafness in mice,[366,414] as does a spontaneous mutation named sex-linked fidget (*slf*).[412] Not surprisingly, developmental defects in the formation of the cochlea also are known to occur in affected animals, including an enlarged internal auditory meatus, stapes malformation, a reduction in the number of cochlear turns, thinning of the bony capsule and spiral limbus, and reduced scala tympani volume. Pou3f4 is expressed extensively in cochlear tissues of mesenchymal origin during development.[413] In humans, mutations of *POU3F4* are associated with X-linked (DFN3) deafness, resulting from both a conductive hearing loss caused by stapes fixation and progressive sensorineural pathology.[106] Reports also indicate that persons carrying this mutation seem to produce large volumes of perilymphatic flow (perilymphatic "gusher") during stapes surgery and exhibit abnormally large internal auditory meatuses.

Other ion transporters involved with homeostasis include pendrin (SLC26A4, PDS), an anion exchanger associated with Pendred's syndrome and prelingual profound deafness, and DFNB4,[325] which involves enlargement of the vestibular aqueduct.[410] Pendrin is expressed in cells of the spiral prominence and in the endolymphatic duct and sac,[152] where it may function to secrete bicarbonate into endolymph[595] and maintain pH homeostasis. Targeted disruption of the *Pds* gene in mice results in deafness and hair cell degeneration.[150,595] Although essential components of the proposed pathway described here remain to be identified, it is clear that homeostasis within the endolymphatic compartment is essential for hearing.

Summary

In the 21st century, the prospect of rescuing the victims of deafness from a life of relative isolation is bright, but the challenge to make sense of the complex interplay between genes and environment that shape the peripheral auditory system is more than significant. As has been emphasized throughout this chapter, the molecular and genetic basis of transduction is complex, and the molecular and cellular mechanisms for both transduction and deafness require further elucidation. Despite the steep learning curve for scientists around the world, reflecting an enormous and an emerging database centered on the role of integral proteins in the development and maintenance of inner ear anatomy and physiology, the precise mechanism of action is understood for only a small number of the known gene products that work harmoniously to support effective mechanoelectrical transduction, we are

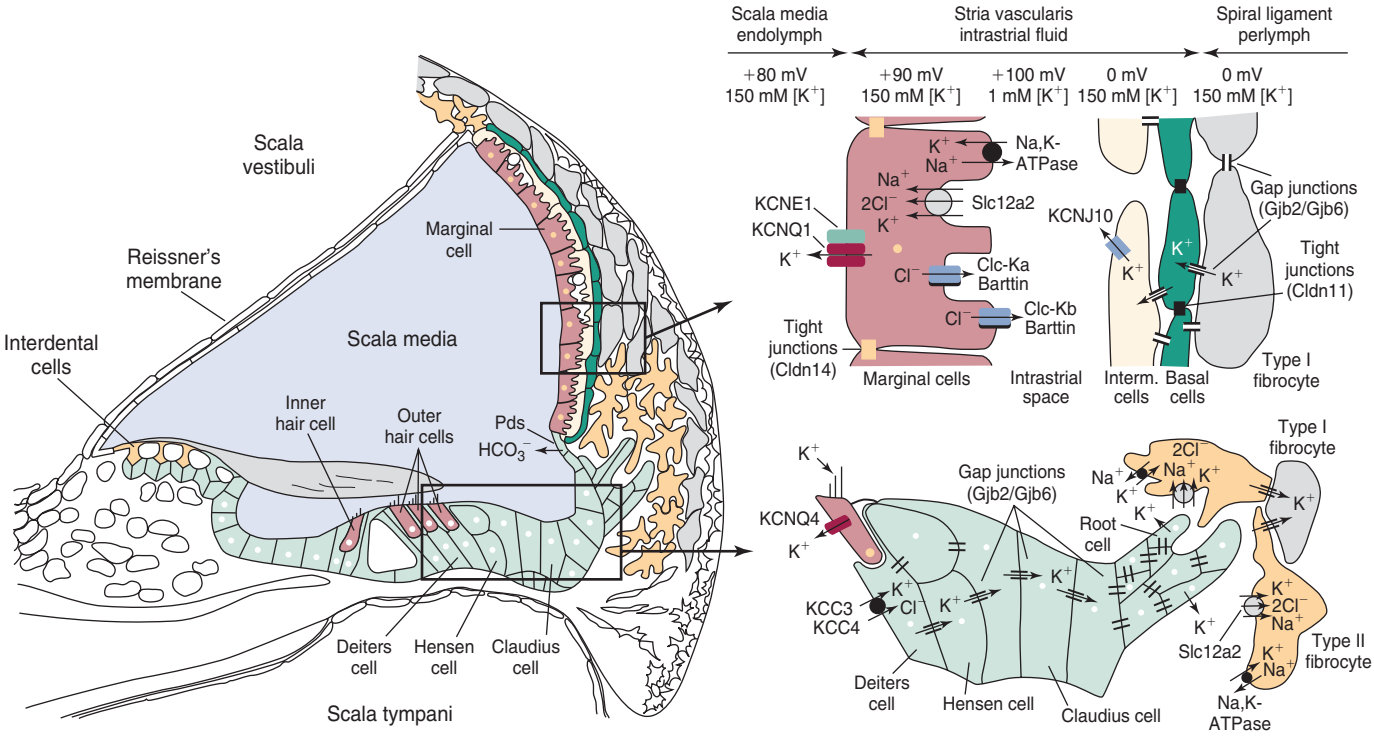

Figure 146-20. A proposed scheme for ion transport within the cochlea focused on K^+ circulation from cells within the stria vascularis *(upper right)* to the endolymphatic compartment *(left)*, through the sensory cells, and transportation back to the stria vascularis through the epithelial cell gap junction network into the outer spiral sulcus, and then through the connective tissue gap junction network of the spiral ligament *(lower right)*. Although the illustrated scheme is focused on a laterally oriented pathway from the organ of Corti toward the spiral ligament, a medial pathway has been proposed as well.[523] Several key proteins within this pathway have been identified as essential for normal hearing. CHAPTER ONE HUNDRED AND FORTY-SEVEN

Genetic Sensorineural Hearing Loss

Michael S. Hildebrand

Murad Husein

Richard J. H. Smith

Key Points

- It is estimated that at least 50% of congenital hearing impairment has a genetic origin.
- A hearing loss can be defined by numerous clinical criteria, including causality, time of onset, age of onset, clinical presentation, anatomic defect, severity, and frequency loss.
- The worldwide rate of profound hearing loss is 4 in every 10,000 infants born.
- The term *homozygosity* means that a person carries two identical alleles of a gene; *heterozygosity* represents the state in which a person carries two different variants of a given gene.
- The basic forms of inheritance can be mendelian (single-gene inheritance—autosomal or X-linked), mitochondrial, or complex (chromosomal, new mutations, germline mosaicism, genomic imprinting, polygenic, and multifactorial inheritance).
- Nonsyndromic hearing impairment in the absence of other phenotypic manifestations accounts for 70% of hereditary hearing loss.
- Mutations in *GJB2* have been shown to cause 50% of autosomal recessive nonsyndromic deafness in many world populations.
- Syndromic hearing impairment refers to deafness that cosegregates with other features, forming a recognizable constellation of findings known as a syndrome. Sensorineural deafness has been associated with more than 400 syndromes.
- The most common syndromic form of hereditary sensorineural hearing loss, Pendred syndrome, is inherited in an autosomal recessive fashion; affected individuals also have goiter.
- A well-performed patient history, physical examination, and audiologic evaluation are keys to assessing the cause of hearing loss, and may aid in ascertaining etiology.
- Prenatal diagnosis for some forms of hereditary hearing loss is technically possible by analysis of DNA extracted from fetal cells.
- Cochlear implantation is becoming an increasingly important option for individuals with severe to profound deafness.

It was famously put by Terry Savage that "… a child will hear his mother's voice for the rest of his life…." Many children never hear their mother's voice, however, and others do not hear it very well throughout their lives. Hearing loss is a common human sensory defect. The incidence of congenital hearing impairment is at least 1 child in every 1000 born.[1] A hearing impairment commonly involves damage to or loss of cochlear hair cells; this is referred to as a sensorineural hearing loss (SNHL). Individuals with SNHL are often referred to as deaf (lower case "d") by the community. The term *Deafness* (capital "D") is used to describe an individual with SNHL who is part of a cultural group based on their use of sign language for communication. Members of this group tend to be the offspring of Deaf parents and generally have congenital SNHL. In contrast, individuals who acquire SNHL later in childhood or adulthood generally do not use sign language and persist with oral communication. These individuals are usually not part of the Deaf community.

It is estimated that at least 50% of congenital hearing impairment has a genetic origin.[1] Late-onset hearing loss can also be caused by genetic defects. As understanding of the genetics of deafness increases, the role of the otolaryngologist in diagnosing, interpreting, and managing this form of hearing loss has mandated a basic understanding of genetics. This chapter provides an introduction to the genetics of hearing loss. An overview of hearing loss is followed by discussion of the fundamentals of genetics and a synopsis of syndromic and nonsyndromic deafness. The final section focuses on the clinical approach to a child with suspected genetic deafness and potential therapies for genetic hearing loss.

Background

Classification of Hearing Impairment

A hearing loss can be defined by numerous clinical criteria, including causality, time of onset, age of onset, clinical presentation, anatomic

Table 147-1

Hearing Loss Classification

Criteria	Classification	Comment
Causality	Genetic Environmental Multifactorial	Hereditary Nonhereditary
Time of onset	Congenital Acquired	At birth Late-onset
Age of onset	Prelingual Postlingual	Before speech development After speech development
Clinical presentation	Nonsyndromic Syndromic	Hearing loss only symptom Hearing loss and other symptoms
Anatomic defect	Conductive Sensorineural Mixed	Dysfunction of outer or middle ear Dysfunction of inner ear
Severity	Mild Moderate Moderately severe Severe Profound	Range 20-40 dB Range 41-55 dB Range 56-70 dB Range 71-90 dB Range >90 dB
Frequency loss	Low-frequency Midfrequency High-frequency	Range <500 Hz Range 501-2000 Hz Range >2000 Hz
Ears affected	Unilateral Bilateral	One ear affected Both ears affected
Prognosis	Stable Progressive	Severity remains unchanged Severity increases over time

Table 147-2

Quantification of Hearing Impairment

Impairment (%)	Pure Tone Average (dB)*	Residual Hearing (%)
100	91	0
80	78	20
60	65	40
30	45	70

*Pure tone average of 500 Hz, 1000 Hz, 2000 Hz, and 3000 Hz.

defect, severity, and frequency loss (Table 147-1). Etiologically based classifications can be broadly divided into genetic versus nongenetic factors. This distinction is important because hereditary deafness does not imply congenital deafness; the latter describes a condition present from birth regardless of causality. Hereditary deafness may be present at birth or develop any time thereafter.

It is well known that heritable and environmental factors can make strong contributions to hearing loss. There are three types of anatomic defects—conductive, sensorineural, or a combination of both (mixed)—and these defects may arise from syndromic or nonsyndromic conditions. Generally, when discussing hereditary deafness, a clinically based classification reflecting the presence or absence of coinherited anomalies—that is, syndromic or nonsyndromic deafness—is most useful. Syndromic and nonsyndromic conditions can be subclassified by inheritance pattern as autosomal dominant, autosomal recessive, X-linked, mitochondrial, or complex. Hearing loss can also be distinguished by differences in severity and frequency loss. Additional features of a hearing loss that are assessed include whether one or both ears are affected, and the prognosis for the condition (see Table 147-1).

Although these classifications assist clinicians in their assessment of patients and lead to better clinical outcomes, they do not adequately represent the complex interactions that underlie most forms of hearing loss. This limitation is exemplified in hearing loss that is attributable to exposure to the ototoxic antibiotics, aminoglycosides. Although at high concentration these antibiotics interfere with the normal function of the cochlea, individuals with an A1555G mutation in their mitochondrial 12S rRNA gene are more susceptible to the ototoxic effect of these drugs.[2] In some cases, hearing loss is attributable to genetic and environmental factors, and this dual causality can make classifying hearing loss less informative.

Diagnosis of Hearing Impairment

The primary diagnosis of hearing loss is by auditory testing to detect loss in hearing acuity. Hearing function is measured in decibels and is considered normal if the lowest level (threshold) a sound can be perceived is between 0 and 20 dB. The value of 0 dB is defined as the point at which a tone burst of a given frequency is perceived 50% of the time by a young adult. The severity and frequency loss sustained during a hearing impairment are given in Tables 147-1 and 147-2. Hearing acuity can be readily measured quantitatively and objectively by numerous physiologic tests, including auditory brainstem response (ABR) measurements, auditory steady-state responses, impedance testing (tympanometry), and otoacoustic emissions. For all these auditory tests except tympanometry, normal middle ear function is required for a normal response to be generated.

ABR testing records the electrophysiologic response of the auditory nerve (eighth cranial nerve) and brainstem to tone bursts (sound wave trains consisting of several cycles of the same frequency) or clicks (unidirectional rectangular voltage pushes) applied to the outer ear.[3,4] The waveform patterns are detected by electrodes connected to the skin, with maximal obtainable values at 94 to 100 dB sound pressure level. Sound pressure level refers to the ratio of the pressure of a sound wave to the standard air pressure level. Otoacoustic emissions are distinct from ABRs in that they are sounds generated only from the cochlea, and represent the activity of outer hair cells in response to transient or continuous stimulation. The emissions are measured in the external auditory canal, and are usually absent in individuals with hearing loss greater than 40 to 50 dB.[4]

The audiometry steady-state response has some similarity to the ABR, but the stimulus is continuous. A continuous tonal stimulus generates a higher sound pressure level than is possible with click stimuli, and allows a better estimation of hearing acuity in profoundly deaf individuals.[4] Impedance audiometry is used in conjunction with ABR, otoacoustic emissions, or auditory steady-state response testing because it does not measure hearing. This technique is used routinely to determine middle ear pressure, movement of the tympanic membrane and middle ear ossicles, and eustachian tube activity.[4]

Epidemiology of Hearing Impairment

Hearing loss is a prevalent human sensory defect. The worldwide rate of profound hearing loss is 4 in every 10,000 infants born.[5,6] The rate of SNHL determined in universal newborn screening programs in developed countries of 2 to 4 children per 1000 born compares favorably with this figure.[7,8] The incidence of congenital SNHL in developing countries is likely to be much higher,[9,10] although more data are required. The implications for the personal and social development of these children are significant.

Historical Background of Genetics

Mendel is considered the father of modern genetics. His work formulating the fundamentals of heredity by experimenting on the garden pea is well known to all school students. From this work, he postulated the principles of segregation and independent assortment, publishing these concepts in 1865. In the early 1900s, the impact of these ideas was recognized. Johannsen described the basic unit of heredity as the gene in 1909, and Avery showed that genes are composed of deoxyribonucleic acid (DNA) in 1944. In 1953, Watson and Crick described the physical structure of DNA, and 3 years later, the correct number of human chromosomes was confirmed to be 46. Sequencing these chromosomes was the goal of the Human Genome Project, initiated in 1991 and completed with first-pass data in 2001. The impact of this project on medicine has been tremendous, with the field of genetic deafness being just one of many areas of medical science to have flourished. A list of the current known deafness genes can be found on the Hereditary Hearing Loss Homepage.[11]

Fundamentals of Genetics

Each person has 46 chromosomes—22 pairs of autosomes and one pair of sex chromosomes (XY in males or XX in females). According to Mendel's principle of segregation, in sexually reproducing organisms, each partner contributes only one member of each chromosome pair to an offspring. This fact means that each individual has inherited one copy of each chromosome from each parent. Carried on these chromosomes are genes, estimated to number approximately 30,000. Variations in these genes impart uniqueness to each individual. These variations, termed *alleles,* can sometimes be deleterious.

If a mutation occurs in the normal or wild-type sequence of a gene expressed in the inner ear, and if the protein translated from this new allele variant does not function as well as the normal protein, deafness may result. If the remaining normal protein (recall that each gene is represented in duplicate) is able to cover for the abnormal protein, however, deafness manifests only in the individuals who carry two copies of the abnormal gene. This scenario is an example of autosomal recessive inheritance. If the abnormal protein interferes with the normal protein function, deafness manifests in an individual carrying a single abnormal gene. This scenario is an example of autosomal dominant inheritance.

In describing these inheritance patterns, we are describing a person's genotype or genetic makeup. The term *homozygosity* means that a person carries two identical alleles of a gene; *heterozygosity* represents the state in which a person carries two different variants of a given gene. The observable consequence that derives from an individual's genotype is his or her *phenotype*. Often individuals carrying identical genetic mutations exhibit a spectrum of different phenotypic features. Not every person with Waardenburg's syndrome type 1 has synophrys, premature graying of the hair, or heterochromia irides, a phenomenon called *variable expressivity*. In some cases, the phenotype can be so subtle as to be entirely absent, and the causative genetic mutation is said to be incomplete or nonpenetrant. This occurrence can give the impression that a disease "skips" generations.

Patterns of Inheritance

The basic forms of inheritance can be mendelian (single-gene inheritance—autosomal or X-linked), mitochondrial, or complex (chromosomal, new mutations, germline mosaicism, genomic imprinting, polygenic, and multifactorial inheritance). Pedigrees for these inheritance patterns are shown in Figure 147-1. Mendelian and mitochondrial forms of inheritance are discussed in this chapter; for the reader who is interested in complex forms of inheritance, we recommend more appropriate texts.[12,13] Punnett squares are used to show inheritance patterns by displaying the outcomes of crosses with both parents and allowing probability estimates for the offspring (Fig. 147-2).

Autosomal Dominant

In autosomal dominant diseases, heterozygotes express the disease phenotype. The affected parent can pass either a disease allele or a normal allele to offspring, with the likelihood of each event being 0.5, or 50%. This fact means that 50% of offspring inherit the normal allele, and 50% inherit the disease allele. In the case of dominant diseases, 50% of offspring express the disease.

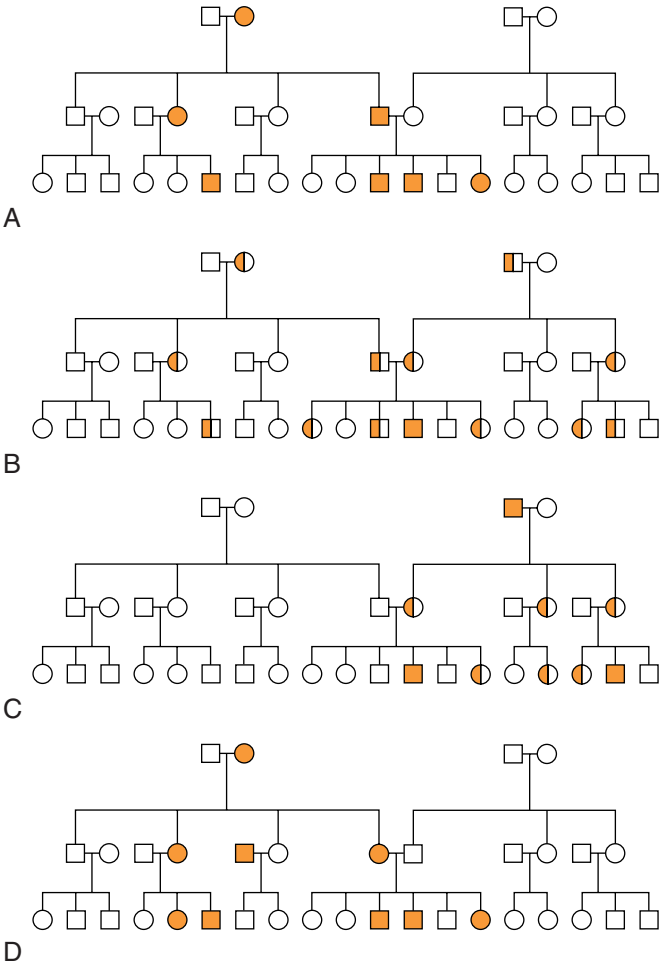

Figure 147-1. Inheritance patterns. **A,** Pedigree illustrating autosomal dominant inheritance. The inheritance pattern shows vertical transmission of the affected phenotype including father-to-son transmission. There are no skipped generations. **B,** Pedigree of autosomal recessive inheritance. Note the disease phenotype is not usually seen in the parents or other ancestors. Likelihood of affected males to females is equal. Refer to Punnett square in Figure 147-2 for estimating risks for recessive inheritance in heterozygous parents. **C,** Pedigree of X-linked recessive inheritance. The disease phenotype is present with one disease allele in the male, but requires a homozygous genotype to be expressed in the female. **D,** Pedigree illustrating mitochondrial inheritance. Note the maternal transmission of the affected phenotype. There is no paternal transmission.

There are several implications of autosomal dominant transmission. First, there is no sexual predilection for the disease phenotype; males and females are equally likely to be affected, and to transmit the disease allele to their offspring. Second, unless the disease gene is nonpenetrant, the disease does not skip generations. This type of transmission is called *vertical transmission*. Third, male-to-male (father-son) transmission is seen. This observation in a pedigree rules out mitochondrial or X-linked inheritance.

Autosomal Recessive

In contrast to autosomal dominant inheritance, in autosomal recessive inheritance, a homozygous genotype is necessary for expression of the disease phenotype. A homozygous parent transmits the disease allele to all offspring, but offspring do not show the disease phenotype unless the other parent carries at least one mutant copy of the same gene. More frequently, however, neither parent is affected, but both carry a single

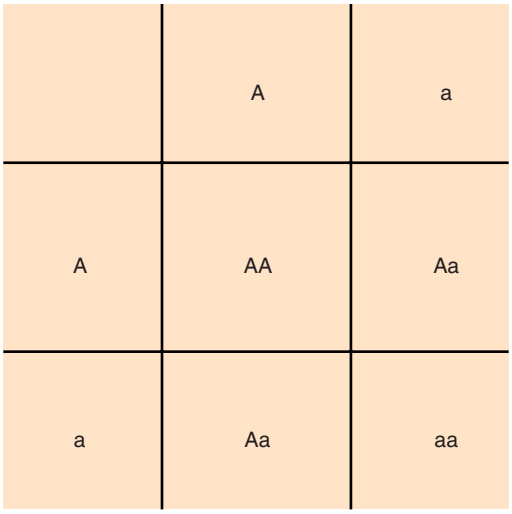

Figure 147-2. Punnett squares may be used to estimate inheritance probabilities for mendelian inheritance patterns. This Punnett square illustrates the mating of two individuals who are heterozygous carriers of an autosomal recessive gene, showing that there is a 25% chance of having a child with the recessive phenotype (aa), a 50% chance of having a child who carries the recessive allele but is not affected (Aa), and a 25% chance of having a child who does not carry the recessive allele (AA).

mutant gene, and by chance each passes this mutant copy on to the offspring. In this scenario, 25% of offspring carry two mutant copies of the gene and express the disease phenotype, 50% of offspring are carriers of a mutant copy (similar to the parents), and 25% of offspring have two wild-type copies of the gene. As with autosomal dominant diseases, there is no sexual predilection—males and females are equally likely to be affected—but vertical transmission is rarely seen. Recessive diseases tend to be generation specific. If the disease is exceptionally rare, the likelihood of parental consanguinity, albeit distant, is high.

X-Linked Inheritance

X-linked inheritance may be either recessive or dominant. In recessive X-linked inheritance, females are unlikely to be affected because a homozygous disease genotype is needed for the disease phenotype to manifest. Heterozygous females do occasionally exhibit subtle aspects of the disease phenotype, however, because of the phenomenon of X chromosome inactivation (the Lyon hypothesis). In each cell, only one of the two X chromosomes in females is active, and if X chromosome inactivation is entirely random, 50% of cells in a heterozygous female express the disease-carrying X chromosome. Through mechanisms that are not clearly understood, this process is not random, and inactivation of the mutated X chromosome is much higher than is inactivation of the normal X chromosome. Males have only a single X chromosome, and always express the disease phenotype.

In a pedigree showing X-linked recessive inheritance, the trait is seen more frequently in males; there is no father-son transmission; affected fathers transmit the disease allele to all female offspring, who may have affected males ("skipped generation"); and heterozygous females transmit the disease allele to half of all sons, who manifest the disease, and half of all daughters, who are heterozygous and phenotypically normal. In X-linked dominant inheritance, affected fathers transmit the disease allele to all daughters who exhibit the disease phenotype (with complete penetrance); there is no father-son transmission. Heterozygous females are affected and transmit the trait to half of all sons and to half of all daughters.

Mitochondrial Inheritance

Mitochondria are the "powerhouses" of the human cell and the site of oxidative phosphorylation, the process that leads to the production of adenosine triphosphate (ATP). Mitochondria possess their own intrinsic DNA, with several copies of the mitochondrial genome in each mitochondrion. The mitochondrial genome is a 16,569 base pair circular molecule that encodes two ribosomal RNAs, 22 transfer RNAs, and 13 polypeptides.[14] The remaining mitochondrial proteins required for oxidative phosphorylation are encoded by the nuclear genome.

Mitochondrial DNA (mtDNA) is inherited solely through the maternal lineage, reflecting the presence of large amounts of mtDNA in the cytoplasm of the egg. If all of the mtDNA molecules are abnormal, a condition known as *homoplasmy,* all progeny cells contain abnormal mitochondria. If normal and abnormal mtDNA molecules coexist, a condition known as *heteroplasmy,* there is a wide range of expression of the mutant phenotype, reflecting the random distribution of mitochondria to progeny cells. Because mitochondria lack a DNA repair mechanism, mtDNA accumulates mutations at a higher rate than nuclear DNA.

Table 147-3

Prevalence of Different Forms of Congenital Hearing Loss

Form	Prevalence (%)

Autosomal recessive	28
Autosomal dominant	7
X-linked and mitochondrial	<1

Genetic Hearing Impairment

Nonsyndromic Hearing Impairment

Genetic hearing loss is common in humans. Nonsyndromic hearing impairment in the absence of other phenotypic manifestations accounts for 70% of hereditary hearing loss.[15] More than half of SNHL that occurs in neonates is attributable to simple mendelian inherited traits (Table 147-3). In most cases, the inheritance pattern is recessive (75% to 80% of cases), and consequently the parents of affected children generally do not exhibit the phenotype. Congenital nonsyndromic hearing loss is inherited in an autosomal dominant (approximately 20%), X-linked (2% to 5%), or mitochondrial (approximately 1%) mode. Nomenclature is based on the prefix "DFN" to designate *nonsyndromic deafness*. DFN followed by an "A" implies dominant inheritance, a "B" implies recessive inheritance, and no letter means X-linked inheritance. The integer suffix denotes the order of locus discovery. DFNA1 and DFNB1 were the first autosomal dominant and recessive nonsyndromic deafness loci to be identified. Table 147-4 lists the genes included in clinical screens for nonsyndromic SNHL.

Autosomal Recessive Nonsyndromic Hearing Impairment

Autosomal recessive nonsyndromic hearing impairment is usually prelingual and severe to profound across all frequencies.[16] To date, 67 loci have been mapped, and 23 causative genes have been cloned (Table 147-5).[11] Although autosomal recessive SNHL is heterogeneous, mutations in the connexin 26 (*GJB2*) gene at the DFNB1 locus contribute about half of all hereditary cases in Australia, the United States, Israel, and many European countries.

DFNB1

In 1994, Guilford and coworkers[17] mapped the first autosomal recessive nonsyndromic deafness locus to 13q12-13 and called it DFNB1. Three

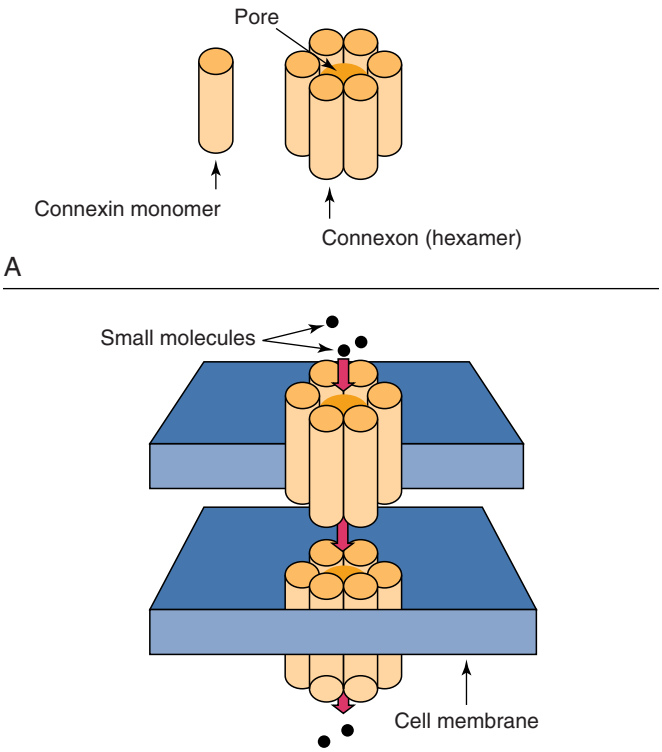

Figure 147-3. Diagram of a gap junction and its constituents. **A,** Three-dimensional view of a connexon hexamer composed of six connexin monomers. **B,** Three-dimensional view of a gap junction composed of two connexons in adjacent cells. Small molecules can pass through the gap junction from one cytoplasm to another without having to cross two cell membranes.

years later, Kelsell and colleagues[18] identified the DFNB1 gene as a gap junction gene called *GJB2*. The encoded protein, connexin 26 (Cx26), oligomerizes with five other connexin proteins to form a connexon; the docking of two connexons in neighboring cells results in a gap junction (Fig. 147-3). These gap junctions are thought to be conduits through which potassium ions are recycled from the outer hair cells back through the supporting cells and spiral ligament to the stria vascularis.[19] The ions are pumped into the endolymph to perpetuate the mechanosensory transduction of hair cells. Mutations in *GJB2* may disrupt this recycling process and prevent normal mechanosensory transduction.[18] This role is consistent with the expression of *GJB2* in the stria vascularis, nonsensory epithelial cells, spiral ligament, and spiral limbus of the inner ear.[18]

Mutations in *GJB2* have been shown to cause 50% of autosomal recessive nonsyndromic deafness in many world populations.[20] More than 90 deafness-causing mutations are described, with several being very common in specific ethnic groups.[21] The 35delG mutation predominates in populations of European descent[22]; this mutation has a carrier frequency in the Midwestern United States of 2.5%.[23] In the Ashkenazi Jewish population, the most common mutation is the 167delT; its carrier frequency is approximately 4%.[24] In Japanese populations, the 235delC mutation is the most common deafness-causing allele variant of *GJB2*.[25]

The DFNB1 auditory phenotype is varied, although homozygosity for protein-truncating mutations is generally associated with impaired gap junction activity and moderate to profound deafness.[21,26] With missense mutations, the degree of residual hearing can be substantially greater.[21] Most frequently, the loss is symmetric between ears, and does not progress over the long-term. Temporal bone anomalies are not part of the DFNB1 phenotype, obviating the need for routine temporal bone imaging.

Genetic testing is available to diagnose *GJB2*-related deafness and is warranted because the relative contribution of this gene to the total genetic deafness mutation load is high. Mutation screening facilitates genetic counseling and prediction of the chance of recurrence. It also provides prognostic information because several studies have shown that cochlear implant recipients with *GJB2*-related deafness do very well.[27]

Autosomal Dominant Nonsyndromic Hearing Impairment

To date, 54 loci for autosomal dominant nonsyndromic deafness have been mapped, and 21 causative genes have been cloned (Table 147-6).[11] Generally, the onset of deafness is postlingual, progressive, and milder than recessive forms, with several loci having characteristic audioprofiles.[28,29] Several common forms of dominant hearing impairment have unique or characteristic audioprofiles. One of the most common types of autosomal dominant nonsyndromic deafness is high-frequency hearing loss resulting from *KCNQ4* mutations at the DFNA2 locus.[30]

DFNA2 (High-Frequency Hearing Loss)

Autosomal dominant high-frequency hearing loss can be the consequence of mutations in numerous different genes (i.e., *KCNQ4* [DFNA2], *DFNA5* [DFNA5], *COCH* [DFNA9], *POU4F3* [DFNA15]). Mutations in some of these genes cause autosomal dominant deafness through a dominant-negative mechanism of action.[30-32] One example is deafness at the DFNA2 locus, which is caused by dominant-negative mutations in *KCNQ4*.[30,32] *KCNQ4* is organized into 14 exons that encode a protein with six transmembrane domains and a P-loop to confer K^+ ion selectivity to the channel pore.[32] A voltage sensor in the fourth transmembrane domain drives a conformational

DFNB31	9q32-q34	*DFN31*	Prelingual profound SNHL[188,189]
DFNB36	1p36.31	*ESPN*	Prelingual hearing loss of unspecified or unknown type[190]
DFNB37	6q13	*MYO6*	Prelingual hearing loss of unspecified or unknown type[191]
DFNB67	6p21.1-p22.3	*TMHS*	Prelingual profound SNHL[192-194]

*Most important references are cited.
†Prelingual deafness also includes congenital deafness.
‡The onset of DFNB8 hearing loss is postlingual (10-12 years old), whereas the onset of DFNB10 hearing loss is prelingual (congenital). This phenotypic difference reflects a genotypic difference—the DFNB8-causing mutation is a splice site mutation, suggesting that inefficient splicing is associated with a reduced amount of normal protein, which is sufficient to prevent prelingual deafness, but insufficient to prevent eventual hearing loss.

change that leads to channel opening. *KCNQ4* subunits are typically organized into homotetramers to form functional channels.[32]

The G285S allele was the first DFNA2 mutation identified, and a knockout mouse model of this variant has been generated.[33] The substitution of a serine for a glycine affects the first highly conserved glycine in a GYG signature sequence of the P-loop of the channel pore, and abolishes channel function by preventing correct subunit assembly. Impaired *KCNQ4* function in the inner ear affects K^+ ion recycling. Normally, mechanosensory transduction leads to an increase in cytosolic K^+ in the outer hair cells of the cochlea, the major site of *KCNQ4* expression. *KCNQ4* channels expressed in the base of these cells transport K^+ extracellularly, where the ion is taken up by supporting cells and cycled back into the scala media.[30] The consequence of abnormal *KCNQ4* function is apoptosis of the outer hair cells. The clinical

manifestation of this damage is hearing loss that is progressive and biased to the high frequencies.[30]

DFNA8/12 and DFNA13 (Midfrequency Hearing Loss)

Identification of phenotype-genotype correlations is crucial in determining the etiology of autosomal dominant sensorineural hearing loss (ADSNHL),[34] and has implications for prognostic and therapeutic outcomes. Some correlations are very robust, such as the low-frequency audioprofile associated with *WFS1*-related hearing loss (DFNA6/14/38)[35] and the "cookie-bite" (midfrequency) audioprofile associated with *TECTA*-related hearing loss (DFNA8/12),[36] whereas other correlations, such as high-frequency hearing loss, are more difficult to define. Hearing loss at the DFNA8/12 locus is unusual among dominant forms because midfrequencies are predominantly affected, it is congenital, and it is nonprogressive.[37] The causative gene at this locus, α-tectorin (*TECTA*), was identified in Austrian DFNA8[37] and Belgian DFNA12[36,38] families. In both families, missense mutations were identified that are thought to have a dominant-negative effect leading to disruption of the structure of the tectorial membrane.[36]

α-Tectorin is the major noncollagenous component of the tectorial membrane of the inner ear. A mouse mutant generated with a *TECTA* missense mutation showed elevated neural thresholds, broadened neural tuning, and decreased sensitivity of the tip of the neural tuning curve, indicating that the tectorial membrane enables the motion of the basilar membrane optimally to drive the inner hair cells at their best frequency.[39] *TECTA* has also been implicated in recessive deafness at the DFNB21 locus.[40,41] Hearing loss in these families was also congenital, but severe to profound across all frequencies rather than restricted to the midfrequencies.

DFNA13 is a related form of dominant hearing impairment that is also characterized by initial midfrequency loss and disruption of the tectorial membrane. In this case, missense mutations were identified in the *COL11A2* gene of American and Dutch DFNA13 families, and were predicted to affect the triple helical domain of the collagen protein.[42,43] A Col11a2$^{-/-}$ mouse model displayed moderate to severe hearing loss and an enlarged tectorial membrane attributable to disorganized and widely spaced collagen fibrils.[43] Defects in genes encoding components of the collagenous and noncollagenous regions of the tectorial membrane can induce autosomal dominant midfrequency hearing impairment.

DFNA6/14/38 (Low-Frequency Hearing Loss)

Mutations in the Wolfram syndrome 1 gene (*WFS1*) at the DFNA6/14/38 locus are a common cause of low-frequency sensorineural hearing loss. *WFS1* was originally identified in human disease as a cause of Wolfram syndrome, an autosomal recessive neu-

rodegenerative disorder comprising diabetes mellitus, optic atrophy, and often deafness.[44] Later, *WFS1* was implicated in autosomal dominant, nonsyndromic hearing loss at the DFNA6/14 locus in six families segregating delayed-onset, slowly progressive, low-frequency SNHL.[45] These families all carried missense mutations located in a region of exon 8 that encodes the C-terminal domain.[45] Although the protein is known to contain nine putative transmembrane domains, its function and role in causing low-frequency SNHL remain unclear. One of the original *WFS1* mutations, V779M, was identified in 1 of 336 control individuals.[45] This frequency is comparable to that of heterozygous carriers of Wolfram syndrome, which has been estimated to be 0.3% to 1%.[46] Because an increased risk of SNHL had been reported for these carriers,[46] it was predicted that *WFS1* was a common cause of low-frequency SNHL. This assumption has been supported by the subsequent discovery of *WFS1* mutations at high frequency in families with low-frequency SNHL from different populations.[47,48]

X-Linked Nonsyndromic Hearing Impairment

X-linked nonsyndromic hearing impairment accounts for less than 2% of nonsyndromic hearing loss.[1] Five loci and one causative gene have been identified (Table 147-7). Re-examination of the original family used to map DFN1 has revealed other cosegregating features, including mental retardation. This type of deafness is now recognized as a form of X-linked syndromic hearing loss.[49] Of the remaining DFN loci, DFN3 is most common. It is due to mutations in a transcription factor called POU3F4,[50] and manifests as congenital stapes fixation with radiologic findings that include widening of the lateral internal auditory canal and dilation of the vestibule.[51] Hearing loss is usually mixed, and stapedectomy is typically attended by a perilymph gusher.[52] The hearing impairment associated with the other loci is variable.[53,54]

Mitochondrial Nonsyndromic Hearing Impairment

Mitochondrial nonsyndromic deafness can be caused by various mtDNA mutations, although the 1555 A-to-G mtDNA has been characterized best (Table 147-8). As mentioned earlier, this mutation is also associated with aminoglycoside ototoxicity. As a cause of nonsyndromic deafness, the phenotype is similar to aminoglycoside ototoxicity with a mild, high-frequency loss that shows progression.[55] The loss is generally of later onset in individuals who have not been exposed to aminoglycosides.[2]

Presbycusis, or age-related hearing loss, also may have a mitochondrial basis.[56-59] Because mtDNA mutations accumulate at several times the rate of nuclear DNA mutations, mitochondrial function ultimately may be impaired, resulting in age-related cochlear dysfunction.[57] In support of this hypothesis, an increase in the mtDNA mutation load has been shown in aged cochlea.[59]

Table 147-8

Mitochondrial Nonsyndromic Hearing Loss

Gene Symbol	Mutation	Phenotype*

Syndromic Hearing Impairment

Syndromic forms of hereditary SNHL are less common than nonsyndromic forms (Table 147-9). Syndromic hearing impairment refers to deafness that cosegregates with other features, forming a recognizable constellation of findings known as a syndrome. Sensorineural deafness has been associated with more than 400 syndromes. A discussion of a few of the more common syndromes follows.

Autosomal Dominant Syndromic Hearing Impairment

Branchio-oto-renal Syndrome

Melnick coined the term *branchio-oto-renal (BOR) syndrome* in 1975 to describe the cosegregation of branchial, otic, and renal anomalies in

†Although Waardenburg's syndrome (WS) is usually inherited in an autosomal dominant manner, sometimes WS2 can be inherited in an autosomal recessive manner. WS4 is always inherited in an autosomal recessive manner.

deaf individuals.[60] Inheritance is autosomal dominant, penetrance is nearly 100%, and prevalence is estimated at 1 in 40,000 newborns.[61] BOR affects 2% of profoundly deaf children.[61] Otologic findings can involve the external, middle, or inner ear. External ear anomalies include preauricular pits (82%), preauricular tags, auricular malformations (32%), microtia, and external auditory canal narrowing[62,63]; middle ear anomalies include ossicular malformation (fusion, displacement, underdevelopment), facial nerve dehiscence, absence of the oval window, and reduction in size of the middle ear cleft[62]; and inner ear anomalies include cochlear hypoplasia and dysplasia.[64] Enlargement of the cochlear or vestibular aqueducts may be seen,[63] or merely hypoplasia of the lateral semicircular canal.[64]

Hearing impairment is the most common feature of BOR syndrome and is reported in almost 90% of affected individuals.[61] The loss can be conductive (30%) or sensorineural (20%), but is most often mixed (50%). It is severe in one third of individuals and is progressive in one quarter.[61] Branchial anomalies occur in the form of laterocervical fistulas, sinuses, and cysts, and renal anomalies ranging from agenesis to dysplasia are found in 25% of individuals.[61] Less common phenotypic findings include lacrimal duct aplasia, short palate, and retrognathia.[61]

One causative gene is *EYA1,* the human homologue of the *Drosophila* eyes absent gene.[65] The gene contains 16 exons encoding for 559 amino acids.[65] *EYA1* mutations are found in approximately 25% of patients with a BOR phenotype, and this phenotype is hypothesized to reflect a reduction in the amount of the EYA1 protein. Mutations in two additional genes, *SIX1* and *SIX5,* also have been shown more recently to cause BOR syndrome.[66,67] Both genes act within the genetic network of the *EYA* and *PAX* genes to regulate organogenesis.

Neurofibromatosis Type 2

Neurofibromatosis type 2 (NF2) is characterized by the development of bilateral vestibular schwannomas and other intracranial and spinal tumors (schwannomas, meningiomas, gliomas, and ependymomas). In addition, patients may have posterior subcapsular lenticular opacities. Diagnostic criteria include (1) bilateral vestibular schwannomas that usually develop by the second decade of life, or (2) a family history of NF2 in a first-degree relative, plus one of the following: unilateral vestibular schwannomas at less than 30 years of age, or any two of meningioma, glioma, schwannoma, or juvenile posterior subcapsular lenticular opacities/juvenile cortical cataract. The causative gene is a 17 exon gene that codes for a 595-amino acid protein named merlin on chromosome 22q12.[68] Merlin is a tumor suppressor that regulates the actin cytoskeleton.[69,70] Although its mechanism of action is not completely understood, microarray analysis has identified numerous other genes that become deregulated during tumorigenesis.[71]

The incidence of NF2 is 1:40,000 to 1:90,000.[70] Hearing loss is usually high frequency and sensorineural; vertigo, tinnitus, and facial nerve paralysis may be associated findings. The diagnosis rests on the clinical and family history, physical examination, and imaging studies (magnetic resonance imaging [MRI]). Treatment of the vestibular schwannomas usually consists of surgery, although Gamma knife surgery is considered in selected cases.[72] Auditory brainstem implants have been used with success in patients with vestibular schwannomas, although their use is limited if there is a history of Gamma knife treatment.[72,73]

Stickler Syndrome

In 1965, Stickler described a family followed at the Mayo Clinic for five generations that segregated syndromic features, including myopia, clefting, and hearing loss.[74] The disease, now known eponymously as Stickler syndrome (SS), has a prevalence of 1:10,000,[75] and is caused by mutations in *COL2A1, COL11A2,* or *CO11A1* genes that encode for the constituent proteins of type II and type XI collagen.[76-79] On the basis of criteria set forth by Snead and Yates,[80] the diagnosis of SS requires (1) congenital vitreous anomaly, and (2) any three of myopia with onset before age 6 years, rhegmatogenous retinal detachment or paravascular pigmented lattice degeneration, joint hypermobility with abnormal Beighton score, SNHL (audiometric confirmation), or midline clefting. Other manifestations include craniofacial anomalies such as midfacial flattening, mandibular hypoplasia, short upturned nose, or a long philtrum. Micrognathia is common, and if severe leads to the Robin sequence with cleft palate (28% to 65%).[81] Clefting may be complete, with a U-shaped cleft palate secondary to Robin sequence, but is more commonly limited to a submucous cleft.[82]

SS type 1 is caused by mutations in *COL2A1*.[76] The phenotype includes the classic ocular findings with a "membranous" vitreous. SS type 2 is due to missense or in-frame deletion mutations in *COL11A2,*[79] and is unique in that there are no ocular abnormalities because *COL11A2* is not expressed in the vitreous. SS type 3 is caused by mutations in *COL11A1*.[77] The vitreous in these patients shows irregularly thickened fiber bundles that may be visualized on slit-lamp examination.[77,80]

The hearing loss associated with SS can be conductive, sensorineural, or mixed. If it is conductive, the loss typically reflects the eustachian tube dysfunction that commonly occurs with palatal clefts. SNHL is more common in the older age groups. Its pathogenesis is incompletely understood, but possible mechanisms include primary neurosensory deficits because of alterations in the pigmented epithelium of the inner ear or abnormalities of inner ear collagen.[81] Computed tomography (CT) has not shown gross structural abnormalities. Patients with SS type 3 tend to have moderate to severe hearing loss, patients with SS type 1 have either normal hearing or only a mild impairment, and patients with SS type 2 fall in between.[75]

The ocular findings in SS are the most prevalent feature and warrant special discussion.[82] Most affected individuals are myopic,[80] but also may have vitreoretinal degeneration, retinal detachment, cataract, and blindness.[74] Retinal detachment leading to blindness is the most severe ocular complication and affects approximately 50% of individuals with SS.[81] Detachment typically occurs in adolescence or early adulthood.

Waardenburg Syndrome

Waardenburg published an article defining a auditory-pigmentary disease in 1951.[83] The association, now known as Waardenburg syndrome (WS), is classified under four types and has an aggregate prevalence of 1:10,000 to 1:20,000.[84] WS type 1 is recognized by SNHL, white forelock, pigmentary disturbances of the iris, and dystopia canthorum, a specific displacement of the inner canthi and lacrimal puncti.[83] Other features include synophrys, broad nasal root, hypoplasia of the alae nasi, patent metopic suture, and a square jaw. WS type 1 is caused by mutations in *PAX3,* a DNA-binding transcription factor homologous to mouse Pax-3, the gene implicated in the Splotch mouse mutant.[85] *PAX3* is expressed in neural crest cells in early development, and strial melanocytes are absent in affected individuals.[85]

WS type 2 is distinguished from WS type 1 by the absence of dystopia canthorum. Approximately 15% of WS type 2 cases are caused by mutations in *MITF,* a transcription factor also involved in melanocyte development.[86] Mutations in *SNAI2,* a zinc-finger transcription factor expressed in migratory neural crest cells, have also been shown to cause WS type 2.[87] WS type 3 is called Klein-Waardenburg syndrome, and is characterized by WS type 1 features with the addition of hypoplasia or contracture of the upper limbs. *PAX3* is the causative gene.[88] WS type 4 is also known as Waardenburg-Shah syndrome, and involves the association of WS with Hirschsprung disease. Three genes have been implicated: endothelin 3 (*EDN3*), endothelin receptor B gene (*EDNRB*), and *SOX10*.[89-91] Although WS types 1 to 3 are inherited as dominant diseases, WS type 4 is autosomal recessive (see Table 147-9).

The hearing loss in WS shows considerable variability between and within families. Congenital hearing impairment is present in 36% to 66.7% of cases of WS type 1 versus 57% to 85% of cases of WS type 2.[84] Most commonly, the loss affects individuals with more than one pigmentation abnormality and is profound, bilateral, and stable over time. Audiogram configuration varies, with low-frequency loss being more common. Nadol and Merchant[92] examined the inner ear of a 76-year-old woman with WS type 1 and found intact neurosensory structures only in the basal turn of the cochlea. Temporal bone imaging is typically normal, although malformation of the semicircular canals and cochlear hypoplasia can be found.[93] Risk chance prediction of the

findings associated with WS is difficult because of variability in disease expression.

Treacher-Collins Syndrome

Treacher-Collins syndrome is an autosomal dominant syndrome characterized by abnormalities of craniofacial development. The phenotype includes maldevelopment of the maxilla and mandible, with abnormal canthi placement, ocular colobomas, choanal atresia, and conductive hearing loss secondary to ossicular fixation.[94] The causative gene is *TCOF,* which encodes for the protein treacle.[94]

Autosomal Recessive Syndromic Hearing Impairment

Pendred Syndrome

The most common syndromic form of hereditary SNHL, Pendred syndrome (PS) was described by Pendred in 1896.[95] The condition is autosomal recessive, and affected individuals also have goiter.[96] The prevalence of PS is estimated at 7.5 to 10 per 100,000 individuals, suggesting that the syndrome may account for 10% of hereditary deafness.[96] The hearing loss is usually congenital and severe to profound, although progressive mild to moderate SNHL is sometimes seen.[96] Bilateral dilation of the vestibular aqueduct is common, and may be accompanied by cochlear hypoplasia. Most cases of PS result from mutations in the *SLC26A4* gene that encodes an anion transporter known as pendrin that is expressed in the inner ear, thyroid, and kidney.[97] Expression of *SLC26A4* has been shown throughout the endolymphatic duct and sac, in distinct areas of the utricle and saccule, and in the external sulcus region within the developing cochlea.[98] Pendrin is thought to be involved in chloride and iodide transport and not sulfate transport.[99]

Affected individuals have thyroid goiter develop in their second decade, although they usually remain euthyroid.[97] Thyroid dysfunction can be shown with a perchlorate discharge test, in which radioactive iodide and perchlorate are administered. Mutations in *SLC26A4* prevent rapid movement of iodide from the thyrocyte to the colloid, and perchlorate blocks the Na/I symporter that moves iodide from the bloodstream into the thyrocyte. The net effect is that iodide in the thyrocyte washes back into the bloodstream in affected individuals, with a release of greater than 10% radioactivity considered diagnostic for PS.[95,100] The sensitivity of this test is low, making genetic testing the preferred diagnostic method.[95] The hearing impairment is usually prelingual, bilateral, and profound, although it can be progressive.[95] Radiologic studies always show a temporal bone anomaly, either dilated vestibular aqueducts or Mondini dysplasia.[95,101]

Mutations in *SLC26A4* also cause a type of nonsyndromic autosomal recessive deafness called DFNB4.[102,103] Whether the phenotype is syndromic or nonsyndromic may reflect the degree of residual function in the abnormal protein. PS and DFNB4 can be diagnosed by screening this gene for mutations. More recently, mutations in the transcription factor *FOXI1* have also been shown to cause PS in patients heterozygous for a mutation in *SLC26A4*.[104]

Jervell and Lange-Nielsen Syndrome

In 1957, Jervell and Lange-Nielsen described a syndrome characterized by congenital deafness, prolonged Q-T interval, and syncopal attacks.[105] Long Q-T syndrome itself can be dominantly or recessively inherited. The dominant disease is called Romano-Ward syndrome. It is more common and does not include the deafness phenotype.[105] The recessive disease is known as Jervell and Lange-Nielsen syndrome (JLNS).

JLNS is genetically heterogeneous with mutations in *KVLQT1* and *KCNE1* causing this phenotype.[106-108] These genes encode for subunits of a potassium channel expressed in the heart and inner ear. Hearing impairment is due to changes in endolymph homeostasis caused by malfunction of this channel and is congenital, bilateral, and severe to profound.[106-108] Although the prevalence of JLNS among children with congenital deafness is only 0.21%,[109] it is an important diagnosis to consider because of its cardiac manifestations. The prolonged Q-T interval can lead to ventricular arrhythmias, syncopal episodes, and death in childhood.[109] Effective treatment with β-adrenergic blockers reduces mortality from 71% to 6%.[109]

Usher Syndromes

The Usher syndromes (US) are a genetically and clinically heterogeneous group of diseases characterized by SNHL, retinitis pigmentosa, and often vestibular dysfunction.[110] Prevalence is estimated at 4.4 : 100,000 in the United States with 3% to 6% of congenitally deaf individuals carrying this diagnosis.[111] It is the cause of 50% of deaf-blindness in the United States.[111]

Three clinical variants of US are recognized. Type 1 is phenotypically distinguished by the presence of severe to profound congenital hearing loss, vestibular dysfunction, and retinitis pigmentosa that develops in childhood[112]; type 2 is distinguished by moderate to severe congenital hearing loss, with uncertainty related to progression, no vestibular dysfunction, and retinal degeneration that begins in the third to fourth decade[112,113]; and type 3 is characterized by progressive hearing loss, variable vestibular dysfunction, and variable onset of retinitis pigmentosa.[112] Within each subtype, there is genetic heterogeneity, and numerous subtypes are recognized, although the two most common forms are US type 1B (USH1B) and US type 2A (USH2A), which account for 75% to 80% of the Usher syndromes.[114] USH1B accounts for 75% of US type 1 and is caused by mutations in an unconventional myosin called *MYO7A*.[115] USH2A is the most common form, and the causative gene encodes a 1551-amino acid protein named usherin that is a putative extracellular matrix molecule.[116] Numerous other genes have been implicated in US subtypes, and these are listed in Table 147-9.

Biotinidase Deficiency

Biotinidase deficiency is secondary to an absence in the water-soluble B-complex vitamin biotin. Biotin covalently binds to four carboxylases that are essential for gluconeogenesis, fatty acid synthesis, and catabolism of several branched-chain amino acids. If biotinidase deficiency is not recognized and corrected by daily addition of biotin to the diet, affected individuals develop neurologic features such as seizures, hypertonia, developmental delay, ataxia, and visual problems. In at least 75% of children who become symptomatic, SNHL develops, and can be profound and persistent even after treatment is initiated.[117] Cutaneous features are also present and include a skin rash, alopecia, and conjunctivitis. With treatment that consists of biotin replacement, the neurologic and cutaneous manifestations resolve; however, the hearing loss and optic atrophy are usually irreversible. If a child presents with episodic or progressive ataxia and progressive sensorineural deafness, with or without neurologic or cutaneous symptoms, biotinidase deficiency should be considered. To prevent metabolic coma, diet and treatment should be initiated as soon as possible.[117,118] If untreated, 75% of affected infants develop hearing loss, which can be profound, and persists despite the subsequent initiation of treatment.[117]

Refsum Disease

Refsum disease is a postlingual severe progressive SNHL associated with retinitis pigmentosa, peripheral neuropathy, cerebellar ataxia, and elevated protein levels in the cerebrospinal fluid without an increase in the number of cells.[119] It is caused by defective phytanic acid metabolism, and the diagnosis is established by determining serum concentration of phytanic acid. Two genes, *PHYH* and *PEX7,* have been implicated in most cases of Refsum disease, although a few patients exist in whom mutations have not been found.[119] Although extremely rare, it is important that Refsum disease be considered in the evaluation of a deaf person because it can be easily treated with dietary modification and plasmapheresis.

X-Linked Syndromes

Alport Syndrome

Alport syndrome (AS) is a disease of type IV collagen that is manifested by hematuric nephritis, hearing impairment, and ocular changes. The inheritance pattern, although predominantly X-linked (approximately 80%), can be autosomal recessive or dominant.[120] Prevalence is estimated at 1 : 5000 in the United States; a significant proportion of renal transplant patients have AS.[121] Diagnostic criteria include at least three of the following four characteristics[122]: (1) positive family history of

hematuria with or without chronic renal failure, (2) progressive high-tone sensorineural deafness, (3) typical eye lesion (anterior lenticonus or macular flecks or both), and (4) histologic changes of the glomerular basement membrane of the kidney.

Mutations in *COL4A5* are the cause of X-linked AS.[123] Type IV collagen is the major component of basement membranes and is formed by the trimerization of various combinations of six type IV collagen genes. Deficiency of this protein results in complete or partial deficiency of the trimerized 3-4-5 complex in the basement membranes of the kidney, cochlea, and eye.[123] More than 300 disease-causing mutations of 5 have been identified with 9.5% to 18% arising de novo.[121,124]

The disease phenotype is more pronounced in males, as expected for X-linked diseases. Gross or microscopic hematuria is the hallmark of disease, and all males ultimately have end-stage renal disease, although the rate of progression depends on the underlying mutation.[125] Ocular manifestations are present in one third of patients and are characterized by anterior lenticonus, an anomaly in which the central portion of the lens protrudes into the anterior chamber of the eye, causing myopia.[125] End-stage renal disease develops before age 30 in patients with anterior lenticonus.[121] Maculopathy and corneal lesions may also be found in patients with AS. Diffuse esophageal leiomyomatosis has been associated with deletion mutations of *COL4A5* and *COL4A6*.[122,125]

Hearing impairment is common in AS and is usually a symmetric, high-frequency sensorineural loss that can be detected by late childhood and progresses to involve all frequencies.[125] Pathogenesis is thought to be related to the loss of the 3-4-5 network, which is important for radial tension on the basilar membrane. Diagnosis currently relies on clinical and histopathologic confirmation, although genetic confirmation can allow the stratification and prediction of severity of the disease phenotype.

Mohr-Tranebjaerg Syndrome

Mohr-Tranebjaerg syndrome was first described in a large Norwegian family with apparent progressive postlingual nonsyndromic hearing impairment and classified as DFN1.[126] Re-evaluation of this family revealed additional findings, however, including visual disability, dystonia, fractures, and mental retardation, indicating that this form of hearing impairment is syndromic, rather than nonsyndromic.[49] The gene for this syndrome, *TIMM8A,* is involved in the translocation of proteins from the cytosol across the inner mitochondrial membrane (TIM) system and into the mitochondrial matrix.[127,128]

Mitochondrial Syndromes

Mitochondrial diseases typically cause a phenotype in tissues with high energy demands, such as muscle, retina, brainstem, pancreas, and cochlea.[55,57] The process by which mitochondrial diseases lead to SNHL is debated and is confounded by the demonstration that nuclear modifier genes have an impact on the outcome.[129] Syndromic mitochondrial diseases are usually multisystemic, with hearing loss present in 70% of affected individuals.[57] Examples include MELAS (mitochondrial encephalopathy, lactic acidosis, and strokelike episodes) syndrome, MERRF (myoclonic epilepsy and red ragged fibers) syndrome, and Kearns-Sayre syndrome (KS) (see Table 147-9).

In MELAS syndrome, hearing loss is sensorineural, progressive, and bilateral, and more severely affects the higher frequencies[130-132]; temporal bone histopathologic findings show severe atrophy of the stria vascularis.[92] MERRF syndrome is characterized by hearing loss, ataxia, dementia, optic nerve atrophy, and short stature. In contrast to MELAS and MERRF, which are caused by point mutations in mtDNA, KS is caused by large duplications and deletions.[133] First described in 1958, KS involves progressive external ophthalmoplegia, atypical retinal pigmentation, and heart block typically starting before age 20.[134,135] SNHL is present in 50% of patients with KS,[57,131] and temporal bone histopathologic findings show cochleosaccular degeneration.[132]

Maternally inherited diabetes and deafness is another syndromic mitochondrial disease. It affects an estimated 0.5% to 2.8% of diabetic patients.[136] The hearing loss occurs late, and is progressive, bilateral, and high frequency; its presence is correlated with the level of heteroplasmy for the 3243 A-to-G mtDNA mutation.[57,130]

Susceptibility to aminoglycoside ototoxicity is also maternally inherited. It is caused by the 1555 A-to-G mtDNA mutation, a nucleotide change found in 17% to 33% of individuals with aminoglycoside-induced hearing loss.[137,138] This mutation changes the 12S rRNA gene, altering its structure to make it more similar to bacterial rRNA, the natural target of aminoglycosides.[137,138] Hearing loss develops even when aminoglycosides are administered at normal doses, with residual thresholds varying widely among individuals. Hearing losses can be seen months after aminoglycoside exposure. Outer hair cells in the basal turn of the cochlea are affected first, but damage eventually extends to include apical outer hair cells and inner hair cells.[139] The same mutation causes nonsyndromic mitochondrial hearing loss.[2]

PATIENT MANAGEMENT

Diagnosis

The evaluation of a deaf patient should involve a team of health care professionals that includes an audiologist, clinical geneticist, ophthalmologist, and otolaryngologist, with the otolaryngologist most frequently coordinating overall care. A well-performed history, physical examination, and audiologic evaluation are keys to assessing the cause of hearing loss.[140]

The American College of Medical Genetics more recently released genetic evaluation guidelines for the diagnosis of congenital hearing loss.[141] Specific details of the family history that should be covered include a pedigree with attention to consanguinity and hearing status of first-degree relatives. Ethnicity, inheritance patterns, audiometric characteristics, and an inquiry of syndromic versus nonsyndromic features are necessary.[141] To assess for the presence of a syndrome related to hearing loss, questions and physical examination regarding endocrine abnormalities (diabetes, thyroid nodules), pigmentary anomalies (white forelock, heterochromic irides), visual anomalies (retinitis pigmentosa, retinal detachment), craniofacial anomalies (dystopia canthorum, aural atresia, cleft palate, branchial anomalies), cardiac manifestations (syncope, arrhythmias, sudden death), and renal anomalies should be performed.[141,142] The patient history and physical examination also should include a search for acquired causes of hearing loss, such as intrauterine infections, meningitis, hypoxia, and ototoxic drugs.

The audiologic evaluation is a crucial part of the initial diagnostic workup. In infants, behavioral testing is often impossible. Electrophysiologic tests such as ABR and otoacoustic emissions provide a means of objectively documenting hearing impairment, and can be used to provide information regarding auditory thresholds. Behavioral tests can be used when infants reach 6 months of age. A trained pediatric audiologist can measure hearing losses of 20 dB in the better hearing ear. The frequency of testing is usually decided on a case-by-case basis, although Tomaski and Grundfast[143] recommend a more rigid schedule in cases of confirmed SNHL in children. They recommend testing every 3 months in the first year of life, followed by every 6 months during the preschool years, and once a year while in school.

No cause of hearing loss may be apparent in 30% of cases even after a thorough history and physical examination.[141] To increase the yield further, additional investigations are necessary. In the past, a battery of tests including thyroid function studies, urinalysis, electrocardiogram, and temporal bone imaging was routinely ordered. Today, genetic screening should supplant these tests. Screening for *GJB2* mutations should be completed; if the diagnosis of DFNB1 is made, further testing is not required.[144] If CT shows dilated vestibular aqueducts or Mondini dysplasia, mutation screening of *SLC26A4* is warranted. Additional known deafness genes may be screened depending on the clinical presentation and the gene testing available at some institutions (see Table 147-4).

Acquired congenital deafness must also be considered. The most frequent cause is in utero cytomegalovirus infection, a diagnosis that can be made definitively only in the neonatal period before the possibility of postnatally acquired cytomegalovirus, which can confound the diagnosis of a congenital infection.[145] MRI has a place in the evaluation of hereditary hearing impairment if a patient is suspected to have NF2, if the hearing loss is progressive, and if the audiologic battery suggests retrocochlear pathology.[143] Other potential investigations include

thyroid function studies, electrocardiogram, urinalysis, renal ultrasonography, and electroretinography.

Genetic Testing

In the United States, congenital SNHL occurs about three times more frequently than Down syndrome, six times more frequently than spina bifida, and more than 50 times more frequently than phenylketonuria, making it the most frequently occurring birth defect.[146] An estimated 4000 infants are born each year with severe to profound bilateral hearing loss,[147,148] and another 8000 are born with unilateral or mild to moderate bilateral SNHL.[5] At least 50% of congenital hearing loss has an underlying genetic cause; this is a compelling reason to provide genetic testing services to all children diagnosed with congenital hearing loss. The implementation of the Early Hearing Detection and Intervention (EHDI) program in the United States and similar universal hearing screening programs around the world has facilitated increased detection, genetic diagnosis, and intervention for these children.[149] In addition, advances in genetic technologies have led to an increase in the availability of genetic diagnostic services for infants with hearing loss.[149]

Despite the fact that genetic SNHL is heterogeneous, mutations in the *GJB2* gene (DFNB1) have been shown to account for at least half of all severe to profound congenital nonsyndromic SNHL in the United States, many European countries, Israel, and Australia.[150-153] *GJB2*-related SNHL also has been repeatedly described in several Asian, Latin American, and African countries, but it is less common in these regions. Based on this frequency, first-pass screening of all individuals with congenital hearing loss for *GJB2* mutations is warranted.

For individuals not diagnosed with DFNB1, US should be the next consideration because it accounts for approximately 3% to 6% of all children who have severe to profound hearing loss and is second to *GJB2* mutations as a cause of deafness in the congenitally deaf cochlear implant population.[154] The three different types of US are caused by mutations in at least nine different genes.[155] Determining which genes to screen can be based on the onset and severity of the hearing loss and the presence or absence of vestibular dysfunction.

The third most common genetic cause of early childhood hearing loss is the PS-DFNB4 deafness spectrum. PS accounts for approximately 10% of all syndromic forms of hearing loss and is present in approximately 3% of individuals with hereditary hearing loss.[156] A diagnostic feature of PS is enlarged vestibular aqueducts with or without cochlear dysplasia (Mondini's dysplasia) that is detectable by CT scanning or MRI; the presence of thyroid goiter differentiates PS from DFNB4. Most cases of PS-DFNB4 are due to mutations in the *SLC26A4* gene, and individuals with diagnosed enlarged vestibular aqueducts should be screened for mutations in this gene. More recently, mutations in another gene, *Foxi1,* have also been found to cause PS-DFNB4, and this gene should also be considered in genetic analyses of these families.[104]

ADNSHL is a genetically heterogeneous disorder that is typically postlingual in onset and progressive. It accounts for approximately 15% of inherited hearing loss. To date, 21 genes for nonsyndromic ADNSHL have been identified, and a further 30 dominant loci have been mapped to chromosomal regions.[157] Individuals with apparent ADNSHL should be considered for genetic screening, with criteria for gene selection based on their audioprofile. Identification of phenotype-genotype correlations is crucial in determining the etiology of ADNSHL,[34] and has implications for prognostic and therapeutic outcomes. Some phenotype-genotype correlations are very robust, such as the low-frequency audioprofile associated with *WFS1*-related hearing loss (DFNA6/14/38)[35] and the "cookie-bite" audioprofile associated with *TECTA*-related hearing loss (DFNA8/12)[36]; other correlations are more difficult to define. Autosomal dominant high-frequency hearing loss can be the consequence of mutations in numerous different genes (e.g., *KCNQ4* [DFNA2], *DFNA5* [DFNA5], *COCH* [DFNA9], *POU4F3* [DFNA15]).

Current recommendations for genetic testing are to screen individuals with low-frequency ADNSHL for mutations in *WFS1* and individuals with midfrequency ADNSHL for mutations in *TECTA*. *WFS1* mutations account for approximately 75% of all cases of low-frequency ADNSHL.[45] For individuals with high-frequency hearing loss, because of the number of potential candidate genes, mutation screening is offered only on a research basis. Computer algorithms are being developed, however, to analyze audiograms and to construct audioprofiles as a method of selecting genes for mutation screening for all types of ADNSHL.

Prenatal Testing

Prenatal diagnosis for some forms of hereditary hearing loss is technically possible by analysis of DNA extracted from fetal cells. Fetal material can be obtained by amniocentesis at 15 to 18 weeks' gestation or chorionic villus sampling at 10 to 12 weeks' gestation. Gestational age is expressed as menstrual weeks calculated from the first day of the last normal menstrual period or by ultrasound measurements. The deafness-causing allele of a deaf family member must be identified before prenatal testing can be performed.

Requests for prenatal testing for conditions such as hearing loss are uncommon. Differences in perspective may exist among medical professionals and within families regarding the use of prenatal testing, particularly if the testing is being considered for the purpose of pregnancy termination, rather than early diagnosis. Although most centers would consider decisions about prenatal testing to be the choice of the parents, careful discussion of these issues is appropriate. Preimplantation genetic diagnosis may be available for families in which the deafness-causing mutation has been identified in a deaf family member.

Treatment

When a diagnosis is made, directed treatment is possible. Appropriate consultation and management of the associated conditions should be considered. A diagnosis of JLNS may necessitate therapy with β-blockers to reduce the chance of life-threatening arrhythmias. If US is considered, close ophthalmologic follow-up is mandatory. In contrast, a genetic diagnosis of *GJB2*-related deafness requires no other consultation because there is no associated comorbidity.

Genetic counseling should be offered to patients and their families by a professional trained in clinical genetics. Most otolaryngologists do not have an adequate understanding of recurrence chances to provide accurate data.[158] Green and coworkers[23] have estimated the recurrence chance for a normal-hearing couple with a deaf child to have a second deaf child at 17.5%, much higher than earlier estimates of 9.8%. Factors that explain this increase include an improved ability to identify syndromic forms of deafness and a decrease in congenital acquired deafness.[23] A well-trained genetic counselor can also help to interpret medical data and potential treatment options. Counseling sessions should occur before and after genetic testing has been done.

Management of hearing loss should be directed at providing appropriate amplification as soon as possible. Hearing aids provide significant benefits to individuals with mild to moderate hearing loss. Cochlear implantation is becoming an increasingly important option for individuals with severe to profound deafness.[27] The Joint Committee on Infant Hearing recommends that diagnosis and rehabilitation be instituted by 6 months of age to minimize delays in communicative language development. Coupled with this recommendation, universal screening is becoming a reality throughout the United States. For the detection of congenital hearing loss, the U.S. government has facilitated the creation of EHDI programs for early newborn hearing screening (http://www.infanthearing.org). EHDI programs aim to screen neonates for hearing loss immediately after birth or before hospital discharge. The programs include a follow-up arm to confirm hearing loss in neonates who do not pass the initial screening test so that intervention can be initiated to prevent delayed language acquisition.[159]

EHDI program guidelines include three phases: screening, audiologic evaluation, and intervention. In the first phase, newborns are screened with otoacoustic emissions and ABR to detect permanent bilateral or unilateral sensory or conductive hearing loss averaging 30 to 40 dB SPL (sound pressure level) or more in the frequency region important for speech recognition. In the second phase, all infants who do not pass the initial screen are evaluated with a series of diagnostic audiologic tests, preferably before age 3 months. In the third phase,

early intervention services are implemented before age 6 months for all infants with confirmed hearing loss.[159]

Prevention of Hearing Impairment

Although experimental methodologies to restore auditory function are currently being developed and tested,[160,161] no effective therapy is clinically available. Existing measures must focus on the prevention of hearing loss to decrease the frequency of acquired and genetic hearing loss.[4] Improved implementation of vaccination programs in developing nations, avoidance of exacerbating factors such as noise, and focused genetic counseling and health education in populations with a high prevalence of consanguinity are several methods that if implemented would reduce the incidence of acquired and hereditary hearing loss.

Cultural Considerations

Having discussed the management of a patient with hearing loss, a mention of the Deaf (written with a capital "D") culture is necessary. Individuals who identify with the Deaf culture consider themselves as culturally Deaf and understandably wish to preserve their culture. Generally, members of the Deaf community look on genetics negatively.[162,163] A study by Middleton and colleagues[163] found that 55% of deaf respondents at a conference on the "Deaf Nation" thought genetics would do more harm than good. Of respondents, 46% thought that the use of genetics may devalue deaf people. This response may represent sample bias, however, because a study by Stern and associates[162] found that most deaf individuals have a positive view of the field of genetics. These studies highlight an important point—that attitudes about hearing loss, or more specifically deafness, are culturally dependent. The medical community must understand and appreciate this perspective, and try to offer advances in diagnosis, counseling, and treatment in a nonjudgmental manner.

Acknowledgment

The authors thank Katy Nash Krahn, MS, CGC, in the Department of Pediatrics, University of Iowa Hospitals and Clinics, for her help in preparing the pedigrees of the various forms of hearing impairment. This work was supported in part by NIH grants DC02842 and DC03544 (R.J.H.S.).

CHAPTER ONE HUNDRED AND FORTY-EIGHT

Otologic Manifestations of Systemic Disease

Saumil N. Merchant

Joseph B. Nadol, Jr.

Key Points

- A wide variety of systemic diseases can affect the temporal bone, including granulomatous and infectious diseases, neoplasms, disorders of bone, storage and metabolic diseases, and autoimmune and immunodeficiency disorders.
- Otologic manifestations of a particular systemic disease are determined by location and extent of involvement within the temporal bone, and the nature of the disease. Any part of the temporal bone may be affected, and the clinical features may include conductive or sensorineural hearing loss, vestibular manifestations, otalgia, and facial nerve paralysis.
- Systemic disease may mimic more common otologic disorders, such as acute or chronic otitis media, sudden idiopathic deafness, and Bell's palsy.
- Otologic manifestations may constitute a small part of a wider constellation of symptoms and signs, or may be the sole and initial presenting feature of a systemic disease.
- Diagnosis may be challenging, requiring a high level of suspicion, with use of ancillary tests such as laboratory studies, radiographic evaluation, and biopsy.
- Management of otologic symptoms must be individualized and often requires coordinated care across multiple disciplines.

Systemic diseases that may involve the ear include granulomatous and infectious processes, tumors, bone disorders, storage diseases, collagen vascular and autoimmune diseases, and immunodeficiency disorders (Table 148-1). In some of these diseases, the initial clinical symptoms may occur in the temporal bone and be confused with other diseases that are limited to the ear.

Granulomatous and Infectious Diseases

Chronic otitis media with otorrhea, inflammation, and granulation of the middle ear and mastoid is one of the most common entities treated by otolaryngologists. Several more generalized disease entities, such as the Langerhans cell histiocytosis (LCH), tuberculosis, Wegener's granulomatosis (WG), and mycotic diseases, may closely mimic the symptoms of chronic suppurative otitis media, whereas others, such as Lyme disease and sarcoidosis, may mimic idiopathic cranial neuropathy.

Langerhans Cell Histiocytosis

LCH (formerly called histiocytosis X) refers to a group of disorders that are characterized by a proliferation of cytologically benign histiocytes. The term *histiocytosis X* was proposed by Lichtenstein,[1] who considered eosinophilic granuloma, Hand-Schüller-Christian disease, and Letterer-Siwe disease to be related disorders because of the similarity of their pathologic lesions. The severity of these diseases and prognosis and treatment differ greatly, however. Histopathologically, the primary lesion of LCH is formed by collections of pathologic Langerhans cells with variable numbers of eosinophils, macrophages, and lymphocytes. Diagnostic characteristics of the pathologic Langerhans cells include nuclei that are deeply indented and elongated on light microscopy, cytoplasm that is pale and abundant, Birbeck granules on electron microscopy, expression of CD1 on the cell surface, and positive immunostaining for S100 protein and for the so-called Langerin protein.[2,3] The etiology and pathogenesis of LCH remain unknown, although more recent research has begun to shed some light on these.[2,4,5] Current thinking favors the notion that LCH results from immunologic dysfunction, resulting in unchecked proliferation of pathologic Langerhans cells.[5]

Unifocal eosinophilic granuloma, which occurs in children and young adults, shows a male predominance. It appears as a solitary osteolytic lesion in the femora, pelvis, scapulae, vertebrae, ribs, mandible, maxilla, or skull (including the temporal bone). The lesion may be asymptomatic, or it may cause pain, local swelling, or pathologic fracture. There are no systemic manifestations. The clinical course is typically benign, the prognosis is excellent, and spontaneous regression may occur. Local curettage with or without low-dose irradiation (approximately 60 Gy)[6] is usually curative. Temporary splinting or casting may be necessary for weight-bearing bones. Follow-up examination with a radiographic skeletal survey should be performed to detect lesions at other sites; such lesions are almost always found within 1 year.

Hand-Schüller-Christian disease may be best understood as a multifocal form of LCH. It usually occurs in children younger than 5 years old, and it is characterized by multifocal osteolytic lesions with limited extraskeletal involvement of skin, lymph nodes, and viscera. Multiple lesions are evident at diagnosis or develop within 6 months after a unifocal lesion appears. Systemic manifestations include fever, anorexia, recurrent upper respiratory infections, anterior cervical lymphadenopathy, otitis media, and hepatosplenomegaly. The classic triad

of osteolytic skull lesions, exophthalmos as a result of orbital bone involvement, and diabetes insipidus secondary to pituitary disease may be seen in 25% of patients.[7] Chest radiograph may show diffuse pulmonary infiltration, particularly in central and perihilar areas. Hilar lymphadenopathy is rare. Diagnosis requires biopsy of an accessible lesion. Spontaneous regression may occur, but the disease is typically chronic, and low-dose chemotherapy may be required to control systemic manifestations.

Letterer-Siwe disease is a disseminated form of LCH that occurs in children younger than 3 years old and manifests with the diffuse involvement of multiple organs. Manifestations include fever, seborrheic or eczema-like rash, oral lesions, lymphadenopathy, hepatosplenomegaly, multiple bony lesions, diffuse replacement of marrow with resulting blood dyscrasias, and pulmonary infiltration with respiratory failure. The disease is virulent, with a poor prognosis and a high mortality rate. Treatment consists of varying combinations of corticosteroids and cytotoxic drugs such as methotrexate, mercaptopurine, vincristine, vinblastine, chlorambucil, cyclophosphamide, and etoposide. High-dose chemotherapy and radiation followed by bone marrow transplantation or hematopoietic stem cell transplantation has been reported to be successful in a few advanced refractory cases of LCH.[8]

Otologic Manifestations

The mastoid is a common site of involvement in LCH. When small, the lesion is asymptomatic. As it expands, the lesion may manifest in several ways: by erosion of the posterior bony canal wall; by erosion through the cortex of the mastoid, zygomatic, or squamosal portions; or by secondary infection.[9] The otic capsule and facial nerve are relatively resistant. Although sensorineural hearing loss (SNHL), vertigo, and facial nerve paralysis can occur, they are infrequent. Similarly, extension beyond the temporal bone involving the jugular fossa and skull base is rare.

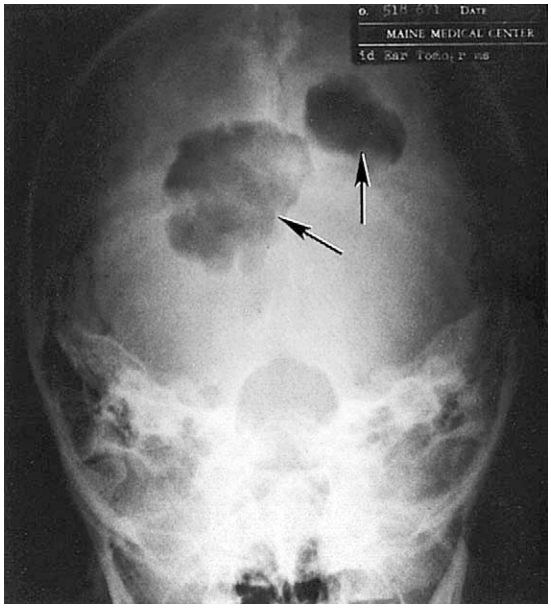

Figure 148-1. Multiple eosinophilic granulomas in a 32-year-old woman. There are two lytic lesions of the skull showing beveled edges *(arrows)* and nonsclerotic margins, which are typical of this disease.

The reported incidence of otologic manifestations in patients with LCH is 15% to 61%,[7] and they may be the initial presentation of the disease. The most common symptom is otorrhea, followed by postauricular swelling, hearing loss, and vertigo.[10,11] The most common sign is granulation tissue or aural polyps in the external auditory canal. The disease may manifest with perforation of the tympanic membrane, otitis media, otitis externa, fistula between the mastoid and the external canal, or nontender postauricular swelling. Occasionally, inner ear symptoms and a positive fistula test are found in the presence of an intact tympanic membrane. The disease often mimics chronic otitis media, and mastoid surgery is frequently performed before the diagnosis is made.[9]

Diagnosis of LCH is suggested by an inflammatory disorder of the middle ear and mastoid that does not respond to routine antibiotic therapy, bilateral destructive ear disease, an elevated erythrocyte sedimentation rate in the absence of acute infection, exuberant granulation tissue after mastoid surgery with a persistently draining cavity, and associated skin and systemic lesions. Radiographs show destructive lesions in the mastoid and temporal bones (Figs. 148-1 and 148-2).[9,10,12] The diagnosis is established by biopsy; because the surface of the granulation tissue often shows infection, necrosis, and fibrosis, tissue should be acquired from deeper parts of the lesion.[13] Microscopic findings include sheets of histiocytes with a variable number of eosinophils, plasma cells, polymorphonuclear leukocytes, and multinucleated cells (Figs. 148-3, 148-4, and 148-5). Areas of hemorrhage and necrosis are common. A definitive diagnosis of LCH is usually made on the basis of immunostaining and electron microscopic studies.[2,4]

Tuberculosis

The incidence of tuberculous otitis media has decreased dramatically. During the early part of the 20th century, 1.3% to 18.6% of all cases of chronic otitis media were reportedly caused by tuberculosis, whereas more recent studies report tuberculous otitis media rates of 0.05% to 0.9%.[14] The last 20 years have witnessed an increase in incidence of tuberculosis, however, which is caused in part by the aggressive nature of tuberculosis in individuals infected with human immunodeficiency virus (HIV), and by an emerging resistance to antituberculosis drugs.[15]

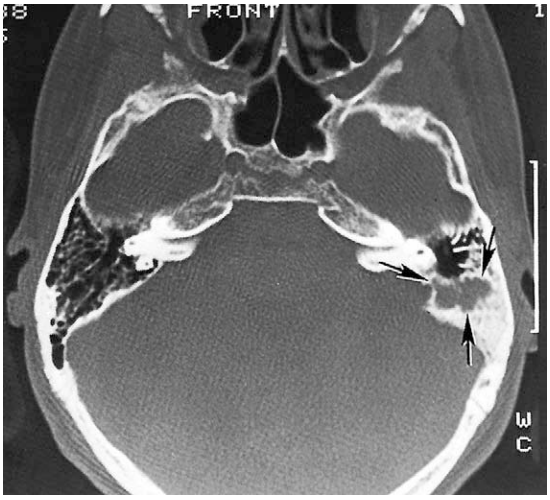

Figure 148-2. Irregular lytic lesion in the mastoid bone *(arrows)* of a 13-year-old boy with unifocal eosinophilic granuloma.

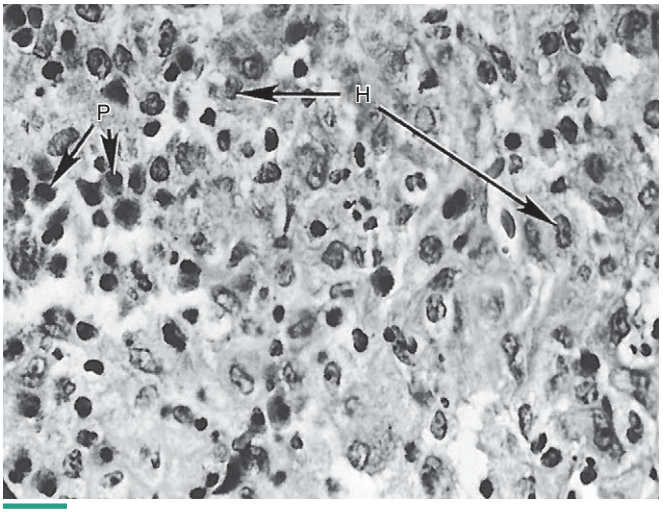

Figure 148-5. Eosinophilic granuloma of the external ear canal with plasma cells (P), eosinophils, and histiocytes (H), which show "folded" nuclei, a morphology that is peculiar to the histiocytoses (×640).

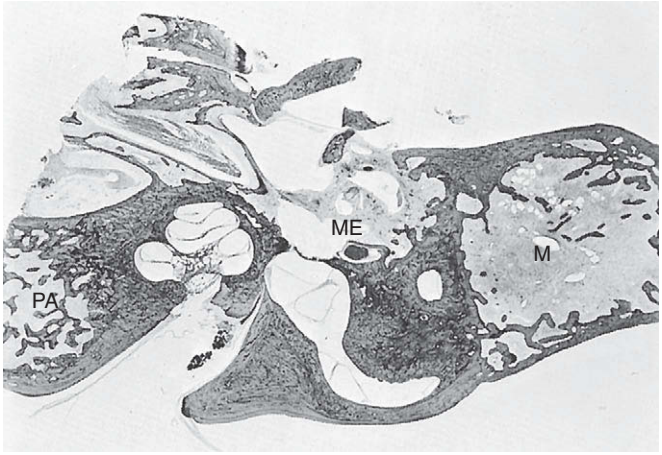

Figure 148-3. Letterer-Siwe disease affecting the temporal bone of a 4-year-old boy. Granulation tissue typical of histiocytosis can be seen in lytic lesions within the mastoid (M), middle ear (ME), and petrous apex (PA) (×4).

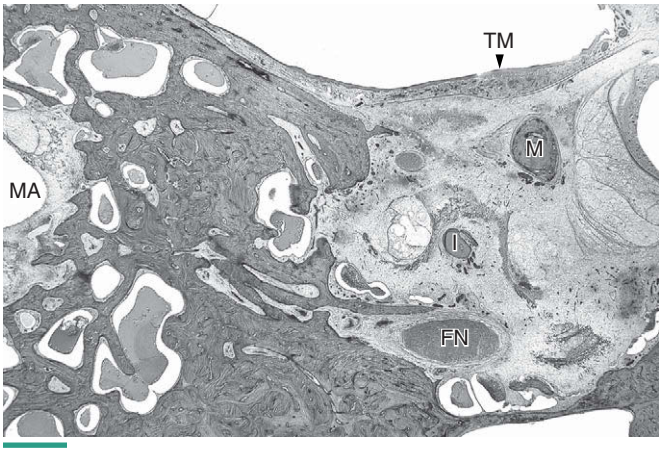

Figure 148-6. Tuberculous granulation tissue filling the middle ear of a 57-year-old man who died of miliary tuberculosis (×12.35). FN, facial nerve; I, incus; M, malleus; MA, mastoid; TM, tympanic membrane.

Figure 148-4. A higher power view of part of the middle ear area seen in Figure 148-3. The infiltrate consists of histiocytes, eosinophils, and multinucleated cells. The incus (I) has been partially resorbed (×45).

Mycobacterium tuberculosis is the infective organism in most cases; occasionally, atypical mycobacteria (e.g., *Mycobacterium avium* and *Mycobacterium fortuitum*) are responsible.[16]

Tuberculosis of the middle ear and mastoid may occur as a result of hematogenous or lymphatic spread, or by extension to the middle ear cleft through the eustachian tube. Direct inoculation through a perforation of the tympanic membrane is also possible. Middle ear involvement in the absence of active pulmonary disease is rare, but may occur.

During the early stages of tuberculous otitis media, the tympanic membrane becomes thickened, and the otoscopic landmarks become obliterated. There is a conductive hearing loss as a result of middle ear effusion, a thickening of the tympanic membrane and middle ear mucosa, and a destruction of the ossicles (Figs. 148-6 and 148-7). There is no characteristic pain or tenderness, but lymphadenopathy in the high jugular chain occurs early. Multiple small perforations of the tympanic membrane may occur, with seropurulent drainage. The perforations quickly coalesce to cause loss of the tympanic membrane. Likewise, a myringotomy site in an intact tympanic membrane may enlarge quickly. The middle ear mucosa appears to be hyperemic with polypoid granulation. Osseous involvement results in the sequestration of bone and the destruction of the inner ear, the facial nerve, or both.

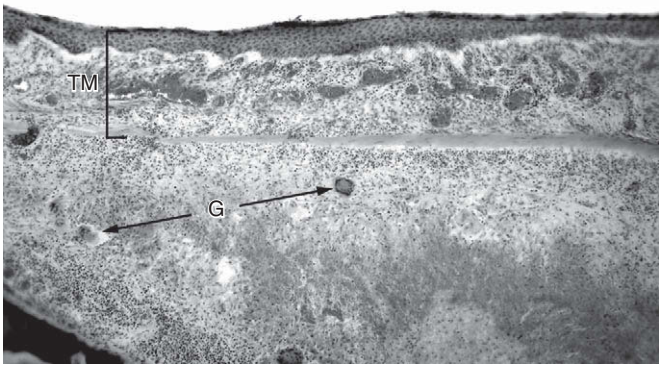

Figure 148-7. A higher power view of the tympanic membrane (TM) seen in Figure 148-6. The TM is intact, but greatly thickened by tuberculous granulation tissue containing the typical epithelioid cells, round cells, and multinucleated giant cells (G) (×100).

CO, cochlea; EAC, external auditory canal; IAC, internal auditory canal; TT, tensor tympani. *(Courtesy of Leslie Michaels, MD, Institute of Laryngology and Otology, London.)*

Destruction of the mastoid tip may result in an asymptomatic, nontender Bezold's abscess (i.e., a "cold" abscess). Rarely, tuberculosis can also manifest as primary tuberculous petrositis,[17] or as SNHL caused by chronic labyrinthitis and tuberculous meningitis.[18]

The diagnosis of tuberculous involvement of the middle ear is usually delayed. The characteristic signs and symptoms include multiple perforations of the tympanic membrane that quickly coalesce to form total tympanic membrane loss, nontender cervical lymphadenopathy, intractable otitis media with polypoid granulation, and bony sequestration; these should alert the physician to this possible diagnosis. Otic capsule involvement with resultant loss of auditory and vestibular function may be the first symptom, which indicates a process that differs from the more typical chronic otitis media. Definitive diagnosis is made by histopathologic examination of tissue from the middle ear or mastoid showing a granulomatous process with multinucleated giant cells (Langhans cells) (see Figs. 148-6 and 148-7) and histologic demonstration of acid-fast organisms of tuberculosis. The accurate identification of the mycobacterial species and drug-resistant isolates by culture is still the gold standard. Culture takes several weeks, however, and is time-consuming. The process is facilitated by the use of several different types of nucleic acid amplification tests that have been approved by the U.S. Food and Drug Administration for rapid identification of *M. tuberculosis*.[15,19]

Multiple perforations of the tympanic membrane, exuberant polypoid granulation within the middle ear, and early loss of inner ear function also are seen in WG. These two diseases are distinguished on the basis of skin tests for tuberculosis and the histologic demonstration of acid-fast organisms of tuberculosis in granulation tissue, cultures of the middle ear, the presence of antineutrophil cytoplasmic antibodies (ANCAs) in WG, and the systemic manifestations of each process.

The mainstay of management of tuberculosis of the middle ear and mastoid is the systemic use of standard antituberculous chemotherapy.[14] Mastoid surgery may be required to remove sequestrated bone. Reconstructive surgery of the ossicles and tympanic membrane is feasible after the infection has been controlled.

Wegener's Granulomatosis

WG is a granulomatous inflammatory process with necrotizing vasculitis. It primarily affects the upper and lower respiratory tracts and kidneys, but WG can involve essentially any organ in the body. The disease occurs equally in men and women, and the mean age of onset is 40 years. Common presenting symptoms include headache, sinusitis, rhinorrhea, otitis media, fever, and arthralgia.[20,21] Upper airway and sinus involvement occurs in 75% to 90% of cases. Pulmonary manifestations include cough, pleuritic chest pain, hemoptysis, and nodular or cavitary infiltrates on chest radiography. Pulmonary manifestations occur in 65% to 85% of cases. Other manifestations include glomerulonephritis (60% to 75% of cases); eye involvement in the form of conjunctivitis, iritis, scleritis, or proptosis (15% to 50% of cases); and dermatologic findings of necrotic ulcerations, vesicles, or petechiae.

Laboratory findings in WG may include normochromic, normocytic anemia; thrombocytosis; positive rheumatoid factor; and hyperglobulinemia, particularly of IgA. The erythrocyte sedimentation rate is almost always elevated. The discovery in 1985 of autoantibodies directed against the cytoplasmic constituents of neutrophils (ANCA, c-ANCA) in patients with WG was a major advance in the diagnosis and understanding of WG.[22] A positive ANCA test, especially proteinase 3–specific c-ANCA, is very helpful in establishing or supporting a diagnosis of WG. The specificity of positive c-ANCA testing in WG is greater than 95%; the sensitivity is variable and depends on the phase and type of WG. c-ANCA is positive in more than 90% of patients with systemic and active WG, whereas in limited WG (e.g., ear or head and neck only or inactive disease), the sensitivity of c-ANCA is only 65% to 70%. In addition, the antibody titer parallels the activity of the disease, although there have been conflicting data about the value in using the titer as a guide for immunosuppressive therapy.

The diagnosis of WG is made histologically by the presence of necrosis, granulomatous inflammation with multinucleated giant cells, vasculitis, and microabscess formation (Figs. 148-8 and 148-9). Small biopsy specimens (e.g., from the ear or upper airways) may lack all of the various diagnostic features, however. In such cases, a diagnosis of WG can be made on the basis of the clinical presentation, ANCA testing, and repeat biopsy specimens taken from the same or related sites.

The etiology and pathogenesis of WG are unknown. Infectious, genetic, and environmental risk factors and combinations thereof have been proposed. The evidence to date suggests that WG is a complex, immune-mediated disorder in which tissue injury results from the interplay of an initiating inflammatory event and a highly specific immune response.[23] Part of this response consists of the production of ANCA, directed against antigens present within the primary granules of neutrophils and monocytes; these antibodies produce tissue damage by interacting with primed neutrophils and endothelial cells.

The prognosis of WG has dramatically improved from a mortality rate of 82% before the era of immunosuppressive therapy to the current remission rate of more than 75% with appropriate medical therapy.[24] Induction of remission is usually achieved with high doses of corticosteroids, cyclophosphamide, or methotrexate given for 3 to 6 months. Maintenance of remission is achieved with lower doses of corticosteroids and less toxic alternatives to cyclophosphamide, such as azathioprine, methotrexate, trimethoprim-sulfamethoxazole, or other drug

Figure 148-9. combinations. Other therapies that have been used include leflunomide, mycophenolate mofetil, and the tumor necrosis factor inhibitors etanercept and infliximab.

Otologic Manifestations

The middle ear and mastoid are the most common sites within the temporal bone that are involved in patients with WG.[20,25] WG may cause obstruction of the eustachian tube with resultant serous otitis media and conductive hearing loss (see Fig. 148-8). Some patients also have purulent otitis media, and others may have frank granulomatous involvement of the middle ear and mastoid. The process can extend to involve the facial nerve and the inner ear, which is usually manifested as rapidly progressive SNHL and loss of vestibular function. Otologic disease may be the sole and initial presenting feature in some patients with WG.

Sarcoidosis

Sarcoidosis is a chronic multisystem disorder of unknown etiology that is characterized by the presence of noncaseating granulomas. It most frequently affects the lungs, although almost all body parts can be affected. The disease shows a female predominance, and is 10 times more common in blacks than in whites. The onset of disease is usually during the third to fourth decade of life. Common presenting manifestations include bilateral hilar adenopathy on chest radiography, cough, and granulomatous skin rash. Other manifestations include iridocyclitis, keratoconjunctivitis, peripheral lymphadenopathy, hepatosplenomegaly, cardiac failure, myalgia, and arthralgia. Neurologic involvement includes central and peripheral manifestations. The facial and optic nerves are the most commonly affected cranial nerves. Either peripheral mononeuritis or polyneuritis may be seen. Laboratory findings may include hilar adenopathy on chest radiography (Fig. 148-10), hypercalcemia, and elevated serum angiotensin-converting enzyme. The histopathologic feature of the sarcoid lesion is noncaseating epithelioid granulomas (Fig. 148-11).

The etiology and pathogenesis of sarcoidosis are unknown. The initial pulmonary lesion is an alveolitis characterized by the accumulation of $CD4^+$ T cells, followed by development of noncaseating granulomas. The antigenic stimulus that initiates the disease process remains elusive. Several possible associations have been investigated, including mycobacteria, certain HLA complexes, abnormalities of T cells and the T-cell antigen receptor, and involvement of several different cytokines.[26]

Spontaneous resolution occurs in many patients. Corticosteroids are beneficial for patients with progressive symptoms or with ocular, cardiac, or central nervous system involvement. For patients who cannot tolerate or do not respond to corticosteroids, alternative drugs include methotrexate, cyclophosphamide, azathioprine, chlorambucil, cyclosporine, chloroquine, pentoxifylline, and antagonists of human tumor necrosis factor-α such as etanercept (Enbrel) and infliximab (Remicade).[27]

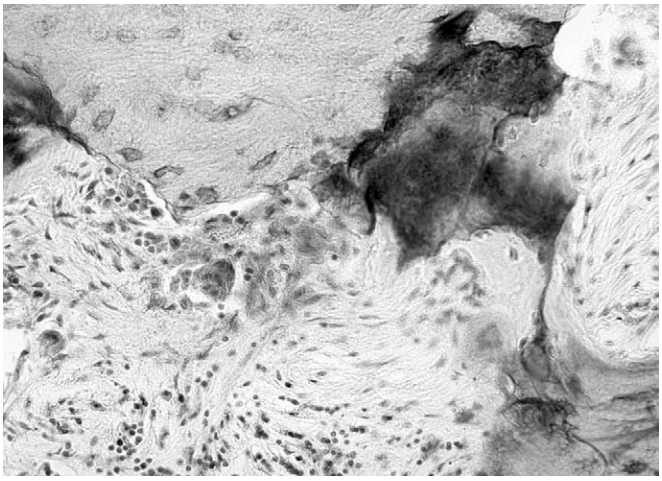

Figure 148-13. Area of active bone resorption in a 43-year-old patient with congenital syphilis. The inflammatory infiltrate includes lymphocytes, plasma cells, and multinucleated giant cells (×396).

Otologic Manifestations

Otologic manifestations of sarcoidosis include SNHL, vestibular dysfunction, and facial nerve paralysis, and occasionally granulomatous disease of the external or middle ear and mastoid.[28-31] The facial nerve is the most commonly affected cranial nerve and is usually involved as part of the triad of uveoparotid fever (Heerfordt's syndrome) that is characterized by parotitis, uveitis, facial nerve paralysis, and mild pyrexia. The facial paralysis may be sudden in onset, it is often bilateral, and it may resolve spontaneously. Histopathology of the temporal bone in sarcoidosis has been reported in only one case; the main findings were perivascular lymphocytic infiltration and granulomatous inflammation involving the cochlear, vestibular, and facial nerves within the internal auditory canal.[32]

Syphilis

Congenital and acquired syphilis may affect the middle ear in the late latent and tertiary forms. In the late latent form, the middle ear and mastoid may be affected by a rarefying osteitis with leukocytic infiltration of the ossicles and mastoid bone (Figs. 148-12 and 148-13). A similar but larger lesion of tertiary syphilis, the gumma, shows obliterative arteritis and central necrosis. A gumma of the ear canal or middle ear may result in perforation of the tympanic membrane and a granulomatous appearance of the middle ear mucosa. Definitive diagnosis of syphilis of the middle ear requires a positive serologic test and a histologic demonstration of *Treponema pallidum*. Syphilitic involvement of the tympanic membrane and middle ear may mimic tuberculosis, and superinfection may result in chronic otitis media.

Inner ear involvement may occur in the absence of macroscopic changes in the tympanic membrane or middle ear. Hennebert's sign, which is the induction of ocular deviation with positive or negative pressure in the external auditory canal, was believed to indicate a true fistula between the middle and inner ear because of rarefying osteitis of the otic capsule. The more probable cause is fibrous adhesions, however, between the stapes footplate and the membranous labyrinth as a result of endolymphatic hydrops.[33] Combined antibiotic and corticosteroid therapy is beneficial for the management of SNHL.[34]

Lyme Disease

Lyme disease is a multisystem inflammatory disorder that primarily affects the skin, nervous system, heart, and joints. It is caused by a spirochete, *Borrelia burgdorferi,* that is transmitted to humans by certain *Ixodes* ticks that are part of the *Ixodes ricinus* complex. The known primary reservoirs of the disease are white-footed mice and white-tailed deer. The disease was initially recognized in 1975 because of a clustering of patients with arthritis in Lyme, Connecticut, but it is now known that Lyme disease has been present for several decades in Europe, where it is called Bannwarth's syndrome.

Infection is usually acquired in the summer, and individuals of all ages and both sexes can be affected. Three clinical stages that are similar to the stages seen with cases of syphilis are recognized.[35] The first stage (early, localized infection) begins 3 to 33 days after a tick bite with a characteristic skin lesion (erythema migrans). This lesion occurs in 60% to 80% of patients and may be accompanied by minor constitutional symptoms. The second stage (early, disseminated infection) occurs within days or weeks after inoculation and begins with hematogenous dissemination of the organism from the site of inoculation. The symptoms, which mimic a systemic viral illness, include fever, migratory arthralgia, myalgia, headache, meningismus, generalized lymphadenopathy, malaise, fatigue, and secondary annular skin lesions.

After hematogenous spread, *B. burgdorferi* seems to be able to sequester itself in certain niches and cause localized inflammation in the nervous system, heart, or joints. Neurologic involvement is manifested by meningitis, encephalitis, cerebrospinal fluid lymphocytosis, peripheral neuropathy, myelitis, or cranial neuropathy (including facial nerve paralysis). Cardiac manifestations include atrioventricular block or other arrhythmias, myocarditis, and pericarditis. Joint disease manifests as brief attacks of asymmetrical oligoarticular arthritis, primarily in large joints (especially the knee). The third stage (late or persistent infection) occurs more than 1 year after onset, and can result in chronic, prolonged arthritis; chronic encephalomyelitis; chronic axonal peripheral polyradiculopathy; keratitis (similar to syphilis); acrodermatitis chronica atrophicans; and localized scleroderma-like lesions. A patient may experience one or all of the stages and the infection may not become symptomatic until the second or third stage. Affected tissues show infiltration by lymphocytes and plasma cells. Mild vasculitis and hypercellular vascular occlusion can occur. There is generally no tissue necrosis. In contrast to the findings in patients with syphilis, granulo-

mas, gummas, multinucleated giant cells, and fibrinoid necrosis have not been observed as yet.[36]

In recent years, the complete genome of the spirochete has been sequenced, and animal models have been developed for studying the pathogenesis of Lyme disease using mice and primates. The animal models have shown that inflammatory innate immune responses are critical in the pathogenesis of the disease, and that genetic factors may be important in determining the severity of some of the manifestations.

The diagnosis of Lyme disease is usually based on the recognition of the characteristic clinical features, a history of exposure in an area where the disease is endemic, and detection of a specific antibody to *B. burgdorferi* by enzyme-linked immunosorbent assay and Western blotting.[35] The antibody test must be interpreted properly using the criteria of the Centers for Disease Control and Prevention because false-negative and false-positive results can occur. In addition, *B. burgdorferi* may cause asymptomatic infection, in which case the symptoms caused by another disease may be wrongly attributed to Lyme borreliosis.

The spirochete is highly sensitive to doxycycline, but only moderately so to penicillin. Other effective antibiotics include amoxicillin, erythromycin, cefuroxime, ceftriaxone, and imipenem. Steroids have been used for severe carditis and arthritis. Among patients managed early in the course of the disease, the specific antibody response usually disappears within months, and patients may become reinfected in the future. Among patients with late manifestations such as arthritis, titers decline after successful management, but patients remain seropositive. Although two vaccines were developed and found to be effective in clinical trials, they are not currently being marketed.[37]

Otologic Manifestations

Facial nerve paralysis is the most common otologic manifestation, with a reported incidence of 3% to 11%[38,39]; it may be bilateral in 25% of cases. This type of paralysis is seen in the second stage of the disease, and it affects patients of all ages and both sexes. The onset is acute, the duration is weeks to a few months, and the return of function is spontaneous and is usually complete. There may be a history of preceding otalgia, ipsilateral facial pain, or paresthesias.[40] Although other neurologic features of the second stage may be seen, facial nerve paralysis can occur as the sole neurologic abnormality (including normal cerebrospinal fluid).

Antibiotics or steroids do not seem to influence the duration or outcome of facial paralysis,[38] but they are recommended to treat concurrent symptoms and to prevent the more serious late complications. There is no role for surgery. The precise cause and histopathology of facial nerve palsy have not been elucidated. Histology from other involved peripheral nerves shows perineural and perivascular infiltration by lymphocytes and plasma cells. In chronic and severe neuropathies, demyelination and loss of nerve fibers similar to wallerian degeneration occur.[36] It is unclear whether neural lesions result from an inflammatory response to the spirochete or an immune-mediated epiphenomenon.

A well-documented otologic manifestation is an unusual skin lesion called a lymphocytoma, in which intensely red and violet nodules occur on the earlobe during the second stage of disease.[35] The lesion consists of benign but hyperplastic lymphocytic follicles in the dermis.[36]

Auditory and vestibular manifestations, such as SNHL, sudden hearing loss, positional vertigo, and Meniere's-like symptoms have been described.[41-44] More clinical data and temporal bone studies are needed to substantiate these preliminary observations.

Mycotic Diseases

Fungi are ubiquitous in the environment and are of low intrinsic virulence. Systemic invasive clinical disease reflects some defect in host defenses, such as diabetic ketoacidosis, chemotherapy for malignancy, corticosteroid therapy, or acquired immunodeficiency syndrome (AIDS). Aspergillosis, mucormycosis, candidiasis, cryptococcosis, coccidioidomycosis, and histoplasmosis are systemic mycoses that can cause disseminated disease, including involvement of the temporal bone. Diagnosis is made by biopsy and culture. Treatment consists of control of the underlying predisposing condition, surgical débridement of necrotic tissues, and systemic chemotherapy, usually with amphotericin B.

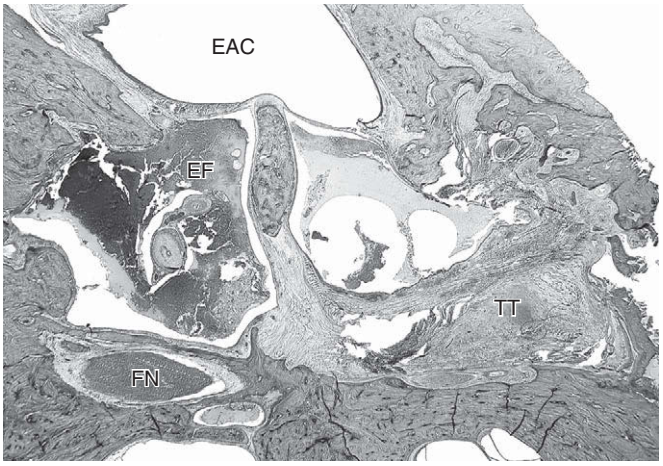

Figure 148-14. Mucormycosis in a 37-year-old man with diabetes. Inflammatory cells have invaded and destroyed the tensor tympani muscle (TT), and there is a hemorrhagic effusion (EF) in the mesotympanum (×12.35). EAC, external auditory canal; FN, facial nerve.

Otologic Manifestations

The middle ear and mastoid can be involved as a result of ascending infection along the eustachian tube and tensor tympani (often seen in mucormycosis) (Fig. 148-14) or through superinfection of existing chronic otitis media.[45] Destruction of the middle ear cleft ensues, often with extension to the surrounding structures, including thrombosis or rupture of the internal carotid artery.[46] Other routes of infection include hematogenous embolic dissemination, which can result in multiple granulomas throughout the temporal bone, and through cryptococcal involvement of the central nervous system, which can cause invasion and degeneration of the nerve trunks in the internal auditory canal.[47]

Neoplastic Diseases

Although neoplasms of the temporal bone are discussed elsewhere (see Chapters 176 and 177), three neoplasms—multiple myeloma, leukemia, and metastatic tumors—warrant mention here because temporal bone manifestations can occur with these diseases.

Multiple Myeloma

Multiple myeloma is a malignancy of plasma cells derived from B lymphocytes, and its major feature is the demonstration of an abnormal monoclonal protein (M component) in blood, urine, or both. There is a slight male predominance, and the median age of onset is 60 years. Clinical manifestations are the result of multiple plasma cell tumors, and consist of severe bone pain, pathologic fractures, failure of the bone marrow, renal failure, hypercalcemia, and recurrent infections.

Laboratory findings include the demonstration of the M component on serum or urine electrophoresis; normochromic, normocytic anemia; hypercalcemia; and elevated blood urea nitrogen levels. Typical radiographic findings include punched-out osteolytic lesions, which are particularly well seen on lateral skull radiography. Bone marrow aspirates show infiltration by plasma cells. For decades, the mainstay of therapy has been the use of alkylating agents, such as melphalan and corticosteroids; with this regimen, the median survival is approximately 3 years. Important advances have been made more recently that have substantially altered therapy for patients with myeloma. These advances include the use of hematopoietic cell transplantation; improved supportive care measures such as the use of bisphosphonates and erythropoietin; and novel agents such as thalidomide, lenalidomide, and bortezomib.[48,49]

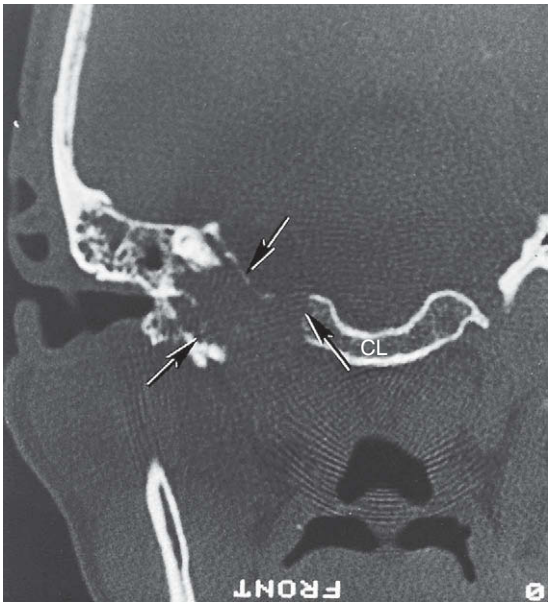

Figure 148-15. Coronal CT scan showing a large lytic destructive lesion *(arrows)* of the clivus (CL), petrous temporal bone, middle ear, and jugular foramen area caused by multiple myeloma in a 72-year-old man. The presenting symptoms were facial nerve paralysis and otorrhea.

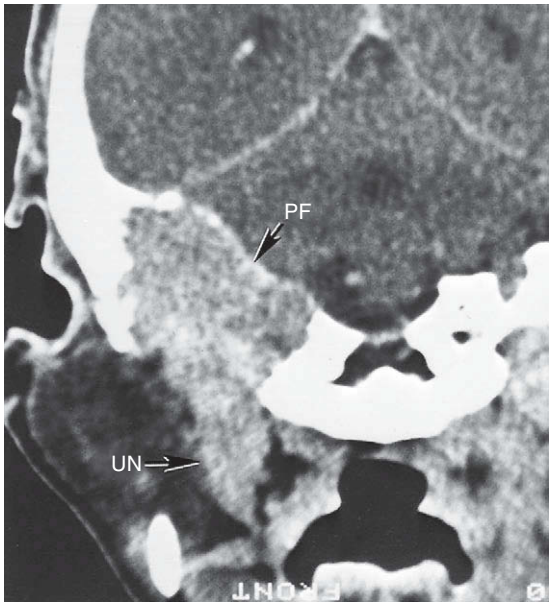

Figure 148-16. Coronal CT scan with contrast enhancement and a soft tissue technique in the same patient from Figure 148-15 shows a slightly enhancing mass that has destroyed the mastoid bone and extends to the posterior fossa (PF) and upper neck (UN).

Occasionally, only one plasma cell tumor (without marrow plasmacytosis) can be found. These lesions can occur in bone (solitary bone plasmacytoma) or soft tissue (extramedullary plasmacytoma), including the temporal bone. Both lesions can affect younger individuals, are associated with an M component in less than 30% of the cases, and have an indolent course with survival rates of 10 years or more. Local radiotherapy (40 Gy) is usually sufficient management. Periodic evaluation of serum and urine globulins and a skeletal radiographic survey should be performed to detect conversion to multiple myeloma.

Otologic Manifestations

The temporal bone is frequently involved in cases of multiple myeloma. Radiography may show rounded lytic lesions of the calvaria and temporal bone (Figs. 148-15 and 148-16). At a microscopic level, the marrow spaces of the petrous bone are commonly replaced by myeloma cells, and discrete lytic bone lesions may be seen in the otic capsule (Fig. 148-17).[50] Symptoms referable to temporal bone involvement are usually overshadowed by manifestations of diffuse disease. Occasionally, these may be the presenting feature of myeloma,[51] or they may be the only evidence of disease (plasmacytoma of the temporal bone).[52] Symptoms are nonspecific and include hearing loss, tinnitus, vertigo, otalgia, and facial paralysis.[53]

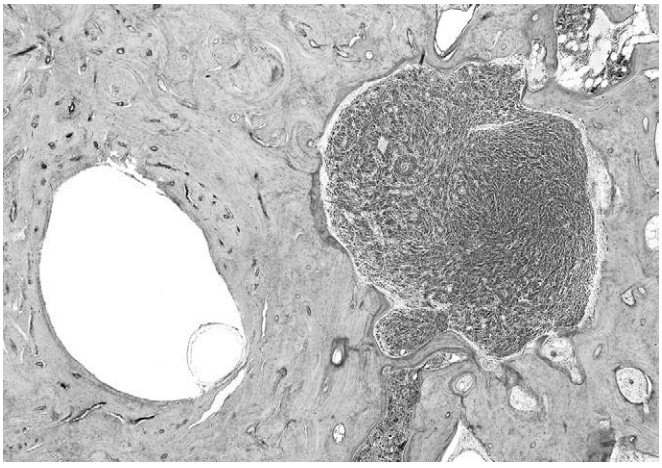

Figure 148-17. One of several osteolytic lesions of the temporal bone of a 69-year-old woman with multiple myeloma. The lesion shows sharp bony margins and consists of immature plasma cells (×39.6).

Leukemia

Leukemic infiltrates may occur in the temporal bone. They are common in the submucosa of the pneumatized areas of the middle ear and mastoid, including the tympanic membrane (Fig. 148-18), and in the bone marrow of the petrous apex (Fig. 148-19).[54,55] Secondary bacterial infection of the middle ear and mastoid often results from an immunocompromised state that is a result of either the disease itself or chemotherapy. Hemorrhage commonly occurs in association with infiltrates and can occur in the middle ear, mastoid, or inner ear. Clinical manifestations include middle ear effusion, acute and chronic suppuration in the middle ear and mastoid, thickening of the tympanic membrane, conductive hearing loss, SNHL (including sudden SNHL), vertigo, facial paralysis, and skin lesions in the auricle or external auditory canal.[56,57]

Granulocytic sarcoma or chloroma is a localized extramedullary tumor that is composed of immature myeloid cells. It is related to acute or chronic myelogenous leukemia, and its appearance may precede, coincide with, or follow the diagnosis of leukemia. Such a lesion can occur in the temporal bone,[58-60] and otologic manifestations can constitute the initial presentation. Management is by local irradiation and systemic chemotherapy.

Metastatic Neoplasms

Secondary malignant tumors usually involve the temporal bone through hematogenous dissemination. The most common sites of origin, in order of decreasing frequency, are the breast, the lung, the prostate, and the skin.[61] The lesions are usually destructive and osteolytic (Fig. 148-20); however, some lesions, such as from the prostate or breast, may be osteoblastic. The petrous apex and internal auditory canal seem to be sites of predilection for metastases, although any part of the temporal bone may be involved (Fig. 148-21). The otic capsule seems to be resistant to neoplastic invasion.[62]

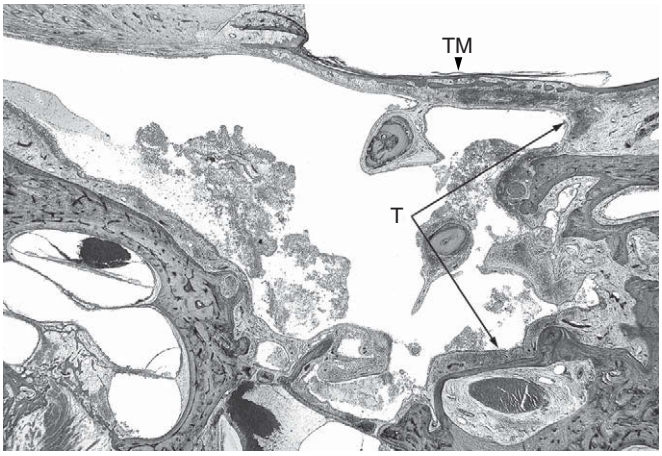

Figure 148-18. Acute lymphocytic leukemia in a 9-year-old boy. Ten days before his death, the patient complained of ear pain. Otoscopic examination revealed a hyperemic tympanic membrane (TM). The TM and mucosa of the middle ear are infiltrated by tumor cells (T), and the middle ear space contains a purulent exudate (×12.35).

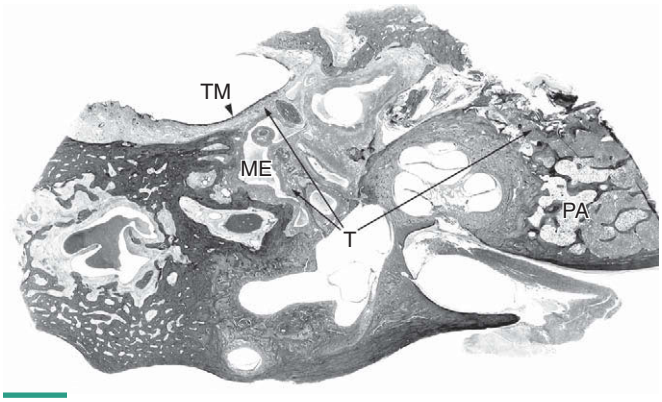

Figure 148-19. Acute myelogenous leukemia in a 38-year-old man. Leukemic infiltrates (T) are seen in the tympanic membrane (TM), middle ear (ME), and marrow spaces of the petrous apex (PA) (×6.7).

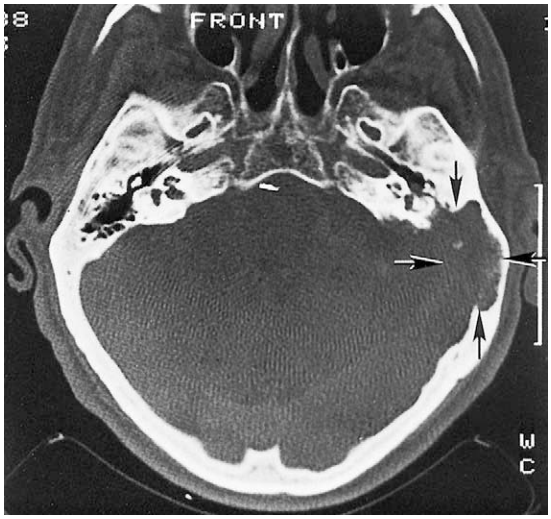

Figure 148-20. Axial CT scan of an 82-year-old woman with metastatic breast adenocarcinoma showing a large lytic lesion *(arrows)* destroying the mastoid, squamosa, otic capsule, and labyrinth.

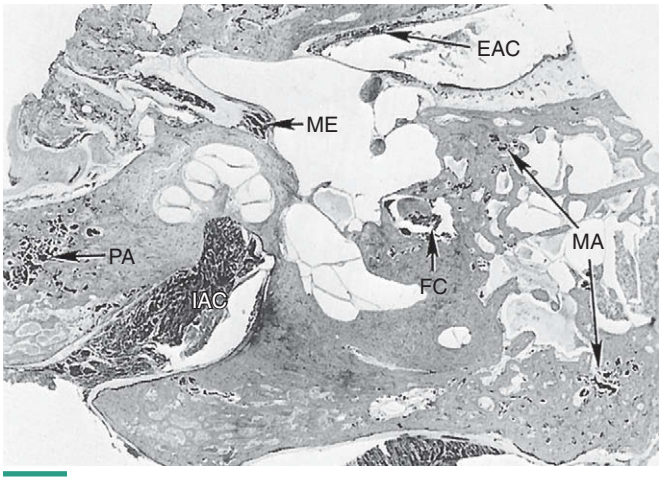

Figure 148-21. Metastatic breast adenocarcinoma in a 75-year-old woman involving the nerve trunks in the internal auditory canal (IAC), petrous apex (PA), subcutaneous tissues of the external auditory canal (EAC), facial canal (FC), middle ear (ME), and mastoid (MA) (×4.5).

Although otologic manifestations infrequently are the first evidence of malignant disease, more often they are preceded by other systemic symptoms. Involvement of the external canal, the middle ear cleft, or the eustachian tube may cause conductive hearing loss and pain; involvement of the otic capsule may produce SNHL, vertigo, and facial nerve paralysis. In meningeal carcinomatosis, rapidly progressive unilateral or bilateral SNHL is a common presenting symptom.[63] Unilateral SNHL may mimic a cerebellopontine angle tumor, and bilateral SNHL may mimic immune-mediated inner ear disease. Diagnosis is made by cytology of the cerebrospinal fluid.

Diseases of the Bone

Several generalized bone diseases affect the middle ear and temporal bone, and occasionally the initial symptoms of the disease occur in the temporal bone. Paget's disease, osteogenesis imperfecta (OI), and osteopetrosis can sometimes mimic the clinical features of otosclerosis.

Paget's Disease

Paget's disease of bone (osteitis deformans) is a chronic and sometimes progressive disease of unknown etiology. It is characterized by osteolytic and osteoblastic changes that mainly affect the axial skeleton. Genetic factors play a role in the pathogenesis of Paget's disease, which may be inherited in an autosomal dominant manner with high penetrance. Four susceptibility loci have been identified, one on chromosome 18, one on chromosome 6, and two on chromosome 5.[64] Mutations in the *SQSTM1* gene encoding the sequestosome 1 protein have been found in some individuals. Viral infection also seems to play a role in the etiology of Paget's disease, based on electron microscopy and immunohistochemical studies.[65,66] It is possible that the disease develops from a slow virus infection in susceptible individuals who have an underlying genetic predisposition.

Paget's disease affects 3% of the population that is 40 years old and older and 11% of the population that is 80 years old and older.[67] Men are affected more commonly than women. The onset of clinical manifestations is usually in the sixth decade of life, and includes enlarging skull; progressive kyphosis; and deformities of the pelvis, femur, and tibia. Radiographic findings (Figs. 148-22 and 148-23) include a thickened skull table; patchy, ill-defined densities of the skull; and poor definition of the cortical margins of the inner ear and internal auditory canal, particularly in the lytic phase of the disease. The bisphosphonates, which inhibit the resorption of bone, constitute the mainstay of medical therapy for symptomatic Paget's disease.[68] Other antipagetic drugs include calcitonin, mithramycin, ipriflavone, and gallium nitrate.

Figure 148-22. Lateral skull radiograph in a patient with Paget's disease. Findings include thickening of the skull table, multiple patchy densities, and platybasia.

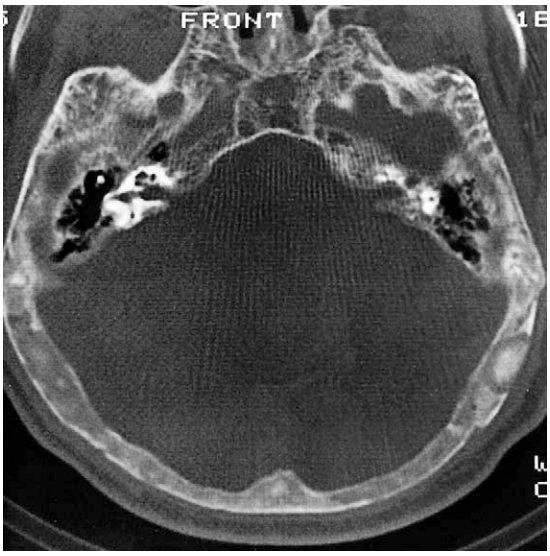

Figure 148-23. Axial CT scan of a 75-year-old man with Paget's disease. There is diffuse expansion of the skull table and involvement of both temporal bones, with patchy demineralization.

Otologic Manifestations

Clinical manifestations include hearing loss, tinnitus, and mild vestibular dysfunction. The facial nerve is spared. Hearing loss occurs in 5% to 44% of patients,[67] and may be sensorineural, mixed, or, rarely, conductive only. Most often, there is a mixed loss, with a descending pattern for bone conduction and relatively flat air conduction thresholds. Hearing losses are progressive and greater than hearing losses of age-matched healthy subjects. Distinguishing features of Paget's disease (compared with otosclerosis, which is the most common differential diagnosis) include a later age of onset (sixth decade), greater SNHL (with a descending pattern), enlarged calvaria, enlargement and tortuosity of the superficial temporal artery and its anterior branches,[67] elevated serum alkaline phosphatase level, and radiographic evidence of pagetic changes in the temporal bones.

None of the many published clinical and histologic reports has clearly identified a consistent pathologic basis for these hearing losses[69]; specifically, the apparent conductive hearing loss is not caused by ossicular fixation, and SNHL is not caused by the compression of cochlear nerve fibers. Attempts at the surgical correction of conductive loss are generally not considered worthwhile. Monsell and colleagues[70,71] reported a statistically significant correlation between the bone mineral density of the cochlear capsule (measured in vivo by quantitative computed tomography [CT]) and the high-frequency pure-tone air-conduction thresholds and the air-bone gap in patients with Paget's disease of the skull. It is unclear whether this finding is only a marker of disease effect, or a phenomenon that is closely related to the mechanism of hearing loss.

Figure 148-24. Pagetic involvement of the temporal bone in a 70-year-old man. The pagetic bone encroaches on the posterior margin *(arrow)* of the internal auditory canal (IAC). The mastoid is largely replaced by pagetic bone (×6.7).

The histopathologic appearance of pagetic bone is variable, and depends on the relative osteoclastic and osteoblastic activity. Typical findings include osteoclastic resorption of marrow-containing bone, with an increase in vascularity and formation of fibrous tissue. New bone formation occurs in an irregular manner and produces its typical mosaic pattern as a result of irregular and curved cement lines (Fig. 148-24). Pagetic bone changes occur in three phases: an initial osteolytic phase, a mixed or combined phase, and an osteoblastic or "burnt-out" phase. In the temporal bone, a fourth phase can be identified, which is the remodeling of inactive pagetic bone into normal-appearing lamellar bone.[69] The disease usually begins in periosteal bone and extends to involve enchondral and endosteal bone.

Osteogenesis Imperfecta

OI (also known as van der Hoeve–de Kleyn syndrome) is a genetically determined disorder of the connective tissue that is characterized clinically by fragile bones that break with minor trauma. Approximately 80% to 90% of patients with OI have mutations of one of the two type I collagen genes (*COL1A1* and *COL1A2*). Many hundreds of unique mutations of *COL1A1* and *COL1A2* have been identified in individuals with OI. The older terms OI congenita and tarda have been replaced by a classification system (OI types I through IV) that is based on clinical features, radiologic criteria, and mode of inheritance.

OI type I has an autosomal dominant mode of inheritance. It is the mildest form and is associated with blue sclerae, nondeforming fractures, and normal stature. Hearing loss is common, occurring in 30% to 50% of cases. OI type II is the most severe form, with multiple fractures occurring in utero and often resulting in stillbirth. This type either is acquired as a sporadic new mutation or is inherited in an autosomal recessive manner. OI type III is characterized by multiple fractures, progressive bone deformity during childhood and adolescence, and sclerae that are bluish at birth but white later in life. Hearing loss occurs in about 50% of individuals. The long bones may be slender and bowed, with abrupt widening near the epiphyses. Kyphoscoliosis, pectus excavatum, weak joints, dental abnormalities, and wormian bone in the skull table are common (Figs. 148-25 and 148-26). The mode of inheritance varies; it may be autosomal dominant, autosomal recessive, or due to a new mutation. OI type IV is a dominantly inher-

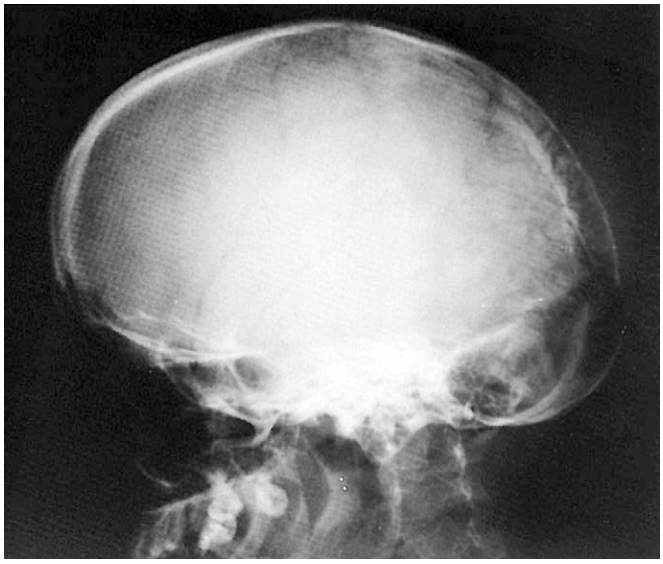

Figure 148-25. Lateral radiograph of the skull in a patient with osteogenesis imperfecta. Wormian bone is seen, particularly in the posterior table.

Figure 148-26. Radiograph of the arm of a patient with osteogenesis imperfecta. There is a pathologic fracture, demineralization of the humerus, and gross abnormalities of the elbow joint.

Figure 148-27. Osteogenesis imperfecta (OI) in a 15-year-old girl. The osteogenesis has replaced the enchondral and periosteal layers of the otic capsule. The neck of the malleus (M) is also involved (×8.5).

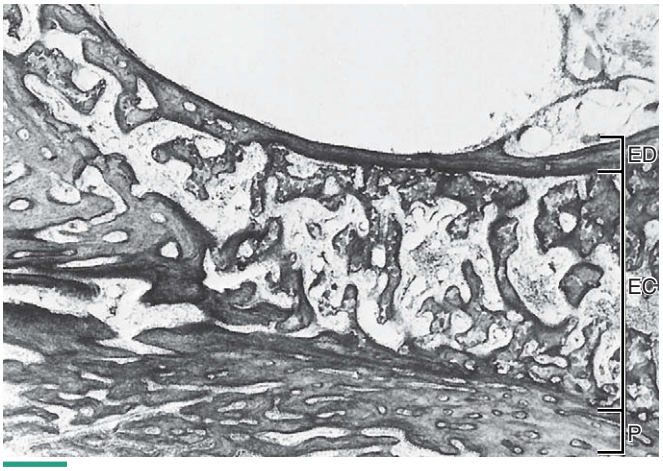

Figure 148-28. Osteogenesis imperfecta involving the otic capsule of a newborn boy. The enchondral (EC) and periosteal (P) layers have been replaced by finely trabeculated bone with an increase in fibrous tissue and vascular spaces. The endosteal layer (ED) is normal (×60).

ited form; it is similar to OI type I except that the sclerae are white (normal). Hearing loss is less common than it is with type I, occurring in 10% to 30% of cases.[72,73]

Management consists of treatment of fractures, orthopedic surgery to correct deformities, use of orthotic devices, and physical and occupational therapy. Bisphosphonate therapy is being increasingly used because these drugs are potent inhibitors of bone resorption and bone turnover.[74] Other therapies under investigation include use of growth hormone and allogeneic bone marrow transplantation.

Otologic Manifestations

Conductive hearing loss and SNHL occur in patients with OI. Severe SNHL has been estimated to occur in approximately 40% of patients, and has a high correlation with gray or white sclerae. Conductive hearing loss usually accompanies blue sclerae, which first becomes apparent by 20 to 25 years of age, and then becomes severe enough to cause the patient to seek medical attention 15 to 20 years later.[75] There is no relationship between hearing loss and frequency or severity of fractures.[73] Some patients with mild OI present with conductive hearing loss similar to that seen with otosclerosis. Early age of onset of hearing loss, high compliance values on tympanometry, a history of fractures after minor trauma in childhood that ceased after puberty, a family history of OI, and blue sclerae are helpful diagnostic clues.

The conductive loss reflects structural changes in the ossicles. Microfractures of the manubrium,[76] fragility of the long process of the incus, and fracture or resorption of the crura of the stapes have been reported.[75,77,78] The stapedial footplate is typically described as thick, soft, and chalklike or granular, and is usually fixed.[79] Rehabilitation can be accomplished by amplification or surgery.[80-82] A stapedectomy can give results similar to those seen with otosclerosis, but the procedure is extremely delicate. Crimping the prosthesis around the incus may cause a pathologic fracture, and a platinum ribbon is preferred to stainless steel wire.[75]

Histopathology of the temporal bone (Figs. 148-27 and 148-28) in cases of OI type II has shown deficient ossification of the endochondral layer of the otic capsule, which shows increased amounts of fibrous tissue with numerous blood vessels. The periosteal layer is often thin and deficient (see Fig. 148-28). The stapes crura are often thin and incomplete. The otopathology in cases of OI type I is very similar if not identical to that seen in cases of otosclerosis.[83,84] The abnormal bone involves the periosteal and endochondral layers of the otic capsule (see Fig. 148-27), and may result in the fixation of the stapes footplate.

Fibrous Dysplasia

Fibrous dysplasia is a benign, chronic, slowly progressive bone disorder of unknown etiology that is characterized by the replacement of normal

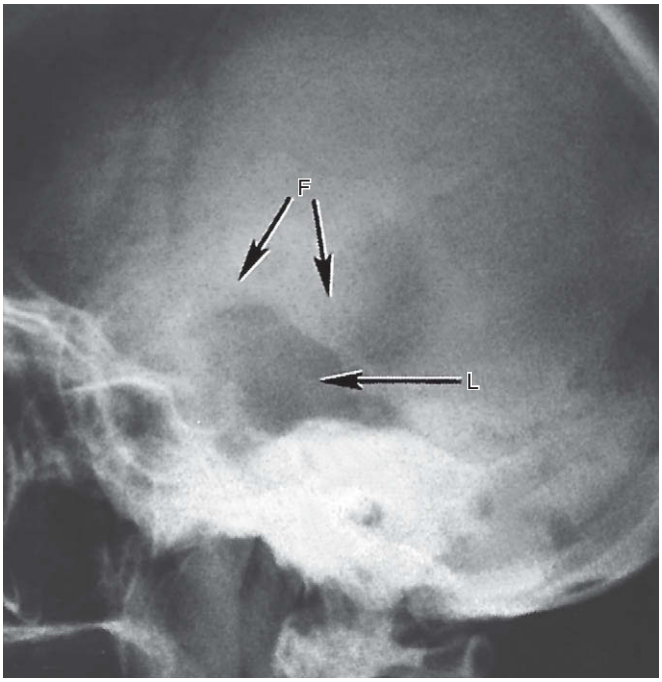

Figure 148-29. Lateral radiograph of the skull of a patient with fibrous dysplasia showing lytic (L) and fibrous (F) phases of disease. Spicules of new bone are responsible for the ground-glass appearance of the fibrous phase.

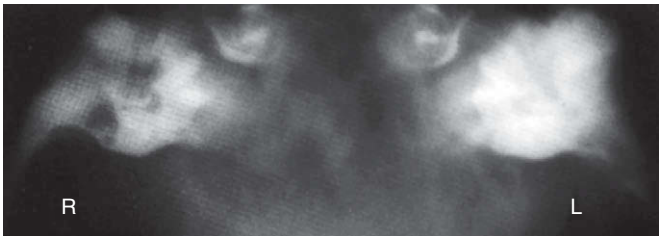

Figure 148-30. Coronal tomographic radiograph of a patient with fibrous dysplasia. New bone formation causes a dense appearance of the involved left temporal bone.

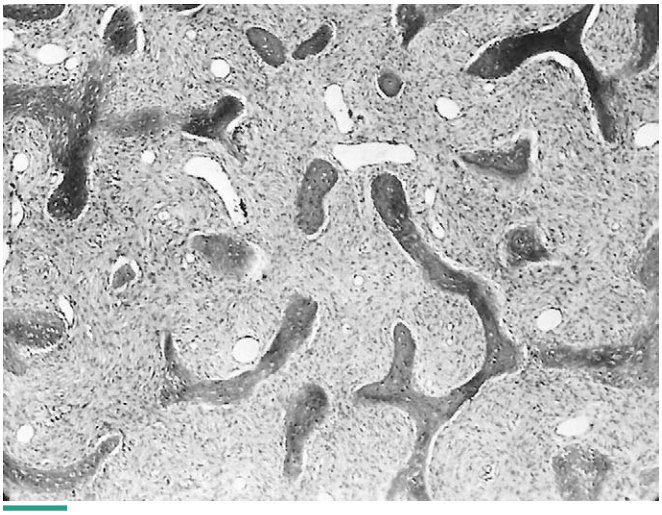

Figure 148-31. Fibrous dysplasia. The irregularly arranged spicules of woven bone in a fibrovascular stroma show a whorled pattern (×64).

bone with a variable amount of fibrous tissue and woven bone. It may occur as part of Albright's syndrome (characterized by multiple bony lesions, abnormal pigmentation, endocrine dysfunction, and precocious puberty in girls), or it may exist alone as the monostotic or polyostotic form. The monostotic form is more common and usually occurs in the skull, ribs, proximal femur, or tibia. In the polyostotic form, skull lesions are seen in more than 50% of patients.

Clinical manifestations of fibrous dysplasia include bony deformity, pathologic fracture, and cranial nerve palsies. The disease starts early in life, usually in childhood; the monostotic form may become quiescent at puberty, whereas the polyostotic form can continue to progress. Sarcomatous transformation can occur, with an estimated incidence of 0.4%.[85] Laboratory findings include elevated serum alkaline phosphatase level in 30% of patients with polyostotic fibrous dysplasia, with usually normal serum calcium and phosphorus levels. The typical radiographic findings include a radiolucent area with a well-defined smooth or scalloped edge and a ground-glass appearance. Areas of increased radiodensity may also be seen (Figs. 148-29 and 148-30). The histopathology of fibrous dysplasia consists of the replacement of normal cancellous bone by a fibrous stroma arranged in a whorled pattern. A variable amount of irregularly arranged spicules of woven bone cause the ground-glass radiographic changes (Fig. 148-31).

Advances have been made toward understanding the cellular and molecular basis of fibrous dysplasia. The lesion is composed of immature mesenchymal osteoblastic precursor cells. There is an activating mutation in the gene that encodes the α subunit of stimulatory G protein.[86] Elevated levels of cyclic adenosine monophosphate result that affect the transcription and expression of multiple downstream genes, which ultimately result in the pathologic lesion.[87] Treatment consists of bisphosphonate therapy and orthopedic surgery for correction of deformities and treatment of pathologic fractures.[88]

Otologic Manifestations

The temporal bone occasionally may be involved in cases of fibrous dysplasia, with about 100 cases reported to date.[89-91] Of these, the monostotic form occurred in 70%, the polyostotic form occurred in 23%, and Albright's syndrome occurred in 7%. All parts of the temporal bone can be involved, but the process generally begins as a painless, slowly progressive swelling that involves the mastoid or squama. Progressive narrowing of the external auditory canal with conductive hearing loss is the most common manifestation and occurs in about 80% of cases. This narrowing may be mistaken for exostoses, but fibrous dysplasia is encountered during the second or third decade of life; at surgery, it is vascular with a characteristic soft, spongy, and gritty consistency. Entrapment of keratin debris medial to a stenotic canal can cause an external canal cholesteatoma. Involvement of the middle ear and ossicles or obstruction of the eustachian tube also can cause conductive hearing loss. Erosion of the fallopian canal with facial nerve paralysis or erosion of the otic capsule with SNHL and vertigo is seen occasionally. An isolated lesion of the mesotympanic bone can simulate a glomus tympanicum tumor and manifest as a reddish mass behind an intact tympanic membrane with pulsatile tinnitus and hearing loss.

Management of fibrous dysplasia is symptomatic. Operative procedures should be limited to biopsy and relief of functional deficits. Stenosis of the external canal often requires surgical removal with canalplasty and meatoplasty. Restenosis as a result of regrowth of fibrous dysplasia occurs, and multiple procedures are sometimes needed. Compared with simple canalplasty, a postauricular canal wall down mastoidectomy with wide canalplasty and skin grafting gives better results, with long-term canal patency. Radiotherapy is contraindicated because of an increased rate of malignant degeneration.[85] Long-term follow-up is indicated because of the potential for facial nerve involvement and for the progression of conductive hearing loss to profound SNHL.[90]

Osteopetroses

Osteopetroses are rare genetic disorders that are characterized by greatly increased bone density.[92-94] Osteopetroses result from the

defective function of osteoclasts, which results in a failure of normal bone resorption while normal bone formation by osteoblasts continues, with deposition of excessive mineralized osteoid and cartilage. Four types of osteopetrosis have been defined, although patients with atypical symptoms are frequent, which suggests that there are additional types.

Malignant osteopetrosis is an autosomal recessive form that manifests in infancy and is rapidly progressive, with a high mortality rate. Many cases have been shown to be due to mutations in the gene encoding for the TCIRG1 subunit of the vacuolar proton pump within osteoclasts. The disease is characterized by the encroachment of bone marrow that leads to anemia, thrombocytopenia, hepatosplenomegaly, increased susceptibility to infection, and encroachment of the neural foramina, which causes neural degeneration. Optic atrophy, facial paralysis, SNHL, hydrocephalus, and mental retardation are common, and death usually occurs during the first or second decade of life. The only effective treatment is bone marrow transplantation. Another type of autosomal recessive osteopetrosis is due to a mutation in the gene for cytoplasmic carbonic anhydrase II. This type is very rare (approximately 50 cases have been reported), and it is associated with distal renal tubular acidosis.

Autosomal dominant type II osteopetrosis (also known as Albers-Schönberg disease and marble bone disease) is the most frequent type. It is associated with normal life expectancy and may be asymptomatic. Many cases have been shown to result from mutations in the *CLCN7* chloride-channel gene.[92] Clinical manifestations include an increased incidence of fractures (osteopetrotic bone is fragile despite its solid appearance); osteomyelitis of the mandible from dental infection; progressive enlargement of the head and mandible; clubbing of the long bones; and cranial neuropathies such as progressive optic atrophy, trigeminal hypesthesia, recurrent facial paralysis, and SNHL. Patients may have syndactyly of the fingers or toes and abnormal fingernails; these abnormalities can aid the physician in making the clinical diagnosis. Radiographic evaluation reveals a great increase in the density of all bones.

Autosomal dominant osteopetrosis type I is an extremely rare type (it has been reported in only three families), and it seems to be linked to a locus on chromosome 11q12-13.[94] Patients with this type of osteopetrosis are often asymptomatic, but some have pain and hearing loss. This is the only type of osteopetrosis that is not associated with an increased rate of fractures.

Otologic Manifestations

The endochondral layer of the otic capsule and ossicles in the temporal bones of infants and children with the malignant recessive form of osteopetrosis consist mainly of dense calcified cartilage.[95] The mastoid is not pneumatized, and the stapes persists in fetal form (Figs. 148-32 and 148-33). The inner ears appear normal. Dehiscence of the tympanic segment of the facial nerve (often with herniation of the nerve into the oval window niche) has been a consistent finding.[95-97] There seems to be no observable nerve compression, however. These children often have recurrent episodes of acute otitis media, serous otitis media, stenosis of the external auditory canal, conductive hearing loss or SNHL, and unilateral or bilateral facial nerve paralysis.[98,99]

In the more benign adult (autosomal dominant type II) form, the temporal bone is markedly sclerotic, with obliteration of the mastoid air cells and a narrowing of the eustachian tube and the external and internal auditory canals. Exostotic overgrowth of the periosteal bone surrounding the tympanic cavity can occur (Fig. 148-34), with ankylosis of the ossicles and obliteration of the oval and round window niches (Fig. 148-35). These changes explain the common finding of conductive hearing loss. SNHL also occurs, but the inner ears appear normal. Narrowing of the eustachian tube predisposes a patient to serous otitis media.[100] Recurrent acute facial nerve paralysis that is similar to Bell's palsy (involving one or both sides) is a frequent manifestation. There is a tendency toward progressive residual weakness with each episode. Radiographic studies should be performed in any child or young adult with recurrent facial nerve paralysis to determine the possibility of osteopetrosis. Total decompression of the facial nerve has been advocated to ameliorate recurrent palsies.[101,102]

Figure 148-32. Recessive osteopetrosis of the temporal bone of a 15-month-old boy. The endochondral layer of the otic capsule and stapes is composed of calcified cartilage (×12.3).

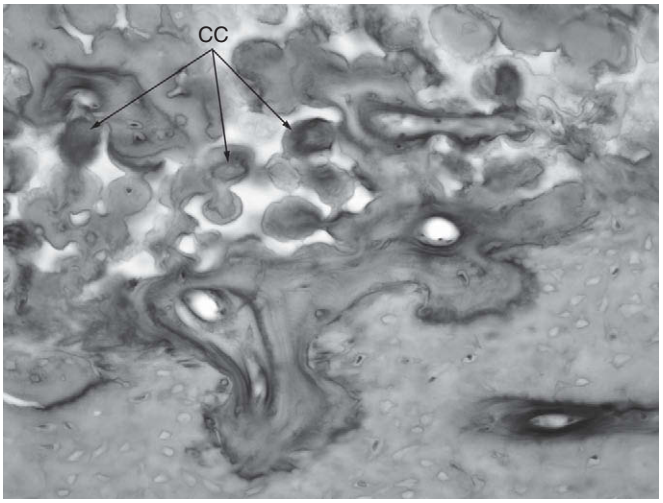

Figure 148-33. Higher magnification of the temporal bone seen in Figure 148-32. The calcified cartilage (CC) of endochondral bone appears as densely staining, round-to-ovoid profiles (×396).

Osteitis Fibrosa Cystica

Osteitis fibrosa cystica (von Recklinghausen's disease) is a bone lesion caused by excess parathyroid hormone, and it is characterized in classic cases by osteoclastic bone resorption, marrow fibrosis, bone cysts, bone pain, and fractures. In most cases, it is caused by primary hyperparathyroidism, which is usually due to an adenoma. Other manifestations relate to hypercalcemia and hypercalciuria. Although the temporal bone can be affected in this disorder,[103,104] it is very rare in clinical practice. The otic capsule is replaced by abnormal bone composed of loosely arranged trabeculae of varying size and shape that are interspersed with marrow spaces that contain fibrous tissue. SNHL has been attributed to osteitis fibrosa involving the temporal bone.

Storage and Metabolic Diseases

Mucopolysaccharidoses

The mucopolysaccharidoses (MPS) are a group of diseases that are caused by an inherited deficiency of one of several lysosomal enzymes that degrade mucopolysaccharides. As a result, undergraded mucopolysaccharides accumulate intracellularly, which gives rise to large cells

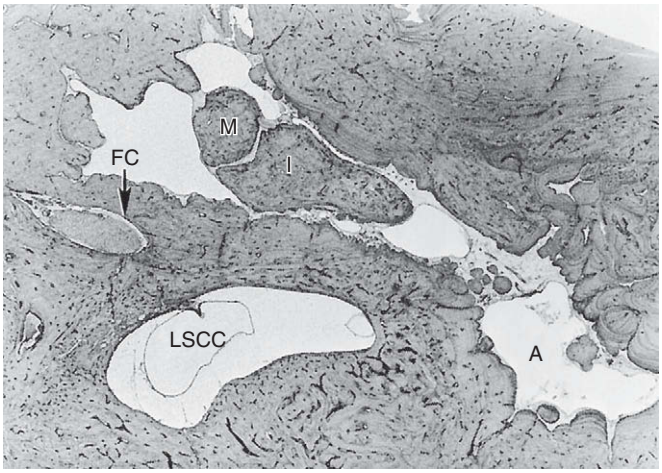

Figure 148-34. Osteopetrosis in a 30-year-old man showing overgrowth of dense lamellar bone around the epitympanum, with jamming of the malleus (M) and incus (I). The facial nerve canal (FC) is narrowed (×9). A, antrum; LSCC, lateral semicircular canal.

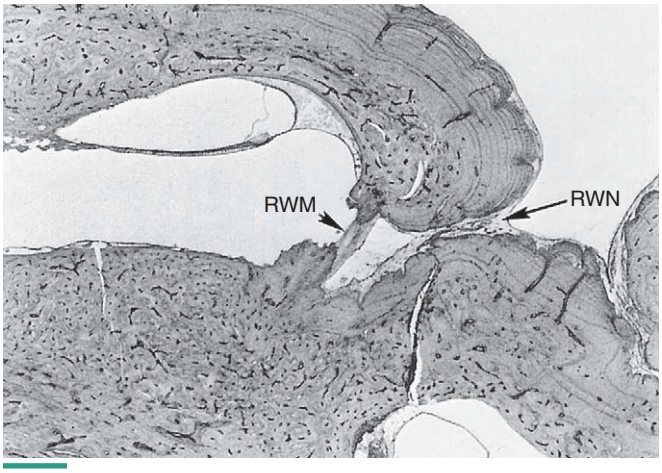

Figure 148-35. Osseous obliteration of the round window niche (RWN) of the same patient as seen in Figure 148-34. There is fluid in the niche adjacent to the round window membrane (RWM) (×18).

with vacuolated cytoplasm. Ten enzyme deficiencies have been identified to date and are classified into seven types or syndromes. All are transmitted as autosomal recessive traits except for Hunter's syndrome (MPS II), which is X-linked recessive. Diagnosis is made either by an assay of the specific enzyme in plasma or serum or by tissue culture using fibroblasts or leukocytes. Management is mainly supportive and symptomatic. MPS are potentially amenable, however, to enzyme replacement therapy and to procedures such as bone marrow transplantation or gene transfer.[105]

Hurler's syndrome (MPS I) is caused by a deficiency of L-iduronidase that leads to the accumulation of heparan sulfate and dermatan sulfate. Clinical manifestations include corneal clouding, abnormal facies, hepatosplenomegaly, mental retardation, dysostosis multiplex, joint stiffness, and hernias. Radiographic features include a broadening and shortening of long bones; hypoplasia and fractures of the lumbar vertebrae, causing kyphosis; and enlargement of the sella turcica. Death usually occurs during the first decade of life.

Hunter's syndrome (MPS II) results from a deficiency of iduronate-2-sulfatase, which leads to an accumulation of heparan sulfate and dermatan sulfate. The syndrome is similar to Hurler's syndrome, but corneal clouding is not seen. Survival to adulthood may occur.

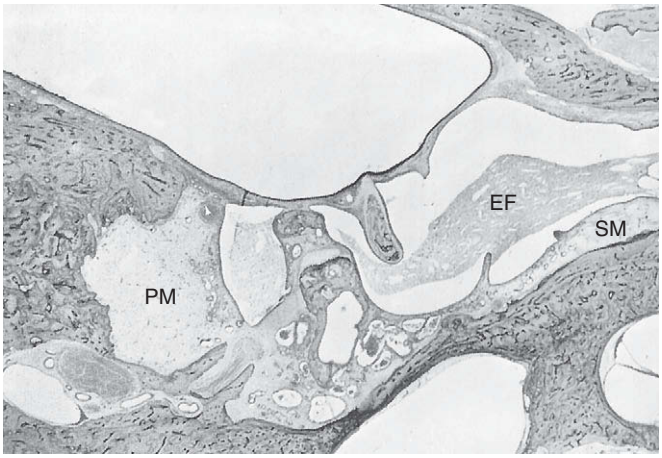

Figure 148-36. Hunter's syndrome in a 24-year-old man. The middle ear contains an effusion (EF) as a result of eustachian tube dysfunction. The submucosa (SM) is thickened, and the posterior mesotympanum (PM) contains unresorbed mesenchymal tissue (×11).

Morquio's syndrome (MPS IV) is attributable to a deficiency of *N*-acetylgalactosamine-6-sulfatase or of β-galactosidase, resulting in excessive urinary excretion of keratan sulfate. Clinical manifestations include spondyloepiphyseal dysplasia. Spinal cord compression caused by hypoplasia of the odontoid process and cervical dislocation are common and may be the cause of death.

Otologic Manifestations

Hearing loss in MPS is usually conductive and sensorineural. The conductive component is attributable to serous otitis media as a result of dysfunction of the eustachian tube and chronic thickening of the mucosa of the middle ear (Fig. 148-36). Unresorbed mesenchyme has been described in the middle ear and mastoid in Hurler's syndrome.[106] Large cells with vacuolated cytoplasm have been described in the middle ear mucosa in both Hunter's syndrome[107] and Hurler's syndrome.[108] The cause of SNHL is unknown, but it has been attributed to abnormal metabolism within neural elements.[107-110]

Gout

Gout is a metabolic disease that results from the deposition of crystals of monosodium urate within joint spaces and cutaneous structures.[111,112] The crystals stimulate production of interleukin-1 and other cytokines by monocytes and macrophages, leading to inflammation and tissue damage. Patients with gout invariably have hyperuricemia (serum urate level >7 mg/dL). Genetic factors influence the renal clearance of uric acid and may be involved in the familial incidence of hyperuricemia and gout. More recent studies have implicated loci on the X chromosome and on chromosome 16 in the pathogenesis of hyperuricemia.[113] Other risk factors for gout include alcohol use, exposure to lead, diuretics, hypertension, and renal insufficiency.

The clinical manifestations of gout include acute gouty arthritis, aggregates of crystal in connective tissue (tophi), urate urolithiasis, and, rarely, gouty nephropathy. Laboratory abnormalities include hyperuricemia, leukocytosis, and an elevated erythrocyte sedimentation rate. The diagnosis of gout depends on the identification of urate crystals within joint fluid or within tophi under polarized light. The treatment of acute gouty arthritis includes bed rest, nonsteroidal anti-inflammatory agents, and colchicine. Uricosuric drugs such as probenecid are useful for patients with hyperuricemia as a result of the decreased renal clearance of uric acid. Xanthine oxidase inhibitors such as allopurinol are useful if excess production of uric acid is the basis of the hyperuricemia.

Otologic Manifestations

Tophaceous deposits can occur in multiple areas in the head and neck.[111] The helical rim of the pinna is the classic site of

involvement. Such tophi are usually asymptomatic and do not require any treatment.

Ochronosis

Ochronosis is a rare disease that is caused by an inherited lack of the enzyme homogentisic acid oxidase. The presence of homogentisic acid in urine is called *alkaptonuria*. The result of this inborn error of metabolism is the deposition of a dark pigment in tissues that are rich in collagen. Patients often present with symptoms and signs during the third decade of life. Manifestations include ochronotic arthropathy, ocular and cutaneous pigmentation, obstruction of the genitourinary tract by ochronotic calculi, and cardiovascular manifestations as a result of ochronosis affecting the aortic valve. There is no effective management or cure for the condition. Treatment is based on symptomatic therapy.[114]

Otologic Manifestations

Ochronosis has manifestations in the external ear; cartilage is a site of predilection for the deposition of the pigment of ochronosis. Blue or mottled-brown macules can appear on the pinna and in other areas of the head and neck, including the nose, buccal mucosa, tonsils, pharynx, larynx, and esophagus.

Collagen Vascular and Autoimmune Diseases

The ear may be a target organ in several systemic (non–organ-specific) diseases that are thought to be autoimmune in nature (e.g., polyarteritis nodosa, relapsing polychondritis, Cogan's syndrome), or it may be the sole target of an immune-mediated (organ-specific) inner ear process that causes progressive SNHL with or without vestibular dysfunction. The latter was described by McCabe,[115] although the theoretical concept was proposed by Lehnhardt in 1958.[116] Histopathologic findings in the temporal bone in both groups of disorders are similar and include destruction and degeneration of the inner ear tissues; scattered infiltrates of lymphocytes, plasma cells, and macrophages; focal or diffuse proliferation of fibrous tissue and bone; and a variable degree of endolymphatic hydrops.[117] The otologic manifestations of these diseases are discussed in Chapter 153 and in published reviews.[118-120]

Immunodeficiency Disorders

Infections of the middle ear and mastoid can occur as part of the clinical spectrum of congenital and acquired immunodeficiency disorders. Occasionally, otologic manifestations may constitute the presenting feature of the disease.

Primary or Congenital Immunodeficiency Disorders

Primary or congenital immunodeficiency disorders constitute a diverse group of conditions that can be subdivided into four broad categories. Humoral immunodeficiency disorders are characterized by the inability to produce antigen-specific antibodies. Patients commonly have recurrent and chronic respiratory tract infections owing to high-grade extracellular bacteria, such as *Haemophilus influenzae, Streptococcus pneumoniae,* and *Streptococcus pyogenes*. Diagnosis is based on the analysis of immunoglobulin subtypes and the assessment of specific antibody production. Management is symptomatic with appropriate antibiotics and replacement therapy with immune human serum globulin. Individual syndromes within the group are classified according to the type of immunoglobulin deficiency, the mode of genetic transmission, and the specific clinical features, including X-linked infantile agammaglobulinemia (Bruton's), autosomal recessive agammaglobulinemia, acquired agammaglobulinemia (common variable immunodeficiency), X-linked immunodeficiency with hyper-IgM, and selective IgA deficiency.

Cellular immunodeficiency disorders exhibit partial or severe deficiencies in the function of T lymphocytes. Patients with these disorders typically have recurrent infections owing to intracellular, low-grade, opportunistic pathogens including viruses, fungi, protozoa, and some bacteria. Diagnosis is based on quantitative and qualitative tests of T-cell function, and there is often an associated deficiency of antibody production. Syndromes include thymic hypoplasia (DiGeorge's syndrome), Wiskott-Aldrich syndrome, ataxia-telangiectasia, chronic mucocutaneous candidiasis, hyperimmunoglobulinemia E (Job's syndrome), and severe combined immunodeficiency.

Disorders of phagocyte function are primarily disorders of neutrophils that leave patients vulnerable to pyogenic bacterial or fungal infections of varying severity and chronicity. This group includes neutropenia, which may be inherited or acquired; if severe, it can cause fulminant sepsis, chemotactic defects that result in pyogenic respiratory infections, and microbicidal disorders such as chronic granulomatous disease and Chédiak-Higashi syndrome. Therapy includes antibiotics, neutrophil transfusions, and bone marrow transplantation.

Complement system defects include deficiencies of the individual components or of the regulatory proteins. Clinical features vary with the type of defect and include recurrent *Neisseria* infections (C5, C6, C7, and C9 deficiency), recurrent staphylococcal infections (C3b inactivator deficiency), lupus-like syndromes (C1, C4, and C2 deficiency), and angioedema (C1 esterase-inhibitor deficiency). All complement defects are inherited (generally autosomal recessive); management is symptomatic and supportive.

Major advances in the understanding of the genetic basis and molecular mechanisms of immunodeficiency disorders have occurred.[121,122] As a result, most of the more than 100 primary immunodeficiency diseases can be diagnosed by molecular techniques. These molecular approaches have also resulted in significant insight into the pathophysiology of the various conditions, which has permitted early diagnosis of many of these conditions by neonatal screening of umbilical cord blood. The immunodeficiency syndromes have also played a major role in the development of human gene therapy, which is being actively pursued in many centers.

Otologic Manifestations

Otologic disease has been described in all four categories of immunodeficiency disorders. Humoral immune defects result in recurrent and persistent acute and serous otitis media. Chronic suppurative otitis media (with all its attendant complications) may develop and is often refractory to medical and surgical therapy.[123,124] A subgroup consists of children with selective IgG subclass 2 deficiency who have been shown to be susceptible to recurrent episodes of otitis media.[125] DiGeorge's syndrome (T-cell deficiency as a result of thymic hypoplasia) can manifest varying degrees of anomalies of the external, middle, and inner ears with conductive, sensorineural, or mixed hearing losses[126]; there is also a high incidence of Mondini's dysplasia in these ears. Recurrent episodes of acute and chronic otitis media have also been described with neutrophil chemotactic defects,[127] microbicidal disorders (chronic granulomatous disease),[128] and complement system defects.[129]

Acquired Immunodeficiency Syndrome

AIDS, which was first recognized in 1981, is caused by HIV. HIV is lymphotropic and attacks primarily T-helper lymphocytes, rendering the patient susceptible to numerous opportunistic infections (see Chapter 15).

Otologic Manifestations

Otologic manifestations are infrequent in patients with AIDS except in children, in whom serous otitis media is common.[130] When otologic disease does occur, the microbiology is similar to that of non-AIDS patients, with the addition of unusual opportunistic organisms (protozoa, fungi, viruses, and mycobacteria).

Middle ear and mastoid manifestations include acute otitis media, acute mastoiditis, serous otitis media, and bullous myringitis; the severity of these infections varies and depends on the immune status of the patient. External ear disease such as otitis externa and Kaposi's sarcoma can also occur. Tissue diagnosis by biopsy or tympanocentesis is indicated to identify the causative agent before initiating therapy.

Pneumocystis jiroveci is an unusual opportunistic protozoan that is a common cause of middle ear and external ear disease in patients with AIDS. Subcutaneous masses in the external canal or aural polyps arising from the canal, the tympanic membrane, or the mesotympanum can result in conductive hearing loss, otorrhea, or otalgia. Presumed routes of infection include hematogenous spread from another source (e.g., pulmonary), ascending infection through the eustachian tube from

pharyngeal colonization, or airborne transmission of the aerosolized organism directly to the external canal.[131,132] A biopsy specimen shows the characteristic organism, and the infection responds to treatment with oral trimethoprim-sulfamethoxazole. Otologic disease resulting from *P. jiroveci* may be the only and the initial presenting symptom of AIDS.[131-133] Inner ear symptoms such as SNHL (including fluctuating and sudden hearing loss), vertigo, and tinnitus can occur.[134,135] SNHL is ascribed to various causes, including otosyphilis, cryptococcal meningitis, tuberculous meningitis, central nervous system toxoplasmosis, and ototoxic medication.[133,136] HIV is neurotropic and may itself be the primary cause of SNHL. The facial nerve can be involved by herpes zoster (Ramsay Hunt syndrome).

In a study of 49 temporal bones from 25 patients with AIDS, Michaels and colleagues[137] found low-grade otitis media in 60% of cases, severe otitis media in 20%, cytomegalovirus inclusion-bearing cells in the inner and middle ears in 24%, labyrinthine cryptococcosis in 8%, and Kaposi's sarcoma deposit in the eighth cranial nerve in 4%. They concluded that the ear is no less susceptible to AIDS-associated diseases than any other organ, and that it is particularly prone to cytomegalovirus infection. The spectrum of otologic manifestations and their pathophysiologic mechanisms in AIDS is most likely to expand as more clinical and histopathologic data accrue.

Genetically Determined Defects

Numerous syndromic disorders secondary to genetic defects may have otologic manifestations consisting of hearing loss or vestibular dysfunction or both. Examples include syndromes caused by mutations in single genes (autosomal or sex-linked), mutations in mitochondrial genes, or chromosomal abnormalities. Such disorders are beyond the scope of this chapter, and the reader is referred to Chapter 147 or other sources.[138]

CHAPTER ONE HUNDRED AND FORTY-NINE

Sensorineural Hearing Loss in Adults

H. Alexander Arts

Key Points

- Sensorineural hearing loss (SNHL) is one of the most common clinical disorders, and is associated with a multitude of etiologies.
- Because of the wide range of genetic, infectious, vascular, neoplastic, traumatic, toxic, iatrogenic, degenerative, and immunologic and inflammatory pathologies that can affect the cochlea, a systematic approach to assessment is crucial to identifying the responsible etiology. Audiologic, serologic, blood chemistry, and radiologic testing can be used strategically for a cost-effective approach to diagnosis of SNHL.
- SNHL results from cochlear hair cell or auditory nerve dysfunction. Psychophysical abnormalities that result from impaired auditory physiology combine to challenge effective listening.
- Sudden SNHL is a clinical syndrome with a lengthy differential diagnosis. Prompt assessment and management of sudden SNHL may offer the opportunity to reverse or ameliorate the hearing loss using more recently developed therapeutic protocols.

Sensorineural hearing loss (SNHL) is an extremely common disorder, with a spectrum of effect ranging from an almost undetectable degree of disability to a profound alteration in the ability to function in society. Because its onset is frequently insidious, and because it is frequently accompanied by subtle compensatory strategies, hearing loss is frequently overlooked by physicians and patients. The auditory system is complex, depending on the performance of many different systems for its continued function. Normal hearing function depends on the mechanical integrity of the middle ear mechanism and cochlear duct, micromechanical and cellular integrity of the organ of Corti, homeostasis of the inner ear biochemical and bioelectric environment, and adequate function of the central nervous system (CNS) pathways and nuclei. These depend on normal vascular, hematologic, metabolic, and endocrine function. As a result, disease of almost any human physiologic system has the potential to affect auditory function.

This chapter addresses the clinical evaluation, differential diagnosis, natural history, and pathogenesis of SNHL in adults, and provides a systematic review of the broad array of etiologies of SNHL. There is inevitably some overlap with other chapters in this text, and in these cases the reader is referred elsewhere for a more detailed discussion.

Clinical Evaluation of the Patient with Hearing Loss

History

Evaluation of patients with sudden SNHL begins with a careful history. The degree of loss from the patient's perspective and its laterality (unilateral or bilateral) and chronicity (sudden onset, rapidly progressive, slowly progressive, fluctuating, or stable) should be assessed. Patients should be questioned for associated symptoms, such as tinnitus, vertigo, dysequilibrium, otalgia, otorrhea, or headache, and ophthalmologic or neurologic complaints should be sought. A sensation of aural fullness or pressure may be present, and may be the patient's only complaint.

A thorough medical history should be obtained with particular attention to cardiovascular, rheumatologic, endocrine, neurologic, and renal disorders, and to any exposure to potentially ototoxic drugs. Surgical history should be evaluated, and a history of skull trauma, penetrating trauma to the ear canal, and compressive force applied to the ear canal (e.g., slap injury) should be queried. The patient's history of exposure to noise, occupational and otherwise, should be specifically addressed. The type of noise, its estimated level, duration of exposure, and use of hearing protection should be documented. Patients and physicians frequently underestimate the importance of a patient's occupational noise exposure, and avocational exposures, such as hunting and power tool use. Finally, family history with regard to hearing loss is particularly important and frequently overlooked.

Physical Examination

Physical examination of the ears in patients with SNHL is frequently unrevealing. The whisper test and tuning fork testing can be used to estimate the degree of hearing loss and to determine whether the loss is predominantly conductive or sensorineural. With the exception of these findings, no abnormality generally is seen in patients with SNHL. Otoscopic examination of the ears should exclude the possibility of acute or chronic otitis media. Neoplasm within the middle ear may rarely be noted. Pulsatile tinnitus may be heard by the examiner with a standard or Toynbee stethoscope. Other cranial nerve abnormalities and stigmata of associated systemic disease or hereditary abnormalities should be specifically sought. The nonotologic portion of the physical examination is more likely to reveal positive findings.

Audiometric Testing

Only a brief discussion of audiometric testing is presented here. Conventional audiometric testing is discussed more thoroughly in Chapter 133, and electrophysiologic testing is addressed in Chapter 134.

Audiometric testing serves to verify and to quantify the degree of hearing loss. Air-conduction, bone-conduction, and speech audiometry and tympanometry constitute the minimum test battery in patients with suspected SNHL. Bone-conduction and air-conduction pure-tone audiometry helps to determine the type of hearing loss (conductive, sensorineural, or mixed). Speech audiometry verifies the pure-tone audiometric results. Speech discrimination testing with assessment of the performance-intensity function helps to define further the nature of the SNHL (cochlear vs. retrocochlear) and provides essential prognostic information regarding the potential benefits of amplification. Tympanometry with acoustic reflex testing verifies the conductive or sensorineural nature of the hearing loss and provides additional clues regarding etiology. Tympanometry can be especially helpful in excluding the possibility of a conductive component in patients with profound losses or bilateral losses in the presence of a masking dilemma.

Basic audiologic tests also can provide essential diagnostic clues as to whether SNHL is cochlear or "retrocochlear" in origin. By "retrocochlear," we mean a lesion proximal to the cochlea, the most common retrocochlear lesion being vestibular schwannoma. The examiner should have a high degree of suspicion for retrocochlear etiologies when there is asymmetry of loss, abnormally reduced or asymmetric speech discrimination, abnormal performance-intensity relationships ("rollover") on speech discrimination testing, or acoustic reflex abnormalities. Other cranial nerve findings, asymmetric tinnitus, or vestibular complaints (even if mild) should increase the level of suspicion.

Auditory brainstem response (ABR) testing is useful in evaluating the possibility of a retrocochlear etiology, and for establishing thresholds in difficult-to-test patients (young children or malingerers). In the past, the ABR was believed to be a highly sensitive test for the presence of a retrocochlear lesion. It is less commonly used in this role today because of reduced sensitivity in patients with small vestibular schwannomas—tumors that are readily detected with the high accuracy offered by magnetic resonance imaging (MRI).[1-3] New modifications of the ABR may increase this study's sensitivity.[4]

Electrocochleography differs from ABR testing in that the reference electrode is placed closer to the cochlea (on or close to the tympanic membrane or promontory). This allows measurement of the cochlear microphonic potential, the summating potential, and the auditory nerve action potential. Wave I of the ABR corresponds to the action potential of electrocochleography. Approximately two thirds of patients with classic Meniere's disease have an elevated summating potential-to-action potential ratio. It is believed that such a finding suggests the presence of endolymphatic hydrops.[5,6] Electrocochleography can also be useful in patients in whom wave I of the ABR is weak or not present because the location of the reference electrode inherently enlarges wave I.

Otoacoustic emissions consist of acoustic energy generated by the cochlea and recorded with a microphone in the external auditory canal. These emissions can be spontaneous in onset or, more commonly, evoked by an acoustic stimulus delivered to the ear canal. If the acoustic stimulus consists of a transient sound (a click or tone pip), the resulting emission is termed a transient-evoked otoacoustic emission. If the stimulus consists of continuous pure tones of two separate frequencies (F1, F2), the resulting emission is a continuous tone of frequency 2F1-F2, and is termed a distortion product otoacoustic emission. Otoacoustic emissions are clearly generated within the cochlea and are believed to be a by-product of the "cochlear amplifier," which is dependent on outer hair cell function. They depend highly on the physiologic state of the cochlea and, if present, suggest normal cochlear function. Otoacoustic emissions are rarely present with hearing thresholds greater than 30 dB HL, regardless of etiology. In addition, for an otoacoustic emission to be present, the middle ear mechanism must be functioning normally because the stimulus and the response must traverse the middle ear. The presence of an otoacoustic emission in an ear with SNHL suggests a retrocochlear etiology or possible pseudohypacusis. Because these etiologies are extremely rare in neonates, otoacoustic emissions also have been useful in neonatal hearing screening programs.

Vestibular Testing

Vestibular testing can be a useful adjunct in the evaluation of SNHL in selected patients. Evidence of ipsilateral peripheral vestibular hypofunction in a patient with unilateral progressive SNHL suggests the presence of a retrocochlear lesion.

Laboratory Testing

Laboratory testing rarely proves to be helpful in determining the etiology of SNHL. In most patients, either the fluorescent treponemal antibody absorption test or the microhemagglutination test for *Treponema pallidum* should be obtained because the prevalence of syphilis is relatively high, it is frequently asymptomatic, it is important to manage, and it is a potentially treatable cause of SNHL. The Venereal Disease Research Laboratory (VDRL) test is not helpful in this regard because it frequently becomes negative with inadequate management, in the latent phase of the disease, or in neurosyphilis. Routinely obtaining hematologic, metabolic, and endocrine studies does not seem to be necessary or cost-effective. Similarly, routine screening for autoimmune disorders does not seem warranted. If these disorders are clinically significant, they typically are apparent from the history and physical examination. In addition, there seems to be no clear relationship between the results of any of these tests and the presence of autoimmune hearing loss.

Radiographic Testing

Radiographic imaging is warranted in selected patients with SNHL. MRI with gadolinium enhancement is currently the gold standard in evaluating potential retrocochlear hearing losses. The role of MRI versus ABR testing in this regard is controversial. It is clear, however, that MRI with gadolinium is much more sensitive than ABR for diagnosis of small lesions.[1-3] Selective T2-weighted fast spin-echo MRI may be almost as sensitive as gadolinium-enhanced standard MRI and is less expensive.[7] Computed tomography (CT) is useful in patients with suspected labyrinthine anomalies, such as large vestibular aqueduct syndrome or Mondini dysplasia. CT may also be useful in patients with suspected labyrinthine fistula or temporal bone fractures. High-resolution CT with reformatted images in the plane of, and perpendicular to, the semicircular canals is the study of choice for showing semicircular canal dehiscence syndrome.[8]

Etiology of Sensorineural Hearing Loss

Developmental and Hereditary Disorders

Hereditary Disorders of Adult Onset

The discussion of hereditary causes of hearing loss in this chapter is limited to the more common etiologies primarily presenting in adulthood. Hereditary factors frequently play a role in SNHL, and research in this area is expanding rapidly. For a complete categorization and review of these disorders, the reader is referred to an excellent and encyclopedic work by Toriello and colleagues.[9]

Nonsyndromic Hereditary Hearing Loss

Most hereditary SNHL is not associated with other hereditary abnormalities. Hereditary hearing loss without associated abnormalities is much more common than generally appreciated and frequently is overlooked. It is likely that genetic factors play a role in presbycusis and in susceptibility to noise-induced hearing loss (NIHL).[10-13] Distinct patterns of hereditary hearing loss transmitted in autosomal-dominant, autosomal-recessive, and X-linked fashion have been well described. Recessive or dominant isolated SNHL can be progressive or static, and may be congenital, present first at birth, manifest in childhood, or manifest in adulthood. Approximately 90% of inherited SNHL is recessive.

Waardenburg's Syndrome

Waardenburg's syndrome is transmitted in an autosomal-dominant fashion and consists of a constellation of findings, including (1) dysto-

Figure 149-1. Ocular findings in Waardenberg's syndrome. Note the dystopia canthorum, the broad nasal root, the confluence of the eyebrows, and the heterochromia iridis.

pia canthorum (lateral displacement of the medial canthi), (2) broad nasal root, (3) confluence of the medial portions of the eyebrows, (4) partial or total heterochromia iridis, (5) a white forelock, and (6) SNHL (Fig. 149-1). There is extreme variability in the expression of this disorder, and the hearing loss can vary from profound to none at all. The hearing loss can be unilateral or bilateral, and can be associated with vestibular abnormalities.

Alport's Syndrome

Alport's syndrome is characterized by interstitial nephritis, SNHL, and, much less commonly, ocular manifestations.[14] This disease is unique because it is more common in women, but typically is much more severe in men. In the past, it has been thought to be transmitted in an autosomal-dominant fashion. It is now clear that there is significant genetic heterogeneity. Hearing loss is progressive and variable, usually beginning in the second decade of life. By age 20 to 40 years, 50% to 75% of men develop end-stage renal failure.

Usher's Syndrome

Usher's syndrome consists of the combination of retinitis pigmentosa and SNHL, with or without vestibular deficits. Three distinct groups have been defined. Usher's syndrome type I accounts for 85% of all cases, and is characterized by profound congenital hearing loss, absent vestibular response, and the development of retinitis pigmentosa by age 10 years. Type II accounts for 10% of cases, and is characterized by congenital moderate to severe stable hearing loss, normal vestibular responses, and onset of retinitis pigmentosa in patients 17 to 23 years old. Type III is typified by progressive hearing loss with onset in childhood or late adolescence and variable onset of retinitis pigmentosa. Approximately 5% of patients have type III. The disease is transmitted in an autosomal-recessive fashion, and it is estimated that 1 of 100 people is a carrier of the trait.

Inner Ear Anomalies

Many patterns of dysplasia of the inner ear have been described, and most have been associated with SNHL. These dysplastic patterns of development may be inherited, sporadic, or the result of chromosomal abnormalities. Commonly used descriptive terms for these dysplasias include Scheibe dysplasia (cochleosaccular dysplasia, involving membranous labyrinth only), Mondini dysplasia (dysplasia of bony and membranous labyrinth), and common cavity deformity (otocyst-like labyrinth with no cochlea or clear vestibular organs). Patterns of labyrinthine dysplasias form a spectrum with all manner of anomalies and patterns of hearing loss.[15]

Large Vestibular Aqueduct Syndrome

One form of inner ear dysplasia is unique because it has been associated with delayed onset of SNHL. An enlarged vestibular aqueduct is commonly seen in combination with other inner ear dysplasias, but more recently, it has been noted as an isolated finding in many ears. These patients may have any level of hearing from normal to a profound loss. Frequently, both ears are affected, and the losses are asymmetric. Fluctuation of hearing is common and usually affects one ear at a time; this may manifest as anacusis in one ear with fluctuation in the other. There is often evidence of a conductive component to the low-frequency portion of hearing loss. In patients who have been followed over time, a progressive stepwise loss has been noted in many.[15] This syndrome

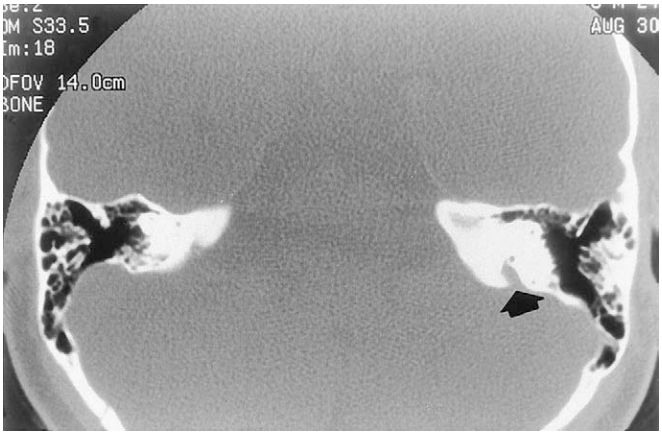

Figure 149-2. CT scan of the temporal bone showing the large vestibular aqueduct syndrome. *Arrow* indicates the enlarged vestibular aqueduct.

has been found to be familial in some cases, and probably occurs much more commonly than generally appreciated.[16] It is seen in isolation, as part of the Mondini malformation, and in patients with branchio-oto-renal syndrome[17] and Pendred syndrome.[18] It is well shown on high-resolution CT imaging of the temporal bone (Fig. 149-2).

Infectious Disorders

Infectious disease is a leading cause of SNHL in children and less so in adults. Infectious etiologies causing SNHL primarily in adults are discussed.

Labyrinthitis

An infectious or inflammatory process within the labyrinth can take two forms pathologically: serous (sometimes referred to as "toxic") or suppurative. Serous labyrinthitis is defined as an abnormal process within the labyrinth, caused by the degradation of the tissue-fluid environment within the inner ear.[19] It may be caused by bacterial toxins or contamination of perilymph with blood, products of tissue injury, or air at surgery. Bacterial toxins may enter the inner ear during the course of acute or chronic otitis media, presumably through either the oval or the round window membranes. Because both acute and chronic suppurative otitis media are common, and because SNHL associated with either condition is rare, these membranes seem to provide an excellent barrier preventing transmission of bacteria or their toxins to the inner ear. The principal abnormal finding in patients with serous labyrinthitis is endolymphatic hydrops, and the hearing loss and vestibular dysfunction associated with this state can be permanent or transient.

Commonly, a clinical diagnosis of labyrinthitis is made when patients present with sudden onset of SNHL and acute vertigo. The exact etiology in cases such as this is uncertain, but it is probably identical or similar to the etiology of sudden SNHL. The evidence tends to support the theory that this is most commonly caused by a viral labyrinthitis.[20,21]

Suppurative labyrinthitis is caused by bacterial invasion of the inner ear, and it is manifested by profound hearing loss and acute vertigo. The route of invasion can be otogenic, from acute or chronic otitis media, most commonly caused by a fistula between the middle ear and the labyrinth. Alternatively, the route of invasion can be meningogenic, through the cochlear aqueduct or internal auditory canal. This is the most common etiology of deafness associated with meningitis.

Otitis Media

SNHL is rarely associated with acute otitis media. No study has shown a relationship between SNHL and frequency of acute otitis media.[22] Patients with long-standing chronic otitis media commonly have a mixed hearing loss. Whether the sensorineural component of this loss is a result of the infectious process itself, or a result of other factors such

as surgery or chronic use of ototoxic topical antibiotics, has been a long-standing controversy. When controlled for sensorineural losses associated with surgery, there seems to be no increase in SNHL in patients with chronic otitis media.[23]

Viral Infections

Herpes zoster oticus is a varicella-zoster infection most commonly associated with facial paralysis and a herpetic skin eruption over the auricle or within the external auditory canal. Although facial paralysis is the most frequent finding, hearing loss and vertigo can occur singly or in combination.

Measles is now rare in the developed world because of widespread vaccination. In the past, measles was a common cause of deafness in children. The hearing loss usually is bilateral and moderate to profound in degree. Vestibular function can be similarly affected.

Similar to measles, mumps is uncommon in the developed world because of widespread vaccination. Mumps is a paramyxovirus infection causing parotitis. Complications of mumps include orchitis, pancreatitis, SNHL, prostatitis, nephritis, myocarditis, and meningoencephalitis. SNHL resulting from mumps is unique because it is almost always unilateral. Bilateral involvement is rare. Unilateral deafness in otherwise healthy children or sudden deafness in adults may be caused by subclinical mumps infection in individuals without previous immunity.

Cytomegalovirus infection is thought by some authors to be a common cause of congenital and progressive hearing loss in children.[24-27] It has been proposed to be a cause of sudden SNHL in adults.[28] Hearing loss associated with acquired immunodeficiency syndrome (AIDS) may represent reactivation of latent cytomegalovirus infections.[29]

Syphilis

Congenital or acquired syphilis has been well established as a cause of SNHL. Although hearing loss is not associated with primary acquired syphilis, its incidence has been estimated to be 80% in patients with symptomatic neurosyphilis, 29% in patients with asymptomatic neurosyphilis, 25% in patients with late latent syphilis, and 17% in patients with congenital syphilis.[19] The mechanism of hearing loss in syphilis is either a meningolabyrinthitis as seen in neurosyphilis, or an osteitis of the temporal bone with secondary involvement of the labyrinth as seen in late congenital, late latent, or tertiary syphilis.[30] Pathologically, a resorptive osteitis is seen in the temporal bone, with progressive endolymphatic hydrops noted within the labyrinth. Clinically, the presentation of syphilitic hearing loss often is indistinguishable from Meniere's disease, with fluctuating hearing loss, tinnitus, aural fullness, and episodic vertigo. Hennebert's sign (a positive fistula test without middle ear disease) and Tullio's phenomenon (vertigo or nystagmus on exposure to high-intensity sound) have been strongly associated with otosyphilis.[19] The generally recommended treatment consists of an antibiotic protocol adequate for neurosyphilis with the addition of systemic corticosteroids.[31]

Rocky Mountain Spotted Fever

Rocky Mountain spotted fever is a tickborne infection caused by *Rickettsia rickettsii*. Headache, fever, myalgias, and an expanding petechial rash follow the tick bite by approximately 1 week. The disease results in systemic vasculitis, resulting in encephalitis, nephritis, and hepatitis. Rapidly progressive SNHL has been associated with Rocky Mountain spotted fever and may be transient.[32,33] Vasculitis involving the auditory system has been postulated to be the etiology of the hearing loss. Diagnosis is made primarily by clinical presentation and is confirmed by serologic titers. Treatment is with broad-spectrum antibiotics.

Lyme Disease

Lyme disease is a tickborne spirochetal illness caused by *Borrelia burgdorferi*. Although the most well-known otolaryngologic manifestation of the disease is facial paralysis, there is some evidence that the disease can be a cause of SNHL.[34-37] Although its true significance remains unclear, Lyme disease should be considered a possible etiology of SNHL in endemic areas.

Pharmacologic Toxicity

Aminoglycosides

At least 96 different pharmacologic agents have potential ototoxic side effects.[38,39] Among these, aminoglycoside antibiotics are perhaps the most common offending agents. This group of antibiotics includes streptomycin, dihydrostreptomycin, kanamycin, neomycin, amikacin, gentamicin, tobramycin, and netilmicin. Drugs that are ototoxic frequently are also nephrotoxic and vice versa (aminoglycosides, loop diuretics, potassium bromates, and nonsteroidal anti-inflammatory drugs [NSAIDs]). Alport's syndrome, described earlier, is a hereditary disorder affecting the kidneys and the inner ear, and there are developmental disorders resulting in renal and inner ear abnormalities. The strong association between pathology of the renal and auditory systems has not been well explained.

Aminoglycosides target the hair cells and enter the hair cell in an energy-dependent process. The end result is death of the hair cell. The reader is referred to excellent reviews of the current understanding of the mechanism of aminoglycoside ototoxicity (see Chapter 154).[40-42] The final common pathway of hair cell damage consists of the generation of reactive oxygen species. Different aminoglycosides have affinities for differing groups of hair cells, which result in different patterns of ototoxicity with different aminoglycosides. Kanamycin, tobramycin, amikacin, neomycin, and dihydrostreptomycin are more cochleotoxic than vestibulotoxic. Others, such as streptomycin and gentamicin, are more vestibulotoxic than cochleotoxic. The time course of the toxicity can vary.[39] Neomycin toxicity is typically rapid and profound, whereas a significant delayed effect has been noted for systemically administered streptomycin, dihydrostreptomycin, tobramycin, amikacin, and netilmicin, and for gentamicin administered through the middle ear.[43]

The hearing loss may be unilateral or asymmetric and can progress during or after cessation of therapy. Some degree of reversibility of the hearing loss sometimes is noted weeks to months after treatment.[39] Protective agents, including antioxidants, show promise for preventing or reducing aminoglycoside toxicity. More recently, the use of salicylates has been proposed.[44] A placebo-controlled clinical trial in China has shown a beneficial effect from the use of aspirin during aminoglycoside administration.[45]

Well-defined risk factors for aminoglycoside-induced ototoxicity have been established and include (1) presence of renal disease; (2) longer duration of therapy; (3) increased serum levels (either peak or trough levels); (4) advanced age; and (5) concomitant administration of other ototoxic drugs, particularly the loop diuretics. Peak and trough serum levels should be routinely monitored when these drugs are being used, and particular attention should be paid to avoidance of dosing intervals that are too short. With the more recent increased use of prolonged home-based intravenous antibiotic therapy, an increase in ototoxic complications has been noted, possibly a result of reduced attentiveness to serum levels and dosing intervals.

Ototopical Preparations

Topical preparations containing neomycin, gentamicin, and tobramycin have long been used directly in the ear for treatment of otitis externa and chronic otitis media. Placement of aminoglycosides within a healthy middle ear space frequently results in cochlear or vestibular ototoxicity as shown in experimental animals and in patients. This effect is now used to perform a titrated chemical labyrinthectomy for patients with Meniere's disease.[46,47] These same drugs have been used extensively over the years in countless ears with chronic otitis media with little to no apparent clinically significant effect on hearing or vestibular function.[48,49] Reduced permeability of the inflamed round and oval window membranes and dilution of the toxic drugs by purulent fluids and increased absorption into the vascular system by the hyperemic mucosa probably account for this decreased toxicity in the presence of otitis media.

It is clear, however, that use of aminoglycosides in the middle ear of animals does cause significant and predictable cochlear and vestibular toxicity in animals.[50] Based on this toxicity, and on the now widespread effective use of aminoglycosides to create a chemical labyrinthectomy, it is now generally regarded as unwise to use topical

aminoglycoside antibiotics for treatment of otitis media. The American Academy of Otolaryngology–Head and Neck Surgery convened a consensus panel in 2004 that, after careful review of the literature, recommended against the use of aminoglycosides in topical form in the middle ear unless no alternative was available.[51] Other ingredients of older ototopical preparations also have ototoxic potential (e.g., polymyxin B, propylene glycol, acetic acid, and antifungal agents).[52,53] It seems prudent to use only agents specifically designed and approved for use in the middle ear for treatment of chronic otitis.

Loop Diuretics

The loop diuretics ethacrynic acid, bumetanide, and furosemide exert their diuretic effect by blocking sodium and water reabsorption in the proximal portion of the loop of Henle. The use of these drugs has been associated with a reversible SNHL and with the potentiation of aminoglycoside-induced hearing loss. The loss typically is bilateral and symmetric, and may be sudden in onset.[54,55] These drugs seem to alter metabolism in the stria vascularis, resulting in alteration of endolymphatic ion concentration and endocochlear potential.[56] Risk factors for loop diuretic–induced ototoxicity include (1) renal failure, (2) rapid infusion, and (3) concomitant aminoglycoside administration.[125]

Antimalarials

Quinine has long been known to be associated with the development of tinnitus, SNHL, and visual disturbances.[57] The drug, derived from the bark of the cinchona tree, has a colorful history as an antipyretic. It was dispensed by quacks and in secret remedies in the 17th and 18th centuries. The syndrome of tinnitus, headache, nausea, and disturbed vision is termed *cinchonism*. Larger doses may cause a more severe form of the syndrome, which also includes gastrointestinal, CNS, cardiovascular, and dermatologic manifestations. Quinine is used as an adjunct in the treatment of malaria and nocturnal leg cramps.[58] The ototoxic effect of quinine seems to be primarily on hearing and usually is transient. Permanent hearing loss may occur with large doses or in sensitive patients. Chloroquine and hydroxychloroquine (Plaquenil) are currently used antimalarial drugs structurally related to quinine. They have also been associated with ototoxicity and retinopathy. Ototoxicity with these drugs seems to be rare and possibly reversible.[59,60]

Salicylates

Aspirin and other salicylates are strongly associated with tinnitus and reversible SNHL. The hearing loss is dose-dependent and can be in the moderate-to-severe range. On discontinuation of the drug, hearing returns to normal within 72 hours.[57] Tinnitus consistently occurs at a dose of 6 to 8 g/day of aspirin and at lower doses in some patients.[61,62] Caloric responses also can be reduced by salicylates.[63] The site of the ototoxic effect seems to be at the level of basic cochlear mechanics, as evidenced by SNHL, loss of otoacoustic emissions, reduced cochlear action potentials, and alteration of the "tips" of auditory nerve fiber tuning curves.[64] These effects may be a result of alteration in turgidity and motility of outer hair cells.[65]

Nonsteroidal Anti-inflammatory Drugs

NSAIDs share many of the therapeutic actions and side effects of salicylates. Although there are isolated reports of hearing loss caused by naproxen,[66] ketorolac,[67] and piroxicam,[68] ototoxicity resulting from use of NSAIDs generally is rare compared with salicylates.[57,69] Similar to salicylates, animal models of NSAID ototoxicity show only reversible physiologic changes, without major morphologic changes.

Vancomycin

Vancomycin generally is believed to be ototoxic, but the available data are difficult to evaluate.[70] In clinical reports of vancomycin ototoxicity, patients almost always also received loop diuretics or aminoglycosides. Vancomycin has been associated with ototoxicity when administered intravenously, but not when given orally. Auditory impairment has been reported to be permanent or transient and is extremely unusual if serum concentrations are less than 30 mg/mL. In animals, vancomycin ototoxicity does not occur, unless toxic levels are administered.[71] Vancomycin is nephrotoxic and excreted by the kidneys. Renal failure can prolong vancomycin half-life and increase the likelihood of ototoxicity. Ototoxicity and nephrotoxicity are reputed to be less common with newer, more purified formulations of vancomycin.[72] When given orally, or in appropriate intravenous doses, vancomycin ototoxicity seems to be very rare, but vancomycin may potentiate other ototoxic drugs.[73,74] There is one reported case of severe, irreversible hearing loss associated with intrathecal administration of vancomycin.[75]

Erythromycin

Numerous case reports document SNHL associated with erythromycin administration.[76] In almost all reports, the drug was given intravenously rather than orally. The hearing loss seems to be uncommon and, in most cases, recovers within 1 to 3 weeks after the drug is stopped. The risk of erythromycin ototoxicity seems to be greater in patients with renal or hepatic insufficiency. There have also been reports of ototoxicity associated with the newer macrolide antibiotic azithromycin.[77] Limited histologic data suggest that the site of lesion in erythromycin toxicity is the stria vascularis.[78]

Cisplatin and Carboplatin

cis-Diamminedichloroplatinum (cisplatin) is a cell cycle–nonspecific cancer chemotherapeutic agent that produces dose-limiting SNHL and peripheral neuropathy, and a dose-related cumulative renal toxicity, hematologic toxicity, and gastrointestinal toxicity.[79] The incidence of hearing loss varies in adults (25% to 86%) and children (84% to 100%). Children seem to be significantly more susceptible to ototoxicity.[80] The hearing loss initially is worse at high frequencies, bilateral, and irreversible. It occasionally is accompanied by tinnitus or vertigo. The degree of hearing loss is dose-related, but there is considerable variability. Occasionally, severe hearing loss can occur after a single dose.[81] If ultra-high-frequency hearing is tested, 100% of patients show a loss. Many factors influence this variability, including mode of drug administration, tumor site, age, renal function, diet, cranial irradiation, interaction with aminoglycosides and loop diuretics, preexisting hearing loss, cumulative dose, and total dose per treatment.[79,82,83]

Carboplatin is a cisplatin analogue with a similar spectrum of antineoplastic activity. Carboplatin is less nephrotoxic than cisplatin. Myelosuppression is the dose-limiting toxicity with carboplatin. It was initially thought that carboplatin was less ototoxic than cisplatin. More recent studies have shown higher rates of ototoxicity than initially appreciated, however. In a series of children, high-dose carboplatin therapy was associated with a very high rate of ototoxicity.[84]

Cisplatin and carboplatin ototoxicity seems to be due to the creation of reactive oxygen species within the inner ear that target the hair cells. Cisplatin results in greater outer than inner hair cell damage, whereas carboplatin seems to affect the inner hair cells preferentially.[85]

Nitrogen Mustards

Nitrogen mustards are antineoplastic agents that include mechlorethamine (Mustargen), chlorambucil (Leukeran), cyclophosphamide (Cytoxan), melphalan (Alkeran), and ifosfamide (Ifex). Of these drugs, only mechlorethamine has ototoxicity as a serious adverse effect, and it has limited usefulness today because of its severe toxic profile. Animal and human studies with mechlorethamine ototoxicity have revealed severe loss of outer hair cells.[69] Other studies have shown shrinkage of the organ of Corti and loss of inner and outer hair cells.[86]

Vincristine and Vinblastine

The vinca alkaloids vincristine and, to a lesser extent, vinblastine are notable for their potent neurotoxicity. Peripheral neuropathy is common. Cranial neuropathies, ataxia, and hearing loss have been reported. Vincristine has been shown in animals to cause loss of hair cells and primary auditory neurons, whereas vinblastine has been shown to result in only hair cell loss.[79]

Eflornithine

Eflornithine (difluoromethylornithine) is a potent inhibitor of ornithine decarboxylase and is very effective in the treatment of trypanosomiasis. It also has proven useful in some patients with *Pneumocystis carinii* pneumonia, cryptosporidiosis, leishmaniasis, and malaria. It has

shown potential as an antineoplastic agent. This drug has been reported to cause major and dose-related SNHL.[87]

Deferoxamine

Deferoxamine is an iron-chelating agent used in some patients with chronic iron overload or acute, severe iron intoxication. Auditory and visual neurotoxicity have been reported, particularly with larger doses in younger patients. SNHL is reversible in some patients when the dosage is reduced.[88]

Lipid-Lowering Drugs

Although optic and vestibulocochlear nerve degeneration (wallerian-like degeneration) have been seen in dogs given high doses of 3-hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA) reductase inhibitors, no clinically significant effect on vision or hearing has been found.

Renal Disorders

Numerous genetic causes of SNHL are associated with renal abnormalities; Alport's syndrome is the most well recognized.[9] Acquired renal disorders have an unclear association with SNHL. Chronic renal failure, especially when managed with hemodialysis or renal transplantation, has been associated with progressive, fluctuating, or sudden SNHL. Oda and coworkers[89] found that 15% of 290 hemodialysis and renal transplantation patients developed SNHL. The etiology of the SNHL is difficult to determine precisely and probably is multifactorial. In addition to the electrolyte and metabolic abnormalities caused by the renal failure and subsequent hemodialysis, these patients typically receive frequent doses of loop diuretics, aminoglycoside antibiotics, and vancomycin. Because of the altered pharmacodynamics of these drugs caused by renal failure, their ototoxic potential is increased.

Trauma

Head Injury

Blows to the head can cause labyrinthine injury and resultant SNHL, either directly through fracture of the labyrinth resulting from temporal bone fracture or indirectly through labyrinthine concussion. The most common type of temporal bone fracture, longitudinal fracture, uncommonly extends through the labyrinth. The hearing loss associated with longitudinal fractures typically is similar to that of acoustic trauma (i.e., limited to the high frequencies and worse at 4 kHz). Similarly, blunt head injury alone, without temporal bone fracture, can result in concussive injury of the labyrinth, resulting in SNHL. Transverse fractures almost always traverse the labyrinth, resulting in complete loss of auditory and vestibular function. Penetrating injuries to the inner ear are rare, but they most commonly involve subluxation of the stapes into the vestibule, with resultant profound SNHL.

Noise-Induced Hearing Loss and Acoustic Trauma

The fact that excessive noise exposure could cause hearing loss was first recognized in the 18th century. In the early 20th century, NIHL was termed "boilermaker's deafness." Careful descriptions of the hearing loss sustained in industry would await development of the audiometer and were first published in the 1930s.[90] NIHL is now recognized as one of the most common occupationally induced disabilities, and noise exposure is now regulated by the Occupational Health and Safety Administration.[91]

Noise can be defined loosely as "unwanted sound," and subdivided by intensity, time course (continuous, fluctuating, intermittent, impact, impulse), and spectral content (pure-tone, narrow-band, broad-band). Impact noise is noise caused by collision of two objects and is common in industry. Impulse noise is noise resulting from sudden release of energy, such as an explosion or weapon fire.

Hearing loss caused by noise is sensorineural in nature. Rarely, extremely intense impulse exposures can result in tympanic membrane perforations, causing a conductive component. Most hazardous noise exposure produces a temporary SNHL that recovers over the next 24 to 48 hours. This reversible loss is termed a *temporary threshold shift* (TTS). If the noise is of high enough intensity or is repeated often enough, a permanent loss of hearing results, and is referred to as a *permanent threshold shift* (PTS). Two distinct types of hearing loss are caused by excessive noise exposure: NIHL versus acoustic trauma. NIHL is caused by repeated exposures to sound that is too intense or too long in duration. Each exposure is followed by a TTS, which recovers, but eventually a PTS develops. Acoustic trauma consists of a single exposure to a hazardous level of noise, resulting in a PTS without an intercurrent TTS.

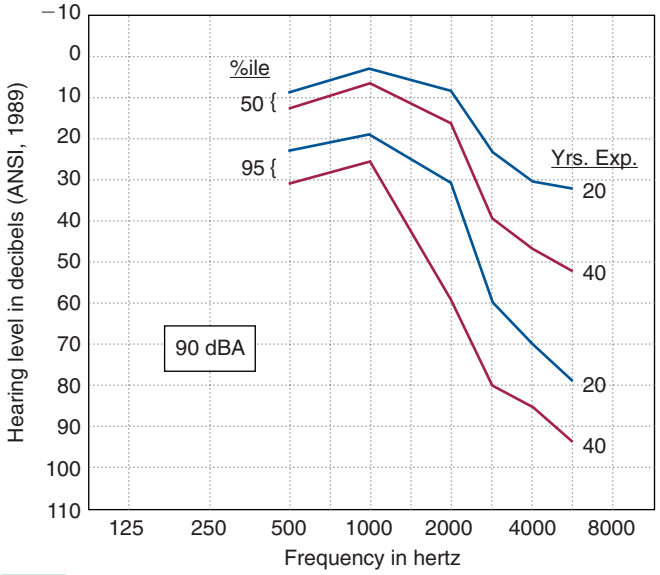

Figure 149-3. Predicted hearing thresholds (median and extreme values) after 20 years and 40 years of occupational noise exposure at 90 dBA. *(ISO-1999, from Dobie RA.* Medical-Legal Evaluation of Hearing Loss. *New York: Van Nostrand Reinhold; 1993.)*

NIHL almost always results in a symmetric, bilateral hearing loss. It almost never results in a profound loss. Early in the course of NIHL, the loss usually is limited to 3 kHz, 4 kHz, and 6 kHz. The greatest loss usually occurs at 4 kHz. As the loss progresses, lower frequencies become involved, but the loss at 3 to 6 kHz is always far worse. The loss progresses most rapidly during the first 10 to 15 years of exposure and thereafter grows at a much-reduced rate. Figure 149-3 shows the 50% and 95% confidence limits for 20-year and 40-year exposures to 90 dBA (decibel, with "A"-weighting that fully weights 700-9000 Hz) sound. Figure 149-4 shows an example of the rate of growth of NIHL over time. The International Organization for Standardization has established standards for determining and quantifying occupational hearing loss and noise-induced hearing impairment.[92]

The hearing loss from acoustic trauma is similar to that from NIHL (i.e., worse at high frequencies with a 4-kHz "notch"), although other patterns also are seen. The other, most common patterns include flat losses and downsloping losses. Acoustic trauma frequently is unilateral or asymmetric. There is considerable variability in hearing loss among subjects with identical exposure. Age, gender, race, and coexisting vascular disease have been carefully studied, and when adequately controlled for other factors, they have not been shown to correlate with susceptibility to NIHL. An attractive theory suggests that patients who are more susceptible to TTS would be more susceptible to PTS and NIHL; this has not been shown to be the case. At present, there is no known way to predict susceptibility to NIHL.

There are three exceptions. Conductive hearing losses are clearly protective for NIHL in the same way that earplugs or earmuffs would be. The lack of an acoustic reflex has been shown to predispose patients to NIHL (the protective effect of the acoustic reflex is primarily ≤2 kHz).[19] Finally, patients with an unusually large PTS already should be considered to be more susceptible. TTS and PTS are commonly accompanied by tinnitus, and tinnitus after a noise exposure should be considered a warning sign.

There is little a clinician can do in the management of NIHL or acoustic trauma. The primary role of otolaryngologists and audiologists is in prevention and early identification. Many hazardous noise expo-

sures are not occupational in origin. Many companies either are unable or unwilling to provide hearing conservation programs.

Barotrauma and Perilymphatic Fistula

Otitic barotrauma consists of traumatic injury of the tympanic membrane and middle ear caused by unequalized pressure differentials between the middle and external ears. The injury typically occurs during flying or underwater diving, and consists of pain, hyperemia, and possible perforation of the tympanic membrane, and edema and ecchymosis of the middle ear mucosa. These symptoms can be followed by the development of a hemotympanum or a transudative middle ear effusion. Conductive hearing loss may result. Any abnormality resulting in compromised eustachian tube function may predispose to barotrauma.

A perilymphatic fistula consists of a pathologic communication between the perilymphatic space of the inner ear and the middle ear. Perilymphatic fistulas can be congenital or acquired in origin. The fistulas can occur at either the round or the oval windows.[93]

Congenital defects can occur in the stapes footplate in patients with labyrinthine anomalies such as Mondini dysplasia.[94,95] These fistulas can communicate with the subarachnoid space and result in cerebrospinal fluid leak and possible meningitis. Typically, these ears have a profound hearing loss. This phenomenon should be a consideration in the differential diagnosis of patients with recurrent meningitis.[96-98]

Acquired perilymphatic fistulas can result from barotrauma, direct or indirect trauma to the temporal bone, or a complication of stapedectomy surgery. A typical history attributed to perilymphatic fistula consists of the sudden development of SNHL and vertigo after a head injury, barotrauma, or heavy lifting or straining. The event is sometimes associated with an audible "pop." Patients may have a positive Hennebert sign and positional nystagmus when the involved ear is placed in a dependent position.[99] Some authors believe that perilymphatic fistulas develop spontaneously.[100,101]

Diagnosis is made by middle ear exploration. Visualization of fluid in the region of the oval or round windows is not definitive evidence of a fistula because serous fluid can ooze from the middle ear mucosa, or lidocaine from the local anesthetic can collect in the vicinity.[102,103] Treatment consists of packing the area in question with tissue. Because of the lack of a definitive diagnostic test for the presence of a fistula, and because even surgical exploration does not reliably diagnose or exclude the possibility of a fistula, there is considerable controversy with regard to the management of this entity.[93,100,104,105] In the 1980s and early 1990s, it was commonly believed that spontaneous perilymphatic fistulas were a common cause of otherwise unexplained hearing loss and vertigo. Many surgical fistula repairs were performed as a result of this belief. It has since become clear that spontaneous perilymphatic fistula is rare.[106] No clear consensus exists regarding diagnosis or management.

Finally, labyrinthine fistula can result from erosion by cholesteatoma, or may develop spontaneously as in the superior semicircular canal dehiscence syndrome. The reader is referred to Chapters 140, 163, and 165 of this book for detailed descriptions of these entities.

Irradiation

The cochlea seems to be resistant to radiation injury at doses less than 45 Gy. At doses greater than 45 Gy, there is a clear, dose-dependent toxicity that manifests as hearing loss.[107-109] Radiation also seems to cause a dose-dependent toxicity to the auditory nerve and brainstem.[110] The latency period from radiation exposure to clinical hearing loss can be 12 months or more. One report notes that early-onset SNHL after radiation can recover to some degree.[111] Fractionated irradiation has been used to a limited extent in the past to treat vestibular schwannoma. Whether it has had an effect on hearing in these patients is difficult to determine because of the limited data available.[112] More recently, there has been much more extensive experience with stereotactic irradiation (radiosurgery) for vestibular schwannoma. This modality seems to be associated with substantial risk of SNHL, at least as high as with microsurgical removal.[113]

There is a relative paucity of published literature on the experimental effects of radiation on hearing. In a histologic study in chinchillas, sacrificed 2 years after fractionated irradiation of the cochlea, Bohne and coworkers[114] showed a dose-dependent loss of inner and outer hair cells. Early studies of the effects of radiotherapy involving the cochlea on human hearing were flawed because lack of controls, inadequate follow-up, and the retrospective nature of the studies. Many well-designed studies now have shown that radiotherapy involving the cochlea causes SNHL in 50% of patients.[107-109,115-117] The hearing loss occurs in a dose-dependent fashion, and seems to increase significantly at doses greater than 45 Gy. Advanced age, preexisting hearing loss, and adjuvant ototoxic chemotherapeutic agents are likely to amplify the effects of radiation. The hearing loss occurs with a latency of 0.5 to 2 years post-treatment and is probably progressive.[111] This delayed onset, and the fact that many patients do not survive for sufficient follow-up, results in underestimation of the frequency and severity of this complication. Dose-dependent injury to the auditory nerve and brainstem also occurs; however, the frequency in the absence of other neurologic complications is difficult to determine.[110]

An understanding of the effects of radiation on hearing has become much more clinically relevant more recently because of the popularity of stereotactic radiotherapy for the treatment of vestibular schwannoma and other similar lesions. Although many reports suggest that the risk of hearing loss is minimal, these studies are limited by (1) their retrospective design, (2) lack of long-term follow-up, and (3) incomplete audiologic characterization. In addition, it is difficult to compare the studies that are available because of differences in tumor size, radiation dose, radiation field, technique of radiation administration, and follow-up. There is a wealth of literature on the treatment outcomes after stereotactic radiotherapy; however, almost all of them are limited by one of the above-mentioned shortcomings. More recent studies report hearing preservation rates (defined in different ways and with different follow-up periods) between 36% and 61%.[118-121] The time course of hearing loss after stereotactic radiotherapy is poorly characterized; available data would suggest that the loss is progressive, and that early results may not predict later outcomes.

Neurologic Disorders

Multiple Sclerosis

Multiple sclerosis is a chronic disease characterized pathologically by multiple areas of CNS demyelination, inflammation, and glial scarring. The clinical course is variable, ranging from a benign, almost symptom-free disease to a rapidly progressive, disabling disorder. Early in the patient's course, the disease is characterized by remissions and relapses.

The disease is said to result in dissemination of neurologic lesions in time (remissions and relapses) and in space (variability of multiple deficits). The age at onset is typically between 20 and 30 years, rarely occurring before age 10 years or after age 60 years. Multiple sclerosis is more common in women than in men. There are striking racial and geographic differences in prevalence, with the disease being most common in whites and in individuals living at higher latitudes. The cause is unknown, but seems to be related to genetic factors, autoimmune mechanisms, and viral infection.

SNHL develops in 4% to 10% of patients with multiple sclerosis.[122,123] The hearing loss can be progressive or sudden in onset, and can be bilateral, unilateral, symmetric, or asymmetric.[124-128] Frequently, the loss is sudden and unilateral, and can recover after days or weeks.[125,129] Audiometrically, speech discrimination can be normal or reduced out of proportion to the increase of pure-tone thresholds. Abnormal patterns of acoustic reflexes can be seen in some patients.[126,130,131] Abnormalities of the ABR frequently are seen and are a diagnostic criterion for multiple sclerosis. Patterns of abnormality vary and include latency prolongation of wave I or the later waves, absence or poor morphology of waveforms, and waveform abnormalities with increased stimulus presentation rate.[124,128,130,132-134] MRI frequently is abnormal in multiple sclerosis and typically reveals periventricular white matter plaques on T2-weighted images. Plaques can be seen in the cochlear nucleus or inferior colliculus in patients with SNHL.[135-138]

Benign Intracranial Hypertension

Benign intracranial hypertension, also known as pseudotumor cerebri, probably is better termed *idiopathic intracranial hypertension* because it is not always benign in nature. The disorder consists of increased intracranial pressure without evidence of mass lesion, obstructive hydrocephalus, intracranial infection, or hypertensive encephalopathy. It is associated with a long list of medical disorders, but frequently manifests as an isolated phenomenon. The underlying pathophysiology is poorly understood. The most common presenting symptoms are headache and visual blurring. Pulsatile tinnitus, SNHL, and vertigo also may be present. It is more commonly seen in obese women.[139,140]

The pulsatile tinnitus is usually objective and is eliminated by jugular venous compression.[141,142] SNHL typically is a fluctuating, low-frequency loss that is unilateral or bilateral. Vertigo and aural fullness also may be present. The most serious manifestation of the disorder is progressive visual loss caused by optic atrophy. The disease is characterized by remissions and relapses. The diagnosis is confirmed by documentation of papilledema on funduscopy or cerebrospinal fluid pressure greater than 200 mm H_2O. ABR and electrocochleography abnormalities can be seen. Management consists of weight loss, acetazolamide, furosemide, and occasionally, lumbar-peritoneal shunting.[142,143]

Vascular and Hematologic Disorders

Migraine

Migraine is a common disorder, usually restricted to headache and sometimes the neurologic symptoms of an aura. Numerous subtypes of migraine are associated with different neurologic deficits. Basilar migraine has been associated with numerous auditory and vestibular symptoms and signs, including episodic vertigo, SNHL, tinnitus, aural fullness, distortion, and recruitment. Fairly complex and specific diagnostic criteria have been established for basilar migraine.[144] In a series of 50 patients meeting the criteria for basilar migraine, 46% had bilateral, low-frequency SNHL, and an additional 34% had unilateral low-frequency SNHL.[145] The hearing loss frequently fluctuated and occasionally was severe. Basilar migraine has been implicated as an occasional cause of SNHL. Because of their similarity, there has been considerable speculation in the literature of an etiologic association between basilar migraine and Meniere's disease.

Migraine headache can be managed with β-blockers, calcium channel blockers, acetazolamide, NSAIDs, and antiserotonin agents. No systematic study evaluating the use of these drugs in patients with basilar migraine is currently available. The reader is referred to the excellent reviews of Olsson[145] and Harker,[146] and to Chapter 165 for a more detailed discussion.

Vertebrobasilar Arterial Occlusion

Several eponyms have been applied to brainstem syndromes, but all apply to neoplasms with the exception of Wallenberg's syndrome (lateral medullary syndrome). Classic brainstem infarction patterns are seen less often than incomplete or mixed clinical pictures. To result in SNHL, the occlusion generally has to involve the anterior inferior cerebellar artery (AICA). Occlusion of the AICA results in ischemic infarction of the regions of the brainstem supplied by this artery. The occlusion typically results from thrombosis or embolism, and rarely from other vascular disorders or surgical occlusion of the vessel. The area infarcted includes the inferior pons, and many of the findings are similar to Wallenberg's syndrome. In addition, the AICA usually gives rise to the internal auditory artery, which is the principal blood supply to the labyrinth. The findings in patients with acute AICA infarction include acute vertigo with associated nausea and vomiting, facial paralysis, SNHL, tinnitus, ipsilateral gaze paralysis, ipsilateral loss of pain and temperature sensation on the face, contralateral partial loss of pain and temperature sensation on the trunk and extremities, and ipsilateral Horner's syndrome. The vertigo and hearing loss are caused by ischemic injury of the cochlear and vestibular nuclei in the brainstem and in the labyrinth itself.[19] Isolated cerebellar infarction can result in hearing loss, vertigo, facial pain or numbness, headache, or ataxia.[147]

Rheologic Disorders and Blood Dyscrasias

Waldenström's macroglobulinemia is a plasma cell disorder in which abnormally large amounts of IgM are synthesized and circulate in the plasma. The result is increased blood viscosity and subsequent ischemic lesions. Progressive and sudden hearing losses caused by this disorder have been reported, and some patients with SNHL have responded to treatment with alkylating agents or plasmapheresis.[148]

Cryoglobulinemia results from immune-complex disease, in which the resulting immune complexes are soluble at body temperature and precipitate at lower temperatures. The deposition of these complexes results in glomerulonephritis, vasculitis, and arthritis. The disorder can be associated with progressive or sudden SNHL.[149]

Sickle cell disease is associated with an increased incidence of SNHL.[150-152] It has been estimated that SNHL is present in 22% of patients with sickle cell disease.[153] The hearing loss may be progressive or sudden, and associated with sickle cell crises.[154-156] Leukemias and lymphomas also have been associated with SNHL caused by either leukemic infiltrates or hemorrhage within the inner ear or by vascular occlusion and resulting labyrinthine ischemia.[19]

Cardiopulmonary bypass has been associated with a slightly increased risk of SNHL.[157-159] The loss most often is sudden, but one study suggests an increased incidence of bilateral high-frequency loss postoperatively.[160] The etiology would seem to be either embolic phenomenon or reduced perfusion of the inner ear.

Vascular loops within the cerebellopontine angle or internal auditory canal have been proposed to be a cause not only of SNHL, but also of tinnitus, vertigo, and Meniere's disease.[161-164] Although the concept of vascular compression of cranial nerves causing intermittent neurologic dysfunction has been reasonably well accepted in trigeminal neuralgia and hemifacial spasm, it has achieved far less support in auditory and vestibular dysfunction. Vessel loops are found in contact with these nerves routinely during cerebellopontine angle surgery for other reasons, and these patients seem to be suffering no ill effects as a result. The entire CNS is subjected to such pulsation continuously. To date, nothing other than anecdotal evidence has been published supporting this theory.

Immune Disorders

Systemic Autoimmune Disorders

Various systemic (non–organ-specific) autoimmune disorders have been associated with SNHL.

Cogan's Syndrome

Cogan's syndrome is perhaps the prototypical autoimmune disorder affecting the inner ear. It consists of attacks of acute nonsyphilitic

interstitial keratitis together with auditory and vestibular dysfunction. SNHL may be unilateral or bilateral, and associated with severe vertigo, nausea, vomiting, and tinnitus. If untreated, the hearing loss frequently progresses to a profound loss over months. Other ophthalmologic findings may be present. If treated early enough, SNHL typically is responsive to aggressive treatment with steroids. Immunosuppressive agents sometimes are required.[165]

Polyarteritis Nodosa

Polyarteritis nodosa consists of a necrotizing vasculitis of small-sized and medium-sized arteries. It can manifest with myriad findings, including weight loss, fatigue, fever, anorexia, arthritis, neuropathy, hypertension, renal failure, abdominal pain, and SNHL. Diagnosis is made by demonstration of the necrotizing vasculitis on biopsy specimen of involved tissue. SNHL may precede the development of systemic symptoms or occur late in the disease. It may be unilateral or bilateral, and either rapidly or slowly progressive. Facial paralysis also may be seen. Aggressive doses of steroids and immunosuppressive drugs are given for management.[166,167]

Relapsing Polychondritis

Relapsing polychondritis consists of an inflammatory reaction in multiple cartilages. The auricles usually are the first cartilages to be affected. Arthritis and eye findings are commonly present. The disorder frequently is present in conjunction with other autoimmune diseases. The associated hearing loss may be conductive, sensorineural, or mixed. SNHL can be sudden or progressive in onset, and may be associated with vestibular disturbances. Therapy includes steroids, immunosuppressive drugs, or dapsone.[168,169]

Wegener's Granulomatosis

Wegener's granulomatosis is a syndrome of necrotizing granulomatous vasculitis involving principally the lungs, airway, and kidneys. Hearing loss usually is conductive because of involvement of the eustachian tube or middle ear. SNHL may be present if the granulomatous disease or secondary infection extends into the inner ear.[170-172]

Other Autoimmune Disorders

Other systemic autoimmune disorders less commonly associated with SNHL include scleroderma,[173] temporal arteritis,[174] systemic lupus erythematosus,[175,176] sarcoidosis,[177,178] and Vogt-Koyanagi-Harada syndrome.

Primary Autoimmune Inner Ear Disease

McCabe[179] first described patients with bilateral SNHL responsive to immunosuppressive drugs. The loss can be sudden or progressive in onset. The loss usually involves both ears, either simultaneously or alternately. The hearing loss frequently is associated with vestibular symptoms and can strongly mimic Meniere's disease. Myriad nonspecific tests of humoral autoimmunity may be abnormal. The hallmark of the disease is the responsiveness of the hearing loss to steroids or cytotoxic drugs. In some patients, a course of drug treatment can produce a long-lasting improvement in hearing, and in others, the hearing improvement depends on continued use of the medications.[180] In these patients, methotrexate is sometimes used to reduce the need for continued high-dose steroids and their resultant side effects.[181] In still others, SNHL progresses despite aggressive treatment.

Sera of many of these patients have been shown to contain an antibody to a 68-kD protein of bovine or guinea pig inner ear extracts. The responsiveness of SNHL to steroid treatment correlates with the presence of this antibody.[182-185] This 68-kD protein has been shown to be a member of the heat shock protein 70 family (HSP70).[186,187] A significant percentage of patients with Meniere's disease show similar reactivity, suggesting that autoimmunity may play a role in at least a subset of patients with Meniere's disease.[188,189] Chapter 153 contains a full discussion of autoimmune inner ear disease.

Acquired Immunodeficiency Syndrome

SNHL is among the numerous neurologic manifestations of AIDS. The hearing loss may be a result of an infectious complication of AIDS, particularly cryptococcal meningitis or syphilis, or as a primary neurologic manifestation of the disease. Human immunodeficiency virus (HIV) should be a consideration in patients with otherwise unexplained SNHL when risk factors are present.[190-197]

Paraneoplastic Syndromes

Neurologic paraneoplastic syndromes consist of neurologic abnormalities associated with malignant neoplasms not metastatic to the nervous system. Rarely, the abnormality may involve the auditory or vestibular system.[198]

Bone Disorders

Otosclerosis

Otosclerosis primarily causes a conductive hearing loss, but it is commonly associated with a progressive SNHL, especially later in the course of the disease. The precise mechanism remains unclear. CT images of the cochlea in these patients frequently reveal a radiolucent area immediately surrounding the cochlea. Histologically, otosclerotic bone frequently involves the endosteum, but the degree of endosteal involvement does not clearly correlate with the degree of SNHL.[199] It is doubtful that isolated cochlear otosclerosis without stapedial involvement (and conductive hearing loss) occurs with any clinically significant frequency.[200] Treatment with sodium fluoride has been reported to retard the progression of hearing loss in these patients.[200-203] The efficacy of this treatment remains controversial.[204-207] Patients with very advanced otosclerosis can have a bilateral profound mixed hearing loss, which can be audiometrically indistinguishable from a profound SNHL. In these patients, stapedectomy can result in useful hearing improvement.[30,208,209]

Paget's Disease

Paget's disease (osteitis deformans) is a common but poorly understood disorder of bone. It is most common in older individuals, with an estimated incidence ranging from 1% in individuals 40 to 49 years old to 19% in individuals 80 to 89 years old. Approximately 50% of patients with Paget's disease manifest hearing loss. The loss can be conductive, sensorineural, or mixed. The stapes footplate is rarely fixed, and surgical ossicular chain reconstruction is rarely beneficial.[210] The treatment of Paget's disease consists of calcitonin or etidronate disodium. Some evidence indicates that medical treatment may stabilize or reverse SNHL.[211,212]

Neoplasms

When patients are initially seen with unilateral or asymmetric SNHL, particularly when the presentation is not typical for Meniere's disease, neoplasm should be a principal diagnostic consideration. All patients with asymmetric or progressive SNHL should be evaluated for a neoplastic etiology. Lesions resulting in SNHL usually are located within the internal auditory canal or cerebellopontine angle, but tumors located anywhere in the skull base or temporal bone can result in SNHL if the labyrinth is invaded.

Vestibular schwannoma is the most common neoplasm resulting in SNHL (Fig. 149-5). Best known as acoustic neuroma, vestibular schwannomas originate from the vestibular nerves, within the cerebellopontine angle or the internal auditory canal. Acoustic neuroma is common, constituting 6% of all intracranial neoplasms.[213] It has been estimated that 2500 new acoustic neuromas are diagnosed in the United States annually.[214] Acoustic neuromas account for approximately 80% of all cerebellopontine angle neoplasms.[213] The most common presenting feature of acoustic neuroma is progressive unilateral SNHL. Any pattern of hearing loss can occur, but most frequently the loss initially involves principally the high frequencies. Commonly, speech discrimination is reduced out of proportion to the pure-tone thresholds. Acoustic neuroma can manifest as a sudden loss in 10% of patients, although most sudden losses are not a result of acoustic neuroma.[215] Unilateral or asymmetric tinnitus, with or without hearing loss, also is a common manifestation of acoustic neuroma. Patients may have mild or severe vestibular symptoms or may have none. Bilateral acoustic neuromas are pathognomonic for neurofibromatosis type 2 (Fig. 149-6). The reader is referred to Chapter 177 in this text for a

more complete discussion of the pathogenesis, evaluation, and management of these common lesions.

Meningiomas account for approximately 15% of cerebellopontine angle neoplasms. The manifestation of cerebellopontine angle meningiomas is very similar to that of acoustic neuromas. For reasons that are unclear, meningiomas generally have less effect on hearing for a given size than do acoustic neuromas (Fig. 149-7). The remaining 5% of cerebellopontine angle lesions include dermoid cysts (congenital cholesteatoma), lipomas, arachnoid cysts, cholesterol granulomas, and hemangiomas. Metastatic lesions, particularly adenocarcinoma, also

can occur in the internal auditory canal. Tumors occurring elsewhere in the skull base that can cause SNHL by involvement of the labyrinth include paragangliomas, chondrosarcoma, hemangioma, middle ear adenoma, rhabdomyosarcoma, lymphoma, and leukemia.[19]

Endocrine and Metabolic Disorders

It would seem logical that the diffuse large and small vessel atherosclerotic disease resulting from diabetes would be associated with an increased incidence of SNHL; however, this has not proven to be the case. There seems to be no significant association between the presence of diabetes and SNHL, when adjusted for expected hearing loss as a result of age.[216]

Although there is a definite association between SNHL and congenital hypothyroidism, there is little to no evidence that adult-onset acquired hypothyroidism can result in SNHL.[217-220] Similarly, reports have suggested that there is an association between hypoparathyroidism and hyperlipidemia. No convincing studies have shown either association.[221-223]

Pseudohypacusis

Pseudohypacusis is simply a factitious or exaggerated hearing loss and is common, especially in situations in which there is secondary gain to patients. Pseudohypacusis should be considered whenever the pattern of loss does not fit the clinical picture. Discordance between the speech reception threshold and the pure-tone average is a strong indicator of a factitious loss. Other audiometric studies, such as the Stenger test, ABR, and otoacoustic emissions, are helpful in clarifying such situations.

Disorders of Unknown Etiology

Presbycusis

SNHL associated with the aging process is termed *presbycusis*. In the strictest sense, only SNHL specifically caused by the aging process, and not by genetic factors, accumulated noise injury, vascular and metabolic factors, and so on, should be attributed to presbycusis. Because of the limitations of controlled studies in such a situation, it is difficult, if not impossible, to establish absolutely the existence of presbycusis. A better term for such a loss is age-related hearing loss, and this applies to any loss associated with age without other apparent etiology. Age-related hearing loss is a major public health issue. Actual prevalence of age-related hearing loss depends on its definition and is difficult to determine. It has been difficult in large epidemiologic studies to exclude

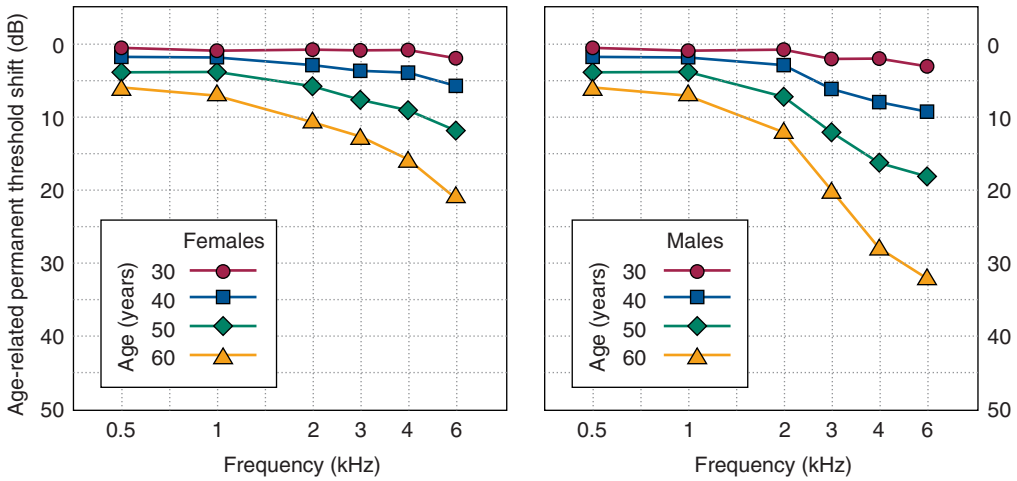

Figure 149-8. Median audiograms for patients with little to no noise exposure as a function of gender, frequency, and age. *(From Dobie RA. Medical-Legal Evaluation of Hearing Loss. New York: Van Nostrand Reinhold; 1993.)*

NIHL from study groups. Approximately 30% of individuals older than 65 years admit to a hearing loss.[91] Because at least 12% of the population is older than 65 years, there probably are more than 9 million people in the United States with age-related hearing loss.

Age-related hearing loss typically is worse for high frequencies and is more severe in men.[224] The rate of loss accelerates with time, so that the older patient is, the greater the threshold shift that can be expected in the future. Many large studies document the degree and prevalence of age-related hearing loss. Figure 149-8 shows the median pure-tone thresholds of a group "highly screened" to exclude noise exposure.

Schuknecht[19] has defined four separate types of presbycusis on the basis of pathologic findings in human temporal bones. In sensory presbycusis, hair cells are progressively lost beginning at the base of the cochlea. Patients with this abnormal pattern tend to have steeply sloping high-frequency hearing losses. Neural presbycusis implies a loss of auditory nerve fibers. These patients tend to have reduced speech discrimination out of proportion to their pure-tone thresholds. Atrophy of the stria vascularis was seen in strial presbycusis, and these patients have relatively flat audiograms. Finally, Schuknecht[19] described a fourth type of presbycusis termed *cochlear conductive* or *mechanical presbycusis*. No light microscopic abnormalities are seen in these specimens, and Schuknecht theorized that an age-related change in the stiffness of the basilar membrane resulted in the hearing loss. These patients have gradually descending (approximately 25 dB/octave) pure-tone thresholds.[19] These patterns are not useful clinically because there is variability of audiometric shape and severity in individuals with age-related hearing loss, and clinically the losses do not fall naturally into these patterns.[225]

Meniere's Disease and Endolymphatic Hydrops

Meniere's disease is a common disorder consisting of fluctuant SNHL, tinnitus, episodic vertigo, and aural fullness. The hearing loss typically begins as a fluctuating low-frequency loss, but progresses, gradually or quickly, to a permanent loss involving any or all frequencies. The tinnitus is most commonly described as "buzzing" or "roaring," and can fluctuate in loudness and character. The aural fullness perhaps is the most consistent and stable complaint, but it also typically fluctuates. The vertigo of Meniere's disease is the most disabling aspect of the disorder.

The typical presentation consists of episodic, spontaneous attacks of severe, spinning vertigo that lasts for several hours. The attacks frequently are associated with nausea, vomiting, and diaphoresis. After the attacks, patients usually are fatigued for 24 hours or more. The attacks of vertigo may be associated with a concomitant or preceding change in their hearing loss, tinnitus, or aural fullness. Many patients also have various combinations of dysequilibrium or motion-provoked vertigo between the classic attacks. Subtypes of Meniere's disease are described that have only vestibular symptoms (vestibular Meniere's) or auditory symptoms (cochlear Meniere's).

The hallmark of Meniere's disease is variability and unpredictability, and this holds true for the hearing loss associated with the disease. The hearing loss may fluctuate wildly or be quite stable over many years. It also may manifest as a sudden, permanent loss. Although most patients progress over the years to a moderate to severe loss, many do not, and progression to a profound loss is rare. The low frequencies are more commonly involved than middle or high frequencies, especially in the early stages of the disease, but there is considerable variability. The disease is bilateral in perhaps 30% of cases.[226-229] Patients who have bilateral disease usually develop bilaterality early in the course of the disease. Patients who maintain hearing loss in only one ear for the first few years rarely develop it in the contralateral ear. This finding supports the idea that the syndrome we have labeled as Meniere's disease is actually the manifestation of several different pathologies.

Although vestibular destructive therapy (chemical or surgical labyrinthectomy, vestibular nerve section) is effective in controlling the episodic vertigo associated with Meniere's disease, no therapy to date has been proven to be effective in the treatment of the hearing loss. The most widely accepted medical therapy for Meniere's disease, a sodium-restricted diet and diuretic administration, is based on the hypothesis that the hydropic distention of the membranous labyrinth can be reduced by altering body water distribution, as in the management of hypertension. This regimen of sodium restriction and diuretics was first proposed by Furstenberg and has gained wide acceptance.[230,231] Despite this wide acceptance, few studies have been able to show definitively that there is a beneficial therapeutic effect with regard to improvement or preservation of hearing.[232-234]

The creation of an intralabyrinthine shunt (cochleosacculotomy) has been proposed as a mechanism to control the hydrops and prevent the recurrent membrane ruptures thought to traumatize the organ of Corti. This procedure has been shown to be beneficial in controlling vertigo, but has been associated with an unacceptably high incidence of severe hearing loss.[235,236] Surgical decompression of the endolymphatic sac, with or without shunting of the sac into the mastoid or the subarachnoid space, has been proposed as a way to correct the presumed defective sac physiology. Although excellent results have been reported, double-blind, randomized studies comparing endolymphatic sac with mastoid shunt procedures with mastoidectomy alone have failed to show any significant difference in maintenance of hearing or control of vertigo.[237-241] The unpredictable, fluctuating nature of Meniere's disease, the lack of an objective diagnostic test, and the high incidence of spontaneous resolution of symptoms make it extremely difficult to come to valid statistical conclusions with regard to therapeutic efficacy in Meniere's disease.

Meniere's disease may be considered to be idiopathic endolymphatic hydrops. Although it is the most common cause of endolymphatic hydrops, many other entities result in similar clinical presentations and pathologic findings. The syndrome of delayed endolymphatic hydrops consists of the initial development of a profound SNHL in one ear, followed by development of symptoms of endolymphatic hydrops years later in either the ipsilateral ear (ipsilateral delayed endolymphatic hydrops) or the contralateral ear (contralateral delayed endolymphatic hydrops).[242] Other pathologic processes have been associated with development of endolymphatic hydrops, including syphilis, temporal bone trauma, serous labyrinthitis, stapedectomy, and autoimmune disease.[19] The reader is referred to Chapter 165 for a more extensive discussion of Meniere's disease.

Sudden Sensorineural Hearing Loss

A subset of patients with SNHL develop hearing loss rapidly, frequently awakening with it in the morning or developing a progressive loss over 12 hours or less. This commonly is a frightening experience for the patient, who might assume that this is a life-threatening disorder or will lead to profound, bilateral deafness. Neither scenario typically is the case. The etiology and appropriate evaluation and management of this common syndrome have been the subject of much debate over the years, illustrated by the fact that there have been more than 100 proposed etiologies for this disorder.[243]

Prevalence, Natural History, and Prognosis

Sudden SNHL is a syndrome and not a diagnosis. Most commonly, the syndrome has been referred to as sudden deafness or sudden SNHL and has many possible etiologies. In most patients, the cause is idiopathic. Among patients with no identifiable etiology, there seem to be several different pathogenetic mechanisms. In reviewing the natural history of the disorder, one should keep in mind that the described natural history is most likely the sum of the histories of patients with differing abnormalities. Because of this, and because of the difficulty of studying such an entity, either in clinical trials or in animal models, much remains to be learned about sudden SNHL.

A universal definition of sudden SNHL does not exist, and the rate of progression of SNHL can vary from seconds to days. For purposes of this discussion, sudden SNHL develops over 12 hours or less. This rate of progression can sometimes be unclear in the history because some patients notice their loss only on using a telephone. In other patients, sensation of fullness or tinnitus is the patient's primary initial complaint. The incidence of sudden SNHL has been estimated to range from 5 to 20 per 100,000 persons per year.[244] In a typical otologic practice, this may account for 2% to 3% of unselected outpatient visits. Any age group can be affected, but the peak incidence seems to be in the sixth decade. The male/female distribution is essentially equal.[245] Bilateral involvement is rare, and simultaneous bilateral involvement is very rare.[246]

The most common presentation is a patient noticing a unilateral hearing loss on awakening. Others notice a sudden, stable hearing loss or a rapidly progressive loss. Occasionally, patients note a fluctuating hearing loss, but most patients have a stable loss. A sensation of aural fullness in the affected ear is common and frequently is the only complaint. Tinnitus is present in the ear to a variable degree, and the hearing loss sometimes is preceded by the onset of tinnitus. Vertigo or dysequilibrium is present to a variable degree in approximately 40% of patients.[247]

Four variables seem to affect the prognosis of untreated idiopathic sudden SNHL: severity of loss, audiogram shape, presence of vertigo, and age. The more severe the loss, the lower the prognosis for recovery, and profound losses have an exceptionally poor prognosis. Upsloping and midfrequency losses recover more frequently than downsloping and flat losses. The presence of vertigo, particularly with a downsloping loss, is a poor prognostic indicator, although not all studies concur on this point. Reduced speech discrimination carries a poor prognosis. Finally, most studies show that children and adults older than 40 years have a poorer prognosis than others.[244,245,247,248] Most recovery occurs within the first 2 weeks after onset; as a corollary, the prognosis for recovery decreases the longer the loss persists. Without treatment of any kind, a significant proportion (30% to 65%) of patients experience complete or partial recovery.[247,248]

Etiology of Sudden Sensorineural Hearing Loss

The management of sudden SNHL should be focused on excluding known causes of the syndrome, especially conditions that require treatment. Similar to causes of SNHL in general, these disorders can be conveniently broken down into infectious, neoplastic, traumatic, ototoxic, immunologic, vascular, developmental, psychogenic, and idiopathic etiologies. Despite a thorough search for an etiology, most cases remain idiopathic. There has been, and continues to be, considerable debate regarding the pathogenesis of the disease in these patients. Principal theories include viral infection, vascular occlusion, intracochlear membrane breaks, and autoimmunity.

Infectious Disorders

Viral Infection

Viral neuritis or cochleitis has long been thought to be the most common cause of sudden SNHL, although much of the evidence for this is circumstantial. SNHL can complicate clinically evident infections with mumps, measles, herpes zoster, and infectious mononucleosis and with congenital rubella and cytomegalovirus. Of patients presenting with sudden SNHL, 28% report a viral-like upper respiratory infection within 1 month before the onset of their hearing loss.[245,249] With the possible exception of mumps parotitis and herpes zoster infections, however, the clinical diagnosis of viral infections is unreliable. Azimi and colleagues[250] reported that 53% of mumps meningoencephalitis occurs without parotitis. Other evidence for a viral etiology for sudden SNHL includes studies documenting increased viral titers in such patients,[249] pathology consistent with viral infection,[251-254] and viral seroconversion studies.[255-258] These seroconversion studies showed a mixture of viruses, including herpes simplex, herpes zoster, cytomegalovirus, influenza, parainfluenza, mumps, measles, and adenovirus. The studies failed to show a relationship between titer results and severity of hearing loss or frequency of recovery.

For some viruses, the evidence of a causative relationship is more convincing. The mumps virus has been isolated from the perilymph of patients with sudden SNHL,[259] and experimental mumps labyrinthitis has been reproduced in hamsters by inoculation of the subarachnoid space with mumps virus.[259,260] Lassa fever, an arenavirus infection endemic in West Africa, has been shown to be associated with sudden SNHL in approximately two thirds of the patients.[261] The time course, the results of audiometric testing, and the patterns of recovery in Lassa fever are very similar to that in idiopathic sudden SNHL.[262] Measles and rubella also are well-documented causes of labyrinthitis,[253] but these cases rarely manifest in a manner typical of sudden SNHL. Herpes zoster oticus also can cause sudden SNHL, although it is a clinical entity distinct from idiopathic sudden SNHL. The evidence that herpes zoster may be associated with idiopathic sudden SNHL is limited to viral seroconversion studies. Sudden hearing loss associated with infectious mononucleosis is rare but has been reported.[263] For a few viruses, there seems to be strong evidence that they may be an occasional cause of idiopathic sudden SNHL. For most other viruses, there is an association with idiopathic sudden SNHL, although convincing evidence of a causal relationship is lacking.

Meningitis

Meningitis is a well-recognized and common etiology of acquired severe to profound SNHL. It is possible that rare cases of idiopathic sudden SNHL may be caused by subclinical meningoencephalitis.

Syphilis

It has been estimated that the incidence of syphilis in patients with sudden SNHL is 2% or less. Syphilitic hearing loss may manifest at any stage of the disease, and may be associated with other manifestations of syphilis, with vestibular symptoms, or alone. It may manifest with unilateral or bilateral sudden SNHL. More typical presentations of syphilitic hearing loss are discussed in other sections of this chapter.

It is important to consider the possibility of reactivation of syphilis in patients with HIV infection.[194,196]

Lyme Disease

Lyme disease is a well-established etiology of acute facial paralysis, and it would not be unreasonable to assume that it could also cause SNHL. Hearing loss has not been strongly associated with Lyme disease, however. The literature contains several descriptions of associations between positive Lyme titers and acute or chronic SNHL, but a causal relationship seems doubtful. In one large study, Lyme titers were found in 21% of patients with sudden SNHL, and there was no difference in outcome between patients with or without positive titers, despite antibiotic treatment of all seropositive patients.[264] Reports of hearing loss in patients with Lyme disease with improved hearing after antibiotic treatment are limited to a few case reports.[35,265]

Acquired Immunodeficiency Syndrome

At autopsy, 88% of HIV-positive patients have evidence of CNS involvement,[266] and approximately 10% of patients with AIDS present because of neurologic symptoms.[190] It is not surprising that sudden SNHL may be associated with HIV infection. Sudden SNHL is not a common manifestation of AIDS, but it has been well documented in the literature.[191-194,197,267] In the presence of HIV infection, sudden SNHL may occur with or without the presence of opportunistic infection, and may occur without clinical evidence of AIDS. Sudden SNHL caused by reactivation of latent syphilis may complicate any stage of HIV infection.[193,194,196] As previously mentioned, some cases of sudden SNHL associated with AIDS may be the result of reactivation of latent cytomegalovirus infection.

Neoplasms

Acoustic Neuroma

It is common for a sudden SNHL to be the initial manifestation of a vestibular schwannoma (acoustic neuroma). According to Moffat and associates,[215] 10.2% of acoustic neuromas initially manifest with sudden SNHL. The prevalence of acoustic neuroma among patients with sudden SNHL is less clear. Estimates range from 0.8%[246] to 3%.[268,269] There are no clear criteria that suggest that sudden SNHL may be a result of an acoustic neuroma. The presence of tinnitus in the ipsilateral ear before sudden SNHL is suggestive, but not present in most cases.[269] In addition, midfrequency and high-frequency hearing loss are more commonly associated with acoustic neuroma than are low-frequency losses, and electronystagmography abnormalities are more common with acoustic neuroma.[269]

Responsiveness of the hearing loss to treatment with steroids is an unreliable indicator that a retrocochlear lesion is not present. There have been many reported cases of steroid-responsive SNHL and SNHL with spontaneous recovery, which have been found to be caused by acoustic neuroma.[269,270] One should have a high level of suspicion for acoustic neuroma in any patient with SNHL. Most investigators recommend that ABR or gadolinium-enhanced MRI be obtained in patients with sudden SNHL.[271] There is no relationship between tumor size and SNHL.[269] Because of this and the numerous more recent reports of false-negative ABR tests in patients with small acoustic neuromas,[3,272-274] it seems warranted to evaluate all patients with sudden SNHL with gadolinium-enhanced MRI.

Other Neoplasms

Neoplasms of the cerebellopontine angle or internal auditory canal other than acoustic neuromas have been associated with SNHL. These include meningioma,[275] cholesteatoma, hemangioma,[276] arachnoid cyst, and metastatic neoplasms. In addition, skull base neoplasms eroding into the inner ear can rarely manifest with SNHL.

Trauma and Membrane Ruptures

Head Injury

Sensorineural hearing loss of any degree can occur after closed or open head injury. The mechanism of injury in such patients has been shown pathologically to vary from mild loss of outer or inner hair cells or cochlear membrane breaks to fracture across the labyrinth or intralabyrinthine hemorrhage.[19] Many of these injuries are pathologically indistinguishable from injuries of acoustic trauma.[277] Some patients experience a variable degree of recovery from head injury–induced hearing loss, a process probably equivalent to the temporary threshold shift seen with acoustic trauma.

Perilymphatic Fistula

Round or oval window fistulas can occur congenitally, after stapedectomy, or after barotrauma. SNHL is well described after events causing barotrauma.[278,279] Some investigators theorize that these fistulas can occur after heavy lifting or straining or even spontaneously. Patients with such fistulas can have sudden or fluctuating SNHL and varying degrees of vestibular symptoms. There is no reliable test for the presence of such a fistula, and even surgical exploration is subject to error.[280] Except in poststapedectomy patients, it is doubtful that perilymph fistula is a significant cause of SNHL.

Intracochlear Membrane Breaks

Intracochlear membrane ruptures and fistulas have been documented pathologically in patients with endolymphatic hydrops.[19] Such breaks have been proposed to be an etiology of SNHL.[281] Schuknecht and Donovan[253] found no evidence of such breaks in a series of temporal bones from patients with sudden SNHL. Gussen[282-284] found evidence to support the membrane break theory in a few temporal bones, however.

Pharmacologic Toxicity

Toxicity from any of the drugs discussed in the previous section on ototoxic causes of SNHL may result in the relatively sudden onset of hearing loss. In addition to these drugs, others have been associated with sudden SNHL. Interferon has been associated with SNHL, which has been reversible in most patients.[285,286] The insecticides malathion and methoxychlor have been associated with bilateral SNHL.[287]

Immunologic Disorders

The finding that many patients with SNHL seem to benefit from glucocorticoid therapy, and the finding of cross-reacting circulating antibodies in many patients with sudden and rapidly progressive SNHL suggest that at least a subset of SNHL cases are caused by inner ear autoimmunity.[185] In addition, many well-known autoimmune diseases have been associated with SNHL, including Cogan's syndrome,[288,289] systemic lupus erythematosus,[175] temporal arteritis, and polyarteritis nodosa.

Vascular Disorders

Sudden hearing loss can occur with occlusion of the cochlear blood supply. Because of the abruptness of onset of SNHL, and the fact that the cochlea depends on a single terminal branch of the posterior cerebral circulation, vascular occlusion has been thought by some authors to be an attractive hypothetical etiology for idiopathic sudden hearing losses. Other aspects arguing against a circulatory etiology include high incidence of spontaneous recovery, significant incidence in young patients, lack of an apparent increased incidence in diabetics, the fact that the loss frequently is limited to just a few frequencies, and the fact that most patients do not have vertigo. Similar to viral etiologies, a few cases of SNHL are clearly a result of vascular occlusion, but most cases remain idiopathic. Temporal bone studies have not found evidence of vascular occlusion in cases of idiopathic SNHL.[19] Series of patients with idiopathic SNHL have been evaluated for hemostatic abnormalities, and no significant association has been found.[290] The role of vascular occlusion versus viral infection in these idiopathic cases has been the subject of extensive debate over the years. At this point, it seems doubtful that a significant proportion of cases of idiopathic sudden SNHL have a vascular etiology.

Migraine,[145,291,292] hemoglobin SC disease,[151,153-156] and macroglobulinemia[148,149] have been documented to be associated with sudden SNHL. Rare cases of thromboangiitis obliterans (Buerger's disease) have been associated with sudden SNHL.[293] Small cerebellar

infarctions may mimic labyrinthine lesions, including sudden onset of hearing loss.[294] Cardiopulmonary bypass[158,159] and noncardiac surgery[157] have been associated with an increased risk of sudden SNHL. Sudden SNHL has been reported after spinal manipulation with probable injury to the vertebrobasilar arterial system.[295]

It has long been believed that patients with diabetes have a higher incidence of idiopathic sudden SNHL than nondiabetics. This belief has been based on the higher incidence of other acute cranial neuropathies and on the diffuse vascular abnormality found in patients with diabetes. Histologic studies of human temporal bones from patients with diabetes mellitus have not consistently found any abnormal alterations.[19,296] In a careful study of the relationship of idiopathic sudden SNHL to diabetes, Wilson[28] found that diabetic patients with idiopathic sudden SNHL were less likely to recover hearing at higher frequencies. There was no significant difference in audiologic pattern between diabetic and nondiabetic patients with idiopathic sudden SNHL. An attempt to compare the incidence of diabetes in patients with idiopathic sudden SNHL with a control population was inconclusive.

Developmental Abnormalities

Large vestibular aqueduct syndrome is associated with SNHL, which frequently occurs in a stepwise fashion associated with minor head trauma. It seems plausible that other, as yet undefined, developmental abnormalities may predispose individuals to sudden SNHL, either spontaneously or after minor head trauma.

Idiopathic Disorders

Meniere's Disease

Some patients seen with typical sudden SNHL ultimately may develop a history more suggestive of endolymphatic hydrops or even frank Meniere's syndrome; this probably constitutes only 5% of all patients with sudden SNHL. In a review of 1270 patients with Meniere's disease, Hallberg[297] found that only 4.4% had initially been seen with sudden SNHL. A subset of these patients very likely have an autoimmune etiology of their hearing loss.

Multiple Sclerosis

Multiple sclerosis is a demyelinating disorder of the CNS manifested by differing neurologic lesions separated by space and time. Sudden SNHL is a rare initial manifestation of multiple sclerosis.[124,137,298] Among patients with multiple sclerosis, auditory abnormalities are common.[127,130]

Sarcoidosis

CNS manifestations are rare (incidence of 1% to 5%), although among patients with neurosarcoidosis, 20% have eighth cranial nerve findings. This eighth cranial nerve involvement may manifest as sudden SNHL, although it only rarely is an isolated finding.[178]

Psychogenic Disorders

Pseudohypacusis frequently manifests as a sudden loss. In most patients, malingering is readily apparent after initial audiologic studies.

Treatment

Treatment of sudden SNHL should be based on its etiology. If an etiology is apparent, the appropriate treatment should follow: appropriate antibiotics for infectious causes, withdrawal of the offending drug for ototoxicity, and so on. Most cases are idiopathic, and treatment decisions should be made on the basis of empirical guidelines. Because of the poor understanding of idiopathic sudden SNHL, controversy surrounds its treatment. Because of the dictum, "first, do no harm," new or unconventional treatment protocols should be well reasoned and carefully applied. It seems prudent to avoid the use of potentially harmful treatment protocols outside of controlled clinical trials because serious complications and deaths have been reported after treatment of idiopathic sudden SNHL.[299]

Steroids in moderate doses have become the most widely accepted treatment option for idiopathic sudden SNHL. Wilson and associates[248] performed a double-blind randomized trial of steroids versus placebo for idiopathic sudden SNHL. Their active drug group was treated with either a 10-day or 12-day course of orally administered dexamethasone or methylprednisolone at tapering doses. They found that all patients ($n = 14$) with midfrequency losses (loss at 4 kHz better than 8 kHz) had a complete recovery regardless of treatment. They noted that among patients with losses greater than 90 dB HL at all frequencies, there was no difference in recovery between the steroid-treated versus placebo-treated groups. Among the remaining patients (nonprofound losses with hearing at 4 kHz better than 8 kHz), there was a significant increase in recovery in the steroid-treated group. Of patients, 78% in the steroid-treated group experienced complete or partial recovery compared with 38% in the placebo-treated group.

In a similar study, Moskowitz and colleagues[300] confirmed a significantly improved recovery rate in a steroid-treated group compared with a nontreated control group. Direct steroid treatment to the inner ear, via middle ear instillation or round window microcatheter, has seen increasing use on an empiric basis. This treatment has the potential advantage of very high steroid concentrations within the inner ear without the associated systemic side effects. Anecdotal reports indicate that this treatment may be more effective than orally administered steroids, and that local complications are infrequent.[301] Refer to Chapter 153 for a more complete discussion.

An alternative management regimen proposed by some investigators involves attempts to improve blood flow or oxygenation to the inner ear. Vasodilators have been used extensively in the treatment of sudden SNHL. Any proposed vasodilator would have to cross the blood-brain barrier and have an effect on intracranial circulation. Intravenous histamine infusion, oral papaverine, and oral nicotinic acid have been used most frequently. Fisch and others[302,303] have shown that breathing a gas mixture with increased partial pressures of oxygen and carbon dioxide (carbogen) results in increased perilymph oxygen tension in cats and humans.

Other agents proposed to improve cochlear blood flow include low-molecular-weight dextran, mannitol, pentoxifylline, and heparin. In addition, the iodinated radiographic contrast agent diatrizoate (Hypaque) was serendipitously noted during a vertebral angiogram to improve the hearing in patients with sudden SNHL. Morimitsu and coworkers[304] showed in the same report that, in a small series, 54% of patients treated with diatrizoate had a complete recovery compared with 19% of a control group treated with vasodilators. It was later shown that triiodinated benzoic acid derivatives such as diatrizoate had a specific effect on the stria vascularis, protecting the endocochlear potential from furosemide-induced depression.[305]

Clinical studies that used the previously mentioned agents have shown poor to mixed results. The varying definition of recovery used by different authors complicates the interpretation of these results. No controlled study has shown a beneficial effect from papaverine, nicotinic acid, or pentoxifylline. Donaldson[306] found no improvement with aggressive heparin therapy in a series of patients. In a prospective, randomized double-blind study, Probst and colleagues[307] found no difference in outcome between placebo and treatment with low-molecular-weight dextran, pentoxifylline, or both. In a randomized prospective trial comparing papaverine/dextran infusion treatment with inhaled carbogen, the average hearing improvement in the carbogen group was better, although no significant difference in hearing recovery was seen between the two groups after 5 days of treatment.[302] After 1 year of treatment, there was a statistically significant improvement in hearing in the carbogen-treated group.[308]

Redleaf and coworkers[309] reviewed their 10-year experience with diatrizoate and dextran, and noted that 74% of their 36 patients showed audiometric improvement with treatment. Only 36% improved to 50% of their premorbid hearing levels, however, very close to the 32% recovery noted in the placebo group of the Wilson study.[248] Another, even more empirical, treatment protocol is the so-called shotgun regimen, which uses most of the proposed agents in hopes that one or more will be beneficial. Wilkins and associates[310] reviewed their results with a protocol of dextran, histamine, diatrizoate, diuretics, steroids, oral vasodilators, and carbogen inhalation. Although it was a

retrospective study and limited by methodologic problems, these authors were unable to show any difference in recovery between patients who had the "full" protocol versus patients who had only portions of the total regimen. Their overall results were no better than the results expected for spontaneous recovery.

Still other treatment ideas are directed at other presumed etiologies. Because endolymphatic hydrops is a common final pathology for many inner ear injuries and may be associated with some cases of sudden SNHL, some authors have advocated treatment with a sodium-restricted diet and a diuretic.[311] Because of the evidence for a viral etiology and specifically evidence of herpesvirus, treatment with oral antiviral medications has been proposed. Because these drugs rarely have adverse side effects, many practitioners routinely treat patients with sudden hearing loss with antivirals in addition to steroids. In a double-blind, randomized, placebo-controlled multicenter trial, Tucci and colleagues[312] found no difference in hearing recovery outcome between patients treated with steroids and valaciclovir versus steroids and placebo. Some authors have advocated aggressive management with very large (mega) doses of steroids or even cytotoxic medications. Clinical studies supporting the efficacy of any of these treatments have yet to be published.

The author believes that a reasonable treatment approach to sudden SNHL is as follows: Sudden SNHL is regarded as an otologic emergency, and patients are evaluated audiometrically and by an otolaryngologist on an urgent basis. Known etiologies are excluded by a thorough history; physical examination; and appropriate laboratory, special audiologic, and radiologic studies. Gadolinium-enhanced MRI of the internal auditory canal and cerebellopontine angle is obtained in all patients. A 10-day course of prednisone, approximately 1 mg/kg/day, is prescribed, followed by a slow taper. If a partial recovery is noted at the end of the 10 days, the full dose is extended another 10 days, and the cycle is repeated until no further improvement is noted. Valaciclovir, 1000 mg three times daily for 10 days, also is considered because it may be beneficial, and because the risks and side effects are minimal. A 2-g sodium diet is recommended with a hydrochlorothiazide-triamterene diuretic combination. Despite the possible efficacy of carbogen treatment, it is not routinely offered to patients with sudden SNHL. The treatment requires inpatient hospitalization, which renders it expensive and inconvenient. Insurers typically regard carbogen as investigational, which results in significant expense to patients. Because of these issues and its controversial nature, most patients do not accept carbogen if it is offered. It would be more strongly considered in exceptional situations, such as a patient with sudden SNHL in an only-hearing ear or in a particularly motivated patient.

CHAPTER ONE HUNDRED AND FIFTY

Tinnitus and Hyperacusis

Carol A. Bauer

Key Points

- Tinnitus is common, affecting 30% of people older than age 55, with an annual incidence of 5%.
- Disturbing tinnitus that impairs daily life activity affects 3% to 5% of individuals with tinnitus.
- Auditory deprivation from hearing loss induces central neural changes that result in tinnitus. Mechanisms responsible for tinnitus involve peripheral triggers and central plasticity.
- Sound therapy is an effective form of tinnitus treatment, and benefits most patients when combined with education and adjunct treatments directed toward factors that exacerbate tinnitus.
- Tinnitus that can be modulated with somatic manipulation may respond to therapy targeting temporomandibular joint and cervical spine disorders.
- Medications are helpful for specific forms of tinnitus.
- Functional imaging studies suggest that temporoparietal cortex and cortical association areas may be important targets for electric and magnetic modulation of tinnitus.
- Clinicians knowledgeable in auditory function and head and neck physiology are well equipped to provide most tinnitus patients with effective treatment, including education, rehabilitation of hearing loss, and identification and treatment of exacerbating factors.

Tinnitus

Tinnitus is the perception of sound without an external source. Although 30 million Americans are estimated to have chronic tinnitus, for most it is not a problem sufficient for them to seek treatment. Tinnitus is a chronic sensation virtually all would prefer not to experience, but for most it is not disabling. Disturbing tinnitus occurs in 3% to 5% of individuals with tinnitus.[1] Until more recently, treatments available for disturbing tinnitus were limited. Significant advances in auditory neuroscience have advanced the treatment of tinnitus beyond the traditional recommendation instructing the patient to "learn to live with it." This chapter reviews current theories and mechanisms of idiopathic subjective tinnitus. It also outlines a clinical strategy for evaluating tinnitus and determining tinnitus subtypes, and reviews current management strategies for tinnitus.

Tinnitus can be classified as objective or subjective. Objective tinnitus can be detected by an observer using a stethoscope or ear canal microphone. Objective tinnitus arises from vascular or muscular sources. Objective tinnitus usually has a pulsatile quality. Table 150-1 lists the causes of pulsatile tinnitus. Many of these causes are uncommon and are not responsible for most instances of tinnitus. Because there are excellent reviews of treatments for objective tinnitus, this uncommon form is not addressed further.[2]

In contrast to objective tinnitus, subjective tinnitus is not audible to an observer. This form is more common, with a 5-year incidence of 5.7%.[3] Estimates of subjective tinnitus prevalence range from 8% to 30%, depending on the definition of tinnitus, tinnitus severity, the population sampled, and assessment methodology.[3-5] In a large population-based study of participants 55 to 99 years old, combining detailed tinnitus questionnaires with audiologic assessment, 30% reported experiencing tinnitus, with prevalence related to audiometric threshold, but not age or gender.[5] Mildly annoying tinnitus was reported in 50% of respondents, and extremely annoying tinnitus was reported in 16%. Tinnitus prevalence in individuals with normal hearing was 26.6% compared with 35.1% in individuals with hearing loss. An estimated 20% of individuals with profound hearing loss do not experience tinnitus.[6] These data illustrate that chronic tinnitus is associated with, and may be triggered by, hearing loss, but they also indicate that hearing loss is not an invariable cause of tinnitus. The pathology necessary to initiate tinnitus may be quite subtle. The survey data also confirm that as a clinical problem tinnitus is more than the presentation of its sensory features.

Idiopathic Subjective Tinnitus

Idiopathic subjective tinnitus is the most common form affecting adults, and is the focus of this chapter. By definition, this form of tinnitus excludes known objective causes, such as conductive hearing loss, endolymphatic hydrops, and cerebellopontine angle neoplasms. Historically, the pathology underlying idiopathic tinnitus was unknown, and the symptom was generally viewed as refractory to intervention. Advances in tinnitus research have revealed mechanisms likely responsible for some forms of idiopathic tinnitus. Two examples are tinnitus-associated pathology of the cochlea or head and neck, and tinnitus susceptible to somatic modulation. Both mechanisms are discussed subsequently.

Subjective tinnitus can be subtyped based on etiology, the pattern of associated hearing loss, psychoacoustic features (simple versus complex), exacerbating factors, psychological comorbidities, and the presence of somatic modulators. Tinnitus subtype classification schemes can be useful in identifying forms of tinnitus that are responsive to specific targeted treatment programs. Table 150-2 lists some useful features for subtyping tinnitus.

Hearing Loss Subtypes

The two most common types of hearing loss associated with tinnitus are noise-induced hearing loss (NIHL) and presbycusis. NIHL is a

Table 150-1

Objective Tinnitus

Pulsatile

- Synchronous with pulse
  - Arterial etiologies
    - Arteriovenous fistula or malformation
    - Paraganglioma (glomus tympanicum or jugulare)
    - Carotid artery stenosis
    - Other atherosclerotic disease (subclavian, external carotid)
    - Arterial dissection (carotid, vertebral)
    - Persistent stapedial artery
    - Intratympanic carotid artery
    - Vascular compression of cranial nerve VIII
    - Increased cardiac output (pregnancy, thyrotoxicosis)
    - Intraosseous (Paget's disease, otosclerosis)
  - Venous etiologies
    - Pseudotumor cerebri
    - Venous hum
    - Jugular bulb anomalies
- Asynchronous with pulse
  - Palatal myoclonus
  - Tensor tympani or stapedius muscle myoclonus

Nonpulsatile

- Spontaneous otoacoustic emission
- Patulous eustachian tube

Table 150-2

Subjective Tinnitus Subtypes

- Pattern of hearing loss
  - Noise-induced hearing loss
  - Presbycusis
  - Unilateral
  - High-frequency hearing loss
  - Outer hair cell dysfunction
- Somatic tinnitus
  - Temporomandibular joint dysfunction
  - Cervical dysfunction
  - Gaze-evoked
  - Cutaneous-evoked
  - General somatosensory modulated
- Typewriter tinnitus
- Exacerbated by sleep or rest
- Musical/complex
- Associated affective disorder
- Intrusive (versus habituated)

significant and growing health problem. Although reduction of exposure to occupational noise has been effective in the last several decades, there has been a notable increase in the incidence of NIHL from recreational and leisure activity in children and adolescents, and military combat–related noise exposure in young adults.[7-9] A Web-based survey of 9693 adolescents determined that 61% of respondents experienced hearing loss and temporary tinnitus after attending concerts.[10] Acute transient tinnitus is nearly universal immediately after unprotected exposure to loud acoustic stimuli such as gunfire and amplified music. Tinnitus prevalence among Army personnel evaluated for hearing complaints after deployment was 30% compared with 1.5% in personnel not deployed.[8]

The prevalence of chronic tinnitus associated with NIHL is 50% to 70%.[11] Subjectively, the sensory aspects of acute and chronic tinnitus can be very similar. Chronic tinnitus occurs in a delayed time course for a significant portion of individuals with a history of exposure to damaging sounds. It is unknown if the pathology of transient acoustic trauma–induced tinnitus is the same as the pathology responsible for chronic tinnitus associated with permanent noise-induced threshold shifts. Chronic tinnitus induced by acoustic trauma occurs at a younger age than tinnitus associated with other types of hearing loss. Consequently, acoustic trauma–induced tinnitus is experienced for a longer portion of the life span than other forms of tinnitus.

NIHL and associated tinnitus are preventable. In addition to obvious proactive methods, such as wearing ear protective hardware, intervention in the periexposure period may prove useful in preventing the onset or progression of NIHL, and possibly the incidence of tinnitus. Intense sound exposure triggers a reduction of blood flow and a cascade of metabolic events in the cochlea, with formation of reactive oxygen and nitrogen species that damage cellular lipids, proteins, and DNA, culminating in increased cell death.[12] Interventions targeting these molecular mechanisms of NIHL include antioxidant therapy such as vitamin E, salicylate, and *N*-acetylcysteine.[13] *Ginkgo biloba* extract contains multiple compounds with vasotropic, potential neuroprotective, and antioxidant effects. Although uncontrolled trials and anecdotal reports have suggested the efficacy of ginkgo, a more recent review failed to show efficacy in treating tinnitus.[14]

Serum magnesium levels have been correlated with NIHL in animals.[15] Controlled studies in humans have shown the prophylactic efficacy of oral magnesium in preventing temporary and permanent NIHL.[16,17] It is unknown, however, if these interventions are also effective in decreasing the risk of immediate or delayed onset of tinnitus after traumatic injury.

Presbycusis is sensorineural hearing loss related to aging. Most cases of presbycusis cannot be strictly and solely attributed to aging, but rather involve some combination of cochlear injury from additional sources, such as cumulative noise injury, metabolic or vascular dysfunction, and genetic predisposition. Elderly patients with diabetes have significantly higher pure-tone thresholds, lower otoacoustic emission amplitude, and lower speech recognition in noise[18] than age-matched individuals without diabetes.[19] Interactions between age and other factors affecting the cochlea and auditory pathway make identification of a single mechanism for presbycusis-associated tinnitus and an effectively targeted intervention a challenge.

Somatic Tinnitus Subtype

Somatic tinnitus is a unique form of tinnitus in which the loudness, laterality, or tonality of the tinnitus can by modulated by somatic stimuli. This form of tinnitus was originally observed in a small group of patients after surgical removal of large vestibular schwannomas.[20,21] Postoperatively, these patients had the ability to modulate their chronic tinnitus by exaggerated eye movements, leg motion, or gentle cutaneous stimulation of the hands or face.[22,23] The presumed mechanism of action for this unusual form of tinnitus is neural sprouting or aberrant reinnervation after auditory deafferentation. Subsequent to these observations, however, a more general form of somatosensory modulation has been found in patients with idiopathic tinnitus. In these cases, tinnitus is modulated by maneuvers or stimulation of the head and neck region. It has been reported that forceful isometric contraction of the head and neck muscles can modify the loudness and pitch of tinnitus in 65% to 80% of patients with mild, idiopathic tinnitus.[24-26] Tinnitus can be induced by strong contractions of muscles in the jaw, head, or neck in 58% of subjects without a history of tinnitus.[25]

The association between tinnitus and somatic pathology of the head and neck is underscored by the reported higher incidence of tinnitus in individuals with temporomandibular joint dysfunction and normal audiometric thresholds compared with controls.[27] One third of patients with symptoms of temporomandibular joint dysfunction reported modulation of tinnitus with jaw movement or pressure applied

to the temporomandibular joint.[28] When tinnitus occurs in association with disorders of the head and neck, such as temporomandibular joint dysfunction, unilateral facial pain, otalgia, and occipital or temporal headache, successful tinnitus alleviation may be possible using interventions targeting the somatic dysfunction.

Animal research has established that multimodal and in particular somatic inputs to the auditory pathway are evident from auditory brainstem to cortex.[29-33] These inputs allow integration of information from vision, head position, and internal sound (e.g., vocalization) to be used in important functions, such as sound localization and auditory selective attention. It has been hypothesized that aberrations in these multimodal connections can either trigger tinnitus or modulate existing tinnitus. Reduction of normal afferent input to the auditory brainstem (e.g., cochlear nuclei) may trigger inappropriate compensatory up-regulation of somatosensory inputs to these regions. Stimulus-driven or spontaneous activity within the nonauditory somatic pathways may be perceived as an audible "sound."[33]

Recognition of somatic tinnitus is important because it may be amenable to targeted intervention. Levine and colleagues[34] systematically reviewed the efficacy of treatments targeting somatosensory systems. They defined somatic tinnitus syndrome as tinnitus that is (1) perceived in the ear and (2) ipsilateral to the somatic trigger and (3) not associated with any new hearing complaints. Tinnitus that is strongly lateralized to one ear in the presence of symmetric hearing (including symmetric hearing loss) would theoretically have a somatic etiologic component by the definition of Levine and colleagues.[34] The review by these authors presents evidence that somatic tinnitus is often responsive to acupuncture, electric stimulation of the scalp and auricle, trigger point treatment, and treatment of temporomandibular joint dysfunction.[34]

Typewriter Tinnitus Subtype

Typewriter tinnitus is defined, as its name implies, by a characteristic sensation. The tinnitus has a staccato quality, similar to a typewriter tapping, popcorn popping, or Morse code signal. Its presence is intermittent and chronic. It may be confused with tinnitus arising from a muscular source, such as spasm of the tensor tympani or stapedius muscle, or palatal myoclonus. That typewriter tinnitus is a condition distinct from these somatic sources is supported by a case history of a patient with typewriter tinnitus that failed to respond to multiple treatments, including tensor tympani and stapedius resection. The patient was successfully treated, however, with carbamazepine (Tegretol). This case illustrates the importance of accurate recognition and diagnosis of typewriter tinnitus.[35] A small case series reporting successful treatment with carbamazepine suggested that typewriter tinnitus may be caused by vascular compression of the auditory nerve ipsilateral to the tinnitus.[36]

Tinnitus Treatment Strategies

Auditory Deprivation and Neural Plasticity

Acoustic-based tinnitus treatments encompass a range of delivery systems and types of sound. The rationale for using external sound to treat tinnitus derives from the hypothesis that hearing loss leads to deafferentation-induced reorganization of the auditory pathway. Hearing loss decreases the afferent stream of neural activity from the cochlea to the auditory cortex. Chronic deafferentation alters activity in the auditory brainstem and midbrain, and may change the tonotopic organization of the auditory cortex. Brainstem spontaneous activity may increase, and midbrain patterns may change (e.g., with aberrant synchronization or bursting) because of compensatory down-regulation of inhibition. Altered activity in the auditory pathway may be responsible for the tinnitus percept. Stimulus interventions that restore afferent input to more normal levels may act through improved inhibition. They may also restore cortical tonotopic organization to normative levels and reduce tinnitus.

A related phenomenon that illustrates the concept and treatment of deafferentation-induced cortical plasticity is phantom limb pain.[37] The phantom limb syndrome is the continued sensation of the presence of an absent limb, in a distorted or painful manner, after amputation. Amputation of a limb is an extreme form of deafferentation. The parallels between tinnitus and phantom limb pain, in terms of onset rate, persistence, and affected ages, are striking. Greater than 90% of amputees experience a vivid limb phantom immediately after amputation.[37] Phantoms are more likely to occur in adults than in children.[38] In many cases, the phantom sensation fades after days or weeks, but it persists chronically for decades in 30% of patients.[37]

It is well known that the adult and the immature brain can undergo plastic change. Neural plasticity is the ability of a neuron or neural network to change its function, organization, and connectivity through long-term alterations in synaptic efficiency.[39] Neurons can significantly alter their response to inputs, and receptive field sizes change, as a consequence of either decreased or increased input and training procedures.[40] The changes can be extensive. Magnetoencephalographic studies have shown that stimulation of intact body areas distant from the amputation site is perceived, with corresponding central neural activity, at the cortical site of the amputated limb.[41] Similar changes of auditory cortical representation may underlie tinnitus.[42] Primary auditory cortex steady-state evoked magnetic fields were enhanced in tinnitus patients compared with controls, and the degree of enhancement correlated with the perceived intensity and intrusiveness of the tinnitus.[43] Functional imaging studies in humans have suggested that expanded representation of frequency regions in the auditory cortex may underpin tinnitus.[44-47]

Animal models have been important in studying the deafferentation-loss-of-inhibition hypothesis of tinnitus, and have been used to evaluate sound therapy for reversal of pathologic neural plasticity. A key study by Norena and Eggermont[48] illustrates the effect of noise trauma and therapeutic sound stimulation on receptive fields of primary and secondary auditory cortex. Cats exposed to a traumatizing noise were evaluated for changes in the location and responsiveness of auditory cortex neurons to acoustic stimuli. The frequency tuning of cortical neurons was altered after the trauma, distorting the overall representation of sound and over-representing frequencies surrounding the exposure sound. A second cohort of cats, exposed to the same traumatizing sound, was subsequently reared in an enriched acoustic environment for several weeks before mapping the auditory cortex. The enriched environment was spectrally composed to compensate for the anticipated frequency distortions induced by hearing loss.

Two important outcomes were obtained in the cats raised in the enriched environment: (1) Their hearing loss was significantly reduced compared with the cats with similar sound exposure raised in a quiet environment, and (2) there was no evidence of plastic reorganization of the auditory cortex. The tonotopic organization of the exposed and treated cats was similar to that of unexposed control cats. These results suggest that tinnitus may be partly the result of abnormal reorganization of the auditory cortex. These results show that therapeutic acoustic intervention may be effective in reducing or eliminating the abnormal cortical organization associated with, and potentially responsible for, tinnitus. The implications for tinnitus treatment using sound therapy are obvious.

Using Sound to Decrease Loudness and Annoyance of Tinnitus

Acoustic stimulation is an important component of successful management of tinnitus in many patients. A wide range of acoustic delivery strategies are currently available. Most patients with tinnitus, including patients with minimal threshold shift on standard audiometric testing, can benefit from acoustic stimulation. Patients with severe to profound hearing loss that is not amenable to conventional amplification can achieve tinnitus relief from other modes of auditory pathway stimulation, such as cochlear implantation or cortical stimulation (discussed later).

Ambient Stimulation

The simplest method of increasing afferent input to reverse putative central reorganization and tinnitus is environmental sound enrichment. Use of supplemental environmental sound to treat tinnitus has been recommended for more than 50 years.[49] Enrichment can be achieved using background music, relaxation tapes or CDs, tabletop nature sound machines, or waterfalls or fountains. Patients are typically instructed to use a source of constant background sound to decrease attention to their tinnitus. Sound enrichment is not intended to mask

the tinnitus in the conventional sense of completely eliminating the tinnitus percept (discussed subsequently). Rather, by elevating the level of ambient sound using a constant, spectrally rich stimulus, the tinnitus sensation becomes less noticeable.

Hearing loss is present in more than 90% of patients with tinnitus. Conversely, epidemiologic studies have reported tinnitus prevalence of 50% in hearing-impaired patients.[50] Effective use of sound stimulation for managing tinnitus in hearing-impaired patients can be achieved only with appropriate amplification. Typically, amplification is achieved with hearing aids. Even without supplemental sound, the therapeutic effect of hearing aids for tinnitus patients is well documented.[51,52] Hearing aids reduce the awareness of tinnitus through amplification of ambient sound and reduce the perception that tinnitus masks hearing and impedes communication.

Surr and coworkers[53] reviewed the initial effect of hearing aid use on tinnitus in 124 patients. Approximately one half of patients reported that the hearing aid reduced (26%) or eliminated (29%) the tinnitus. Folmer and Carroll[54] reviewed their clinical experience with 50 patients with mild to moderate sensorineural hearing loss fitted with hearing aids for tinnitus management. Patients were re-evaluated 6 to 48 months after initial fitting (mean 18 months), and 70% reported significant improvement in their tinnitus. Similar results were obtained in a larger study of 1440 patients fitted with hearing aids for unilateral or bilateral hearing loss.[55] In this study, digital hearing aids provided significantly greater tinnitus relief than analog hearing aids. Of patients fitted with digital hearing aids for unilateral hearing loss, 65% reported greater than 50% improvement in tinnitus compared with 39% reporting a similar degree of improvement after fitting with an analog aid. An even greater therapeutic effect was obtained with bilateral digital hearing aids: 85% of patients reported greater than 50% improvement in tinnitus compared with 30% fitted with bilateral analog aids.

Programmable digital hearing aids can selectively amplify within the high-frequency range, a region where most tinnitus patients typically have some measurable threshold loss. Current-generation digital aids have significant output gain up to 10 kHz, which significantly benefits tinnitus patients with hearing loss in the high-frequency range. An open-fit, nonoccluding ear mold is crucial to minimize the occlusion effect, which can amplify the tinnitus percept.[56]

Personal Listening Devices

Tinnitus management can be implemented through the use of personal listening devices, such as flash-memory music players. Miniaturization, data storage, and digital software have greatly expanded the available tools that clinicians and patients can use to produce a customized sound library. Inexpensive online sources are also available for downloading digital sound specifically developed for tinnitus therapy (e.g., http://www.vectormediasoftware.com). Patients can build and use a small library of sounds, which may include music to their liking, nature sounds, and noise bands of different spectral composition. Important key features of any regimen of amplified sound therapy are (1) use of open-fit, nonoccluding ear level drivers, (2) long-term exposure to the sounds, (3) sound spectral composition that is reasonably broad, and (4) sound levels below that of the perceived tinnitus.

Appropriate patient education is crucial to successful treatment. Many treatment failures occur because patients erroneously expect complete elimination of tinnitus after a few days to weeks of treatment. Patients must be counseled about the typical slow time course of improvement, and must be encouraged to have realistic expectations about the benefits of sound therapy. Sound therapy can decrease the subjective loudness and significantly decrease the annoyance of tinnitus, but this may require weeks to months of daily application.[57,58]

Total Masking Therapy

Total masking therapy is the use of sound with spectral characteristics and sufficient volume to render the tinnitus inaudible. This form of sound therapy has likely been used for centuries, and derives from empirical experience that certain environmental sounds are efficient tinnitus maskers. The clinical use of total masking therapy has a long history.[59] A formal masking therapy program was first proposed by Vernon and Schleuning.[60] Patients are fitted with ear-level devices that generate sound. The devices can be adjusted to have outputs with different frequency spectra and levels. There is no codified scheme for selecting effective masker characteristics. The general fitting principle is to determine the minimum level of broadband noise that masks the tinnitus without interfering with communication. The fitting is empirical because there is a wide range of patient preference in the type and level of sound that masks the tinnitus and is not perceived as annoying.[61,62] Two significant benefits likely attend the successful application of total masking therapy: (1) Patients have control over their tinnitus, and (2) patients experience immediate relief with complete elimination of tinnitus.[63]

Benefits from masking therapy have been shown in a large prospective controlled study of chronic significant tinnitus in U.S. veterans.[64] Validated standardized tinnitus severity questionnaires were used to screen and enroll 123 subjects with clinically significant tinnitus. Subjects were quasirandomly assigned to either the total masking group or a tinnitus retraining therapy (TRT) group. Subjects in the total masking group received hearing aids, maskers, or combination instruments, and all received information counseling over an 18-month follow-up period. Subjects in the TRT group received standardized TRT treatment (see later). All subjects were evaluated for response to treatment at 6, 12, and 18 months. Subjects in both treatment groups showed improvement on multiple measures of tinnitus over the course of the study. Subjects in the total masking group who rated their tinnitus as a "moderate" problem had effect sizes between 0.27 and 0.48 compared with effect sizes for the TRT group of 0.77 and 1.26 at 18 months. Mean effect sizes in subjects with tinnitus rated as a "very big problem" were 0.64 in the total masking group and 1.08 in the TRT group. Although both therapies resulted in clinically significant improvement in tinnitus with medium (>0.5) to large (>0.8) effect sizes, optimal outcomes were obtained with long-term TRT treatment.

Acoustic Stimulation Combined with Education and Counseling

TRT combines sound therapy with a formalized program of directive counseling to achieve habituation to tinnitus.[65] TRT is based on the assumption that tinnitus distress derives from activation of an emotional and an autonomic response to tinnitus.[66] Within this theoretical framework, tinnitus emerges as a result of damage or dysfunction within the auditory pathway, and is detected at subcortical levels of the brain. The critical event that leads to clinically significant tinnitus is not its sensory features, but rather the perception and evaluation of the tinnitus-related neural activity that occurs in the auditory cortex, and subsequent cortical interaction with the limbic system, prefrontal cortex, and cortical association areas.[65] According to Jastreboff and Hazell,[65] tinnitus becomes clinically significant when a negative affective response to the tinnitus has been established.

The goals of TRT are to remove, decrease, or change the perception of tinnitus by promoting habituation of the reactions to the tinnitus sensation. Habituation of the reaction to tinnitus would reduce the derived annoyance, anxiety, and stress. A key feature of TRT involves behavioral retraining of the associations induced by the tinnitus sensation. TRT uses five distinct levels of therapy, aimed at stratified patient groups. Stratification is based on tinnitus distress, associated hearing impairment, presence of sound-induced exacerbation of tinnitus, and comorbid hyperacusis (see later). The five strata are (1) patients with tinnitus that causes minimal distress (category 0); (2) patients with tinnitus causing distress (category 1); (3) patients with distressing tinnitus and hearing loss (category 2); (4) patients with distressing tinnitus, normal hearing, and hyperacusis (category 3); and (5) patients with distressing tinnitus, normal hearing, hyperacusis, and prolonged sound-induced exacerbation of tinnitus (category 4). Treatment is specific for each patient category, and uses directive counseling, auditory enrichment, hearing aids, and sound generators.

Jastreboff and Hazell[65] described directive counseling as a teaching session in which patients are instructed on the mechanisms of tinnitus generation. Directive counseling demystifies tinnitus for the patient, and attempts to eliminate anxiety and fear of tinnitus through education. Auditory enrichment is typically achieved through the use of broadband noise generators. Ear-level devices physically similar in design to maskers are used, but sound output is distinctly lower than

that used in masking therapy where sound levels render the tinnitus inaudible. In TRT, the volume of noise is set at a partial masking level, which allows continued perception of the tinnitus. The concept is that habituation would normally occur to the noise, much as one habituates to the background sound of a running air conditioner. Because the external noise and the internal tinnitus are equivalent in loudness, or "mixed," habituation generalizes to the tinnitus and its attendant emotional reactions.

Retrospective clinical trials evaluating the efficacy of TRT have generally been positive with a consensus that TRT reduces the annoyance and impact of tinnitus within a time frame of 12 to 18 months. Sheldrake and associates[67] reported a retrospective review of clinical outcomes on 224 patients completing a course of TRT. Outcome measures were percentage of time of tinnitus awareness, tinnitus distress, and the number of life factors affected by tinnitus. A successful outcome was defined as either a 40% improvement in tinnitus annoyance and awareness or 40% improvement in annoyance or awareness plus an improvement or facilitation of one life factor. At 6 months, 70% of patients had a successful outcome, and this percentage increased to 84% by 18 months. The mean awareness of and distress related to tinnitus before therapy were 63% and 45%, whereas after 18 months of therapy these percentages were 15% and 5%.

Bartnik and colleagues[68] retrospectively reviewed the 12-month outcomes of 108 clinic patients treated with TRT for chronic tinnitus. Significant improvement was defined as a minimum decrease of 20% in at least three of these parameters (impact on daily life, time aware of tinnitus, degree of annoyance, and tinnitus intensity). Significant improvement was reported for patients treated with counseling alone (79%), counseling combined with noise generators (73%), and counseling combined with hearing aids (88%).

Berry and coworkers[69] reported the 6-month results of a nonrandomized, prospective analysis of 32 patients treated with TRT. Treatment outcomes included psychophysical measures of loudness discomfort levels; minimal masking levels; and a standardized, validated measure of tinnitus severity and disability (Tinnitus Handicap Inventory [THI]; see later). Average THI score (pretreatment total score 52) significantly improved after 6 months of therapy (post-treatment total score 24; $P < .001$). Nine patients with sound sensitivity (hyperacusis) before treatment had a significant ($P < .05$) increase in sound tolerance after therapy, indicated by a 14 dB HL improvement in loudness discomfort level.

TRT is derived from a reasonable set of assumptions about the mechanism of disruptive chronic tinnitus, and may provide an effective therapeutic option for some patients. Evaluation of TRT effectiveness using the gold standard of a randomized controlled trial with multiple outcome measures is yet to be reported, however.

Acoustic Desensitization Protocol

The acoustic desensitization protocol is a proprietary tinnitus treatment program (Neuromonics, Bethlehem, PA) that combines features of sound therapy; systematic desensitization; directive counseling; and supportive intervention for stress management, sleep disruption, and coping strategies. Systematic desensitization is a psychological technique originally developed for the treatment of phobias. Progressive gradual controlled exposure to the phobic stimulus within the context of a deeply relaxed state of mind results in a gradual desensitization of the phobic response to the stimulus.[70] This technique has been adapted to the treatment of tinnitus, by targeting the individual's tinnitus as the stimulus that provokes the phobic, or at least negative emotional, response.

Patients listen to their tinnitus in gradual, progressive increments within a background context of pleasant, relaxing therapeutic sound. The therapeutic sound has three key features that are fundamental to the protocol. The sound used is music spectrally modified in accord with the patient's hearing loss, with enhancement of loudness levels of frequencies where hearing loss is pronounced, re-establishing stimulation of the auditory pathway over a wide frequency range. Music that is nonintrusive and has a slow rhythm is used to maximize relaxation during treatment. The music has a dynamic component that permits intermittent tinnitus perception alternating with tinnitus masking. The gradual exposure to one's tinnitus in the context of therapeutic music is achieved using a staged treatment program. In the initial stage, the spectrally modified music is embedded within a background sound of high-frequency noise that masks the tinnitus. In the second stage, the masking noise is removed, and the tinnitus percept becomes gradually and progressively more audible.

A Neuromonics-sponsored outcome study of the acoustic desensitization protocol has shown positive effects.[71] In the study, 35 patients with moderate to severe tinnitus received Neuromonics tinnitus treatment and were tested for subjective (distress, awareness) and objective (minimum masking levels, loudness discomfort levels) changes at four time points, including 1 year, after therapy. Within the first 6 months of treatment, 91% of participants reported an improvement in tinnitus distress, reflecting a mean improvement of 65% in the Tinnitus Reaction Questionnaire. The reported "percent of time aware of tinnitus" before therapy was 90%, which was significantly reduced to 30% after 12 months of therapy.

Cognitive-Behavioral Therapy for Tinnitus

Cognitive-behavioral therapy (CBT) is a well-established psychotherapy based on identification of maladaptive behaviors and their modification using therapist-mediated cognitive restructuring. The technique has been successfully applied to tinnitus for many years, and forms the basis of another type of habituation therapy for tinnitus.[66] CBT for tinnitus is based on the concept that the normal response to meaningless stimuli is habituation, and tinnitus distress results from a failure to habituate. Jakes and associates[72] summarized the causes of habituation failure to include emotional responses, orientation to stimuli, arousal, and unfavorable signal-to-noise ratio. When a normal subject is presented repeatedly with a meaningless stimulus, responses to the stimulus, such as orientation, attention, and cognitive processing, soon habituate (i.e., the responses drop out). When the same subject is presented repeatedly with a noxious stimulus (e.g., the cry of a baby), sensitization occurs (i.e., the response to the stimulus becomes more pronounced and may have an emotional component). CBT uses techniques of reassurance, relaxation training, and selective attention distraction to induce habituation to tinnitus. It may be, as suggested by some, that defusing the emotional component of tinnitus, with or without concomitant changes in tinnitus loudness, is sufficient for improving patient outlook and perception.[72]

A review of CBT as a tinnitus treatment by the Cochrane Collaboration evaluated six trials comprising 285 participants.[73] The primary outcome measure was subjective tinnitus loudness, and the secondary outcome measures were improvement in symptoms of mood disturbance and quality-of-life evaluation. The pooled results for the five trials reporting subjective loudness before and after treatment showed no significant difference between treatment with CBT and either a waiting list control or an alternative treatment. There was also no significant treatment effect for the secondary outcome measures of depression and mood disturbance. There was a significant improvement, however, in the quality of life of CBT participants, as measured by a global decrease in tinnitus severity, with a standardized mean difference of 0.70 (95% CI 0.33 to 1.08). The reviewers conclude that CBT has a significant impact on the qualitative aspects of tinnitus and contributes positively to the management of tinnitus.

Nevertheless, controversy continues regarding the relative benefits of CBT and sound stimulation in promoting psychological and physiologic habituation in patients who have chronic tinnitus. Hiller and Haerkotter[74] followed 124 outpatients with chronic tinnitus, randomly assigned to either CBT alone or CBT combined with sound stimulation using noise generators. Tinnitus-related distress and psychosocial functioning were significantly improved in both groups, with no additive benefit observed in the sound-stimulation group.

Transcranial Magnetic Stimulation

The more recently developed diagnostic and treatment technique of transcranial magnetic stimulation (TMS) has opened a novel avenue for investigating the causal and associational aspects of tinnitus-related cortical activity, and may provide an effective tinnitus therapy for some patients. TMS uses a brief intense current in a surface coil applied to the scalp to induce a magnetic field in the underlying brain. The mag-

netic pulse induces a temporary focal disruption of neural activity in a discrete area of cortex. This "virtual lesion" briefly, and reversibly, disrupts cortical activity and allows the investigator to determine if the cortical region of interest contributes to a specific behavior or perception.[75] The effect of a single pulse-induced magnetic field is short-lived, on the order of milliseconds. Repetitive TMS over seconds to minutes causes neuronal depolarization within the superficial cortex. Low-frequency (<1 Hz) repetitive TMS decreases cortical excitability,[76] whereas high-frequency (5 to 20 Hz) repetitive TMS increases cortical excitability.[77] All repetitive TMS frequency parameters can induce long-term plastic changes in cortical function that reportedly outlast the stimulation period by hours to days.[78]

TMS can be combined with functional imaging techniques to locate regions of interest for TMS application, and to examine the effect of cortical stimulation on distant structures. The combined techniques of TMS and functional brain imaging may be useful for investigating cortical mechanisms of tinnitus, and may be of clinical value as a treatment for some forms of tinnitus. Enhanced cerebral blood flow in temporoparietal cortex was shown using positron emission tomography (PET) imaging in patients who could modulate their tinnitus with orofacial movement[46] or eye position.[45] The association between tinnitus loudness and temporoparietal cortical blood flow was also observed in studies using lidocaine as a tinnitus modulator.[47,79,80] To date, there have been no studies correlating changes in regional cerebral blood flow and altered tinnitus sensation modulated by repetitive TMS, although combining these methods might be revealing.

The functional relevance of temporoparietal cortex activity to tinnitus was first suggested by studies examining the effect of repetitive TMS on auditory hallucinations. Three patients with schizophrenia and persistent auditory hallucinations were studied in a double-blind crossover design using low-frequency (1 Hz) repetitive TMS to the left temporoparietal cortex versus sham stimulation. All three subjects reported significant improvement in severity of hallucinations after active treatment compared with sham stimulation. Two subjects had near-complete cessation of hallucinations for 2 weeks after treatment.[81] Meta-analysis of the effect of repetitive TMS on auditory hallucinations in schizophrenic patients has supported these early results, and shows a significant positive effect.[82]

Plewnia and coworkers[83] showed short-term suppression of idiopathic subjective tinnitus after high-frequency (10 Hz) TMS stimulation of temporoparietal cortex. Fourteen adults with chronic tinnitus were stimulated at 12 cortical locations with 10 Hz repetitive TMS for 3 seconds, repeated five times, and at two control locations for sham stimulation. Eight of the 14 subjects reproducibly reported on more than one trial an immediate decrease in tinnitus loudness after repetitive TMS, ranging from slight decrease to complete suppression. Five subjects did not perceive a reproducible attenuation of tinnitus, and one subject reported transient increase in tinnitus loudness that persisted for 2 weeks. Post-hoc analysis showed that the strongest tinnitus attenuation was obtained with stimulation of left temporal and left temporoparietal cortex.

Long-term inhibition of cortical hyperactivity can be induced using low-frequency repetitive TMS.[76,84] In a double-blind, crossover, placebo-controlled (sham stimulation) trial of low-frequency repetitive TMS, PET-guided neuronavigation was used to target hyperactive areas within the superior temporal gyrus of 14 patients with chronic tinnitus (tinnitus durations of 1 to 30 years). The left temporal lobe was targeted in 12 patients, and the right lobe was targeted in 2 patients. After 5 days of treatment (2000 stimuli/day) there was a 7-day nontreatment interval, followed by 5 days of sham treatment. A significant reduction in standardized tinnitus questionnaire score was observed after active treatment ($P < .005$), but not after sham stimulation ($P = .336$).[85] At 6-month follow-up, five patients reported worse tinnitus, with a mean increase in tinnitus questionnaire score of 5, and eight patients had an average 12. 4 decrease in tinnitus questionnaire score. Three of the eight patients had a clinically significant reduction in score of 16 to 34 points. There was no correlation between initial tinnitus severity or tinnitus duration and the response to active treatment.

Plewnia and coworkers[86] subsequently examined the immediate effect of neuronavigated low-frequency repetitive TMS and sham stimulation on tinnitus loudness in another eight subjects in a single-blind crossover trial. Tinnitus loudness was assessed using an 11-point visual analog scale, with −5 indicating suppression of tinnitus, 0 no change, and +5 indicating increased loudness. Areas shown to be correlated with the tinnitus percept on PET imaging were primarily in sensory association cortex, but not primary auditory cortex. These included the left middle and inferior temporal cortex, the right gyrus angularis, and the posterior cingulum. Two of the eight subjects showed a decrease in tinnitus loudness (−3 and −5) after active low-frequency repetitiveTMS, and no change after sham stimulation. Three subjects were nonresponders during active and sham stimulation, and the three remaining subjects reported moderate (−2) to significant (−5) reduction in tinnitus loudness after active stimulation and sham stimulation. The outcomes of these evaluations of TMS were very mixed.

If TMS is effective in reversing neurogenic pathology, its mechanism of action remains unclear. High-frequency repetitive TMS can result in long-lasting clinical improvement in cases of chronic neurogenic pain, suggesting that the therapeutic effect may not be related to a reduction in cortical excitability, but rather be through reversal of chronic maladaptive plastic changes.[87] The long-term effect of different repetitive TMS stimulation rates delivered to the left temporoparietal cortex was assessed in 39 subjects with chronic tinnitus (duration 6 months to 25 years).[88] Subjects were randomly assigned to one of four stimulation groups (1 Hz, 10 Hz, 25 Hz, or sham stimulation) and treated with five sessions over a 2-week period. All subjects in the active repetitive TMS groups reported significant improvement ($P < .05$) in tinnitus severity on the standardized THI questionnaire at 4 months after completing treatment compared with the sham treatment group. Tinnitus improvement occurred regardless of stimulation rate for active repetitive TMS. A greater proportion of subjects experienced an 80% or greater improvement in THI score after treatment with 10 Hz (29%) and 25 Hz (35%), however, than after 1 Hz (6%). As reported in other studies, there was a negative correlation between tinnitus duration and percent improvement 4 months after treatment.

Further work is needed in this area to understand the mechanisms of TMS and its efficacy in treating tinnitus. It is unknown if the tinnitus-associated hyperactivity in secondary auditory cortex normalizes after subjectively successful treatment with repetitive TMS. There currently is no consensus on the relationship of hemispheric dominance and metabolic hyperactivity to tinnitus. Some studies have shown left temporoparietal activity is associated with tinnitus,[45,46] and others have shown right-sided dominance.[47,80] Finally, there are conflicting results on the effect of tinnitus duration on responsiveness to TMS.

Electric Stimulation

Electric stimulation has been used to treat tinnitus since the advent of Volta's battery in the early 19th century.[89] Although anodal direct current has been used by multiple investigators to suppress tinnitus, practical use is limited by tissue damage induced by chronic stimulation with direct current.[90] Nondestructive methods of delivering electric current required the development of improved noninvasive techniques, such as transcutaneous electric stimulation, and surgically implanted devices using alternating current, such as cochlear implants and cortical stimulators.

Transcutaneous Electric Stimulation

Initial systematic attempts to decrease tinnitus using transcutaneous electric stimulation used the Audimax Theraband, a device that delivers inaudible, transdermal electric current to the mastoid eminence. Lyttkens and colleagues[91] showed complete tinnitus suppression in one of five patients treated with transcutaneous stimulation. In a larger double-blind crossover study, 20 patients were treated first using the active device followed by a placebo device in which the internal circuitry was deactivated. Four patients (20%) reported reduction with the placebo, whereas two patients (10%) reported tinnitus reduction with the active device. One of the responders was examined further with random trials of either active or placebo stimulation, and reported a median 70% tinnitus decrease during active stimulation and 16% decrease during placebo stimulation.[92] A subsequent single-blind cross-

over study of 30 patients showed a similar proportion of patients responded to stimulation.[93] Levine and coworkers[34] reviewed the characteristics of tinnitus patients who respond to transcutaneous electric stimulation and concluded that the common finding present in all cases is tinnitus with features of somatic modulation.

Herraiz and associates[94] prospectively studied the effect of transcutaneous electric nerve stimulation in 26 patients with tinnitus categorized as somatically modulated. Although the trial lacked a placebo control, a striking effect was obtained in this sample from a selected population, with tinnitus elimination in 23% and tinnitus improvement in 23%. Further analysis by tinnitus type showed that the group most responsive to transcutaneous electric nerve stimulation treatment had typewriter tinnitus, with 88% experiencing improved or eliminated tinnitus.

Cochlear Implants

Suppression of tinnitus as a secondary benefit of cochlear implantation was noted in the early days of cochlear implant development.[95] Although there is a large variability in the methods of assessing and reporting tinnitus, most studies report a consistent and clinically significant beneficial effect of cochlear implantation on tinnitus suppression.[96] A significant proportion of patients (38% to 85%) report either a decrease or complete suppression of tinnitus after intracochlear electrode insertion before initial stimulation.[97] Although there have not been extensive studies, there does not seem to be a significant difference in effective tinnitus suppression with different device manufacturers. Cochlear stimulation has been reported to reduce tinnitus intensity perceived in the ear contralateral and ipsilateral to the implant.[97] This is not paradoxical because the brainstem cochlear nuclei have contralateral connections, and bilateral elevation of spontaneous activity in the dorsal cochlear nucleus has been shown in animals with tinnitus induced by unilateral acoustic trauma.[98]

The effectiveness of cochlear stimulation on decreasing tinnitus loudness increases over time. Tinnitus was suppressed in 65% of patients on initial stimulation, but after a 2-month period, stimulation suppressed tinnitus in 93% of patients. These observations suggest that the mechanism responsible for tinnitus suppression by cochlear implants may relate to reversal of maladaptive central plastic changes associated with auditory deprivation.

Multiple factors may contribute to the efficacy of tinnitus suppression after cochlear implantation, including etiology, duration, and extent of hearing loss, and stimulation strategy. Potentially, there is much to be learned about tinnitus mechanisms from patients with cochlear implants. Studies that systematically investigate the impact of these factors are few, however.

Pharmacologic Tinnitus Treatments

Written accounts indicate medical treatment of tinnitus dates back to the Egyptians (2660-2160 B.C.E.).[99] An ear that was bewitched or humming would be infused with oil, frankincense, tree sap, herbs, and soil. Mesopotamian writings considered the psychological aspects of tinnitus, possibly the earliest recognition that stress and emotional factors are significant components of tinnitus dysfunction. These early attempts at treatment contained elements that presage modern views of tinnitus pathology.

Until more recently, most pharmacologic interventions for tinnitus were empirically determined. Anecdotal experience and fortuitous observations of tinnitus relief were the primary sources of innovation. Over the past 50 years, pharmacologic treatment of tinnitus has become more rational. Anesthetics (lidocaine, tocainide, mexiletine), anticonvulsants (carbamazepine, gabapentin), and tranquilizers (diazepam, clonazepam, oxazepam) have been investigated as tinnitus treatments. They have in common the general property of facilitating neural inhibition. Antidepressants such as trimipramine, nortriptyline, amitriptyline, and selective serotonin reuptake inhibitors have been tested for their ability to ameliorate the comorbid mood disturbance associated with tinnitus. Considering only well-controlled trials, mixed results have been obtained for all drugs tested to date.

The hypothesis that tinnitus emerges from increased central neural activity after loss of inhibition can be used to guide pharmacologic intervention. Animal models of tinnitus support the loss of inhibition and enhanced neural activity hypothesis.[98,100,101] The loss-of-inhibition hypothesis provides a rational basis for numerous pharmacologic interventions, including lidocaine, carbamazepine, alprazolam, and gabapentin.

Despite the increase in targeted tinnitus drug trials, using a single agent to treat a heterogeneous large sample of subjects has been for the most part unsuccessful. Several reasons, not mutually exclusive, may account for this lack of success. Most tinnitus clinical trials randomly select and assign participants to treatment groups. There is emerging evidence, however, that tinnitus is a heterogeneous disorder with variable pathologic features.[34,102,103] Testing drugs with a single mechanism of action is unlikely to succeed when using randomly determined heterogeneous sample groups. For the same reason, trials using small dose ranges may fail.

Studies that enroll subjects with a single tinnitus etiology may be more likely to identify successful treatments. A study that examined the effect of gabapentin on tinnitus in two specific patient subpopulations obtained positive results.[104] The study was designed to test the hypothesis that acoustic trauma leads to a loss of inhibition in the auditory pathway mediated by the inhibitory neurotransmitter γ-aminobutyric acid (GABA). The hypothesis was advanced after an animal experiment that showed gabapentin, a GABA analogue, to be effective in reducing the loudness of tinnitus in rats.[100] This study used a very wide dose range, and tested one group of patients with objective and historical evidence of traumatic sound exposure, and a second group without such evidence. Gabapentin was found to reduce tinnitus annoyance significantly in the trauma group at a daily dose level of 1800 to 2400 mg. In contrast, a subsequent clinical trial studying the effect of only a single dose in a randomly selected group of patients did not obtain a significant effect.[105] The therapeutic effect was likely missed because only a single dose level was used, and the treatment group included various tinnitus etiologies. Drugs with a specific mechanism of action are unlikely to be effective in all subjects characterized by such heterogeneity. Stratified study designs with segregation of tinnitus types, etiology, and hearing characteristics should be more successful in identifying effective drug therapies.

The most extensively used drugs for tinnitus treatment are antidepressants. Attempting to treat tinnitus with antidepressants is sensible for two reasons. There is a well-recognized association between severe tinnitus and mood disorders. The pharmacologic mechanism of action of many antidepressants involves receptors and neurotransmitters that are located in the auditory pathway.[106] Although GABA deficiency seems to contribute to tinnitus pathology,[104,107-109] the role of other neurotransmitter systems in triggering or maintaining tinnitus is currently unknown. Serotonin is known to function as a modulator of sensory systems, learning, and memory. Along with acetylcholine, serotonin can affect behavioral conditioning and associated plastic changes in auditory cortex. Both neurotransmitters may be important in the distress associated with tinnitus.

Treatment with sertraline, a selective serotonin reuptake inhibitor, improved tinnitus loudness ($P = .014$) and severity ($P = .024$) in a group of tinnitus patients with an associated depressive or anxiety disorder.[110] Despite this positive evidence, it is unclear whether selective serotonin reuptake inhibitor treatment improved tinnitus directly or indirectly through alleviation of mood disorder. A placebo-controlled trial of the selective serotonin reuptake inhibitor paroxetine in a group of subjects without coexisting mood or anxiety disorder did not produce improvement in any tinnitus measure over placebo.[111]

Clinical Evaluation of Tinnitus

Clinical treatment of a patient with tinnitus should begin with a general medical evaluation followed by a complete head and neck examination. Objectives of the evaluation include a descriptive characterization of the tinnitus (psychoacoustic properties, impact on daily life, reactive components); determination of etiology; and identifying factors that exacerbate, ameliorate, or trigger the tinnitus. At a minimum, the results of the examination educate the patient about the tinnitus. Patient education is a powerful therapeutic component of the clinical process, which should not be undervalued or underestimated. A thor-

ough examination also facilitates development of a directed individual treatment plan.

Tinnitus can be described in terms of its psychoacoustic properties and in terms of the affective or reactive responses to the tinnitus. The psychoacoustic properties of tinnitus can be determined from psychophysical assessment of its features. Important features include tonality; noise aspects such as hissing, buzzing, humming, sizzling, and roaring; unilateral-bilateral localization in the head; temporal features (e.g., pulsatile vs. steady); and interaction with external sounds, including masking, inhibition, and exacerbation. The affective or reactive components include the comorbid problems of depression, sleep disruption, difficulty with concentration, sadness, anxiety, and fear. The reactive components of tinnitus are highly individual and are significant factors in tinnitus disability. Careful evaluation of both components is important for the clinician to appreciate fully the impact of the tinnitus on the individual, and to formulate a directed treatment plan.

The auditory qualities of tinnitus can be assessed using standardized questionnaires and psychophysical measurements. Basic information about the auditory characteristics of tinnitus includes localization (left, right, in the head, outside of the head), constancy (episodic, fluctuating, constant, pulsatile), pitch, loudness, and sound quality (tonal, hissing, buzzing, clicking, ringing). This information can be useful in determining etiology. Pulsatile tinnitus can imply a vascular source. Fluctuating tinnitus may be linked to specific triggers, such as foods, illnesses, stress, or acoustic trauma. Episodic tinnitus may relate to unstable hearing thresholds deriving from cochlear dysfunctions, such as hydrops or perilymph fistulas. Clicking or tapping tinnitus may occur with mechanical disorders affecting either the middle ear muscles (stapedial or tensor tympani spasm) or the auditory nerve (vascular loop or demyelination). Identification of tinnitus with specific characteristics such as these is very useful, and can lead to a directed course of therapy.

Standardized Outcome Measures

Numerous standardized questionnaires are available for measuring tinnitus severity and perceived disability. Standardized assessment is useful for documenting clinical outcomes and reporting the results of clinical trials. Standardized measures are also crucial for determining the subjective impact of tinnitus. Finally, standardized questionnaires are useful for stratifying patients according to the severity and impact of their tinnitus, which facilitates identification of specific problems, and serves to triage patient care from minimal counseling to intensive rehabilitation.

The THI is a widely used self-assessment tool.[112] It is a 25-item questionnaire that has good construct validity, strong internal consistency, and good test-retest reliability. The THI yields a total score and three subscale scores. The subscales encompass functional limitations in mental (e.g., difficulty concentrating), social, occupational and physical domains (e.g., difficulty sleeping); emotional responses to tinnitus (e.g., anger, depression, anxiety); and catastrophic reactions to tinnitus (e.g., desperation, loss of control, failure to cope). In addition to its good internal consistency and test-retest reliability, the THI has high convergent validity with the 27-item Tinnitus Handicap Questionnaire and the 52-item Tinnitus Questionnaire.[113] The 95% confidence interval for the THI is 20 points, suggesting that a difference in scores of 20 points or greater represents a statistically and clinically significant change.[112]

Tinnitus Comorbidities

As previously mentioned, severe debilitating tinnitus is frequently associated with depression, anxiety, and other mood disorders.[114-116] Comorbid emotional disturbance is not unique to tinnitus, and has been shown to accompany many chronic illnesses.[117,118] It is well recognized that coexisting mood disorders hamper improvement and interfere with treatment of conditions such as chronic pain and tinnitus. Identifying and treating comorbid conditions in tinnitus patients is an important aspect of the clinical evaluation. Tools are available to screen for mood disorders in an outpatient setting (e.g., Beck Depression Inventory, Hamilton Anxiety Scale). An important therapeutic adjunct is teaching coping skills through behavior modification and cognitive therapy.[119]

Tinnitus and Insomnia

Patients commonly report that tinnitus interferes with their ability to fall asleep, and sleep disruption is a significant comorbid condition in adults and children.[120,121] A robust correlation has been shown between the reported loudness and severity of tinnitus and degree of sleep disruption.[122,123] A positive feedback loop may exist in which tinnitus leads to sleep deprivation, and the sleep deprivation exacerbates somatic complaints, tinnitus among them. Depression and anxiety exacerbated by sleep loss may significantly interact with and compound the cycle of tinnitus and poor quality sleep. Coping ability may also deteriorate as a result of sleep deprivation or lack of restorative sleep. Interventions that break this cycle by improving sleep have been shown to improve tinnitus.

Pharmacologic sleep aids such as melatonin can reduce tinnitus severity, particularly in patients with pronounced sleep difficulties.[14,125] Bedside sound generators have also been shown to improve sleep quality significantly and lessen tinnitus distress. The bedside sounds most frequently chosen are often selected for their perceived positive emotional effect.[126]

Sleep difficulties include insufficient sleep, poor quality sleep, and nonrestorative sleep. Psychological and behavioral management of sleep disturbance is an effective treatment modality.[127] McKenna and Daniel[128] have outlined a treatment strategy that addresses tinnitus and insomnia as components adversely affected by anxiety.

Hyperacusis

There is no single, universally accepted definition of hyperacusis, and there is no consensus on the physiologic mechanisms that cause the condition. Hyperacusis has been defined as noise intolerance, annoyance caused by ordinary sounds, and abnormal discomfort for suprathreshold sound.[129] These definitions distinguish hyperacusis, considered by many to be a central phenomenon, from recruitment. Recruitment is the rapid growth of perceived loudness with increasing stimulus level, and is observed in association with cochlear hearing loss and outer cell dysfunction. Hyperacusis frequently occurs in association with tinnitus, but can be present without tinnitus or any associated hearing loss. Hyperacusis can occur after the loss of the stapedial reflex in association with acute facial paralysis,[130] in association with general conditions such as migraine attacks,[131] in association with Lyme disease,[132] as a result of benzodiazepine withdrawal,[133] or as part of a syndrome.[134] Patients with tinnitus and hyperacusis frequently have loudness discomfort levels that are lower than loudness discomfort levels of individuals with similar levels of sensorineural hearing loss, indicating that these phenomena are distinctly different from recruitment.[135]

Andersson and associates[136] assessed the prevalence of hyperacusis in the general population in two surveys of the adult Swedish population. The point prevalence of hyperacusis was 5.9% (postal survey) and 7.7% (Internet survey). Participants reporting hearing impairment were excluded from the prevalence calculations, minimizing the inclusion of patients with cochlear damage and reduced dynamic range in the sample. Other reports of hyperacusis prevalence in the general population are 22%.[137] The prevalence of hyperacusis within the tinnitus population is unknown. Estimates range from 40% to 80%, but no systematic survey has been conducted for accurate estimation.[138,139] In the general population and the tinnitus population, the adopted operational definition of hyperacusis would determine its estimated prevalence.

Objective tests of loudness discomfort or sound intolerance in patients with hyperacusis have been adapted from procedures developed for assessing recruitment.[140,141] There are several variations on the technique for measuring loudness discomfort levels, but no consensus or standardization has been established. In addition, issues of intersubject and intrasubject variability,[142] test-retest reliability,[143] operator dependency, and poor face validity for test stimuli all limit the utility of adapting measures of loudness intolerance to patients with hyperacusis.

There are very few validated, well-established self-report questionnaires that specifically target hyperacusis. Two questionnaires developed in France are available, but have not yet been validated in English translation. Dauman and Bouscau-Faure[139] have developed a scale for

assessing hyperacusis in patients with tinnitus: The Multiple-Activity Scale for Hyperacusis (MASH). MASH employs a structured interview for rating the annoyance induced by sound exposure from different physical and social activities. Dauman and Bouscau-Faure[139] reported hyperacusis was present in 197 of 249 (79%) clinical patients screened with the instrument, with substantial to severe annoyance from hyperacusis present in 42%. There was no correlation between the severity of hyperacusis, as indicated by MASH, and audiometric threshold shift, indicating that hyperacusis is a phenomenon distinct from loudness recruitment. The Hyperacusis Questionnaire is a 14-item instrument, also developed in French, in which hyperacusis is assessed using a four-alternative Likert scale.[144]

The impact of hypersensitivity to sound can range from general avoidance of social situations such as concerts and restaurants to specific sound aversions (e.g., vacuum cleaners, traffic, clinking dishes, children playing). In extreme cases, patients with severe hypersensitivity become housebound in an effort to control acoustic exposure, wearing ear plugs and ear muffs for extended periods. In all cases of sound hypersensitivity, it is important to address the physiologic component of loudness discomfort and reduced dynamic range, and the psychological component of fear, anxiety, social withdrawal, and maladaptation that accompanies the condition. The cognitive influence on sound sensitivity has been shown by the high correlation of loudness tolerance with anxiety.[99]

The efficacy of sound therapy for treating hyperacusis has had mixed results. Dauman and Bouscau-Faure[139] reported that TRT was more effective in improving hyperacusis (63%) than tinnitus (47%) in 32 patients evaluated at three time points after therapy. They reported that hyperacusis remains a problem for a significant proportion of patients treated with TRT. Gold and associates[145] reported a retrospective study on the effect of TRT on selected patients with reduced sound tolerance. Hyperacusis was defined as average loudness discomfort levels for 1 kHz, 2 kHz, 4 kHz, and 8 kHz below 100 dB HL and patient reports of physical discomfort with exposure to sounds. Hearing thresholds were unchanged between initial measures and follow-up after 9 months of therapy; however, mean loudness discomfort levels were improved 12.48 dB, and the dynamic range was significantly increased by a mean 11.32 dB. A corresponding improvement in the number of activities avoided because of sound tolerance problems was noted as well.

CHAPTER ONE HUNDRED AND FIFTY-ONE

Noise-Induced Hearing Loss

Brenda L. Lonsbury-Martin

Glen K. Martin

Key Points

- Noise-induced hearing loss (NIHL) is second only to age-related hearing loss as the most prevalent form of hearing loss.
- NIHL resulting from relatively brief noise exposures can be reversible, as happens with exposure occurring at an evening spent in a loud entertainment venue.
- Permanent NIHL is caused by either an acoustic trauma (i.e., a brief exposure to a very intense blastlike sound) or a chronic long-term exposure to the loud sounds associated with a noisy occupation.
- An accelerating incidence of high-frequency hearing loss in younger individuals points to early, chronic noise exposure, possibly from personal entertainment devices.
- NIHL is a complex condition that is influenced by environmental and genetic factors.
- Genetic association studies have identified genetic factors primarily related to oxidative stress that influence an individual's susceptibility to NIHL.
- Current research on the administration of certain antioxidants before or after noise exposure shows promise for developing a pharmacologic treatment for NIHL in the near future.
- NIHL is a preventable condition and the otolaryngologist plays a critical role in educating patients about protecting their ears from the adverse effects of noise overexposure.

One of the most common causes of permanent hearing impairment is exposure to excessive sounds. Millions of individuals worldwide have noise-induced hearing loss (NIHL), resulting in a reduced quality of life because of social isolation, and possible inexorable tinnitus and impaired communication with family members, coworkers, and friends.[1] The costs in terms of compensation and early retirement payments for work-related NIHL are immense. The U.S. Department of Veterans Affairs spends approximately $700 million a year on disability compensation and treatments for NIHL. NIHL is the single largest disability expenditure of the Veterans Benefits Administration.[2]

This chapter presents and discusses more recent perspectives on the effects of excessive noise on hearing that address the scientific and practical aspects of NIHL. Although NIHL has been studied experimentally for more than a century, only in the last few decades have some major breakthroughs occurred in our basic understanding of the ear's reaction to damaging sounds, along with a better understanding of the environmental and genetic factors that contribute to NIHL. This steady progression in the knowledge base about NIHL promises to improve significantly the detection and treatment of this disorder over the coming years.

Measurement of Noise

The term *noise* is commonly used to designate an undesirable sound. In the scientific and clinical fields that deal with hearing, this term has come to mean any excessively loud sound that has the potential to harm hearing. The temporal patterns of environmental noise are typically described as continuous, fluctuating, intermittent, or impulsive.[3] Continuous or steady-state noise remains relatively constant, whereas fluctuating noise increases and decreases in level over time, and intermittent sounds are interrupted for varying time periods. Impulsive or impact noises caused by explosive or metal-on-metal mechanical events have rapidly changing pressure characteristics consisting of intense, short-lasting (i.e., milliseconds) wave fronts, followed by much smaller reverberations and echoes that occur over many seconds. The amount of noise, usually referred to as the sound pressure level (SPL), is conventionally measured by a sound-level meter in decibel (dB) units using a frequency-weighting formula called the A-scale. The dBA-scale metric of sound level essentially mimics the threshold-sensitivity curve for the human ear, so the low-frequency and high-frequency components are given less emphasis as auditory hazards. Standard sound-level meters have electronic networks designed to measure noise magnitude automatically in dBA, whereas to measure impulse or impact noise, a more intricate peak-reading sound-level meter is needed that is capable of accurately measuring sounds with essentially instantaneous onset times.

The personal noise dosimeter is typically used to measure noise exposure in the workplace. This instrument provides readout of the noise dose or the percent exposure experienced by a single worker, typically over a specific shift. The logging dosimeter integrates a function of sound pressure over time and calculates the daily (8-hour) dose with respect to the current permissible noise level for a continuous noise of less than or equal to 85 dBA lasting 8 hours. More recently, personal noise dosimeters have been offered to the consumer as a portable, compact, and affordable device that can be used as hearing protectors. The instrument measures and displays noise dose continuously for 16 hours. The dosimeter provides an early warning that the user is approaching overexposure and should use hearing protection. A particular noise (e.g., from power tools, music concerts, sporting events) can also be measured for 2 minutes, and then the estimated dose per

hour is calculated and displayed to determine if permissible exposure levels would be exceeded. By putting valuable health information into the hands of consumers, such easy-to-use, inexpensive (<$100) dosimeters empower them to take appropriate steps to prevent NIHL.

Nature of the Hearing Loss

Depending on the level of the sound exposure, either reversible or permanent damage can occur to the peripheral auditory end organ. The reversible loss, typically referred to as a *temporary threshold shift* (TTS), results from exposures to moderately intense sounds, such as might be encountered at a philharmonic orchestra concert. Hearing problems associated with TTS include elevated thresholds, particularly for the higher midfrequency region that includes the 3- to 6-kHz frequencies. The TTS condition is often accompanied by many other common symptoms of hearing impairment, including tinnitus, loudness recruitment, muffled sounds, and diplacusis. Depending on the duration of the exposure, recovery from TTS can occur over periods ranging from minutes to hours and days. After exposure, if TTS does not recover before the ear is re-exposed to excessive sound, a permanent change in hearing can occur, which is referred to as a *permanent threshold shift* (PTS).

In PTS, the elevation in hearing thresholds is irreversible because lasting structural damage occurs to the critical elements of the cochlea. The precise relationship between the TTS and PTS stages of hearing loss caused by noise exposure is unknown. Although it seems logical to assume that repeated episodes of TTS would eventually lead to PTS, experimental findings imply that the fundamental processes underlying the development of reversible versus permanent NIHL are unrelated. Nordmann and colleagues[4] using a survival fixation approach showed that the histopathologic manifestations of TTS and PTS noise damage to the chinchilla cochlea are distinct. Specifically, TTS was correlated with a buckling of the supporting pillar cell bodies in the frequency region of the maximal exposure effect. The morphologic abnormality that was consistently correlated with PTS was a focal loss of hair cells, and a complete degeneration of the corresponding population of nerve fiber endings. Because PTS eventually develops from repeated exposures to stimuli that initially produce only TTS, it is likely that the latter condition is also associated with subtle changes to the sensitive outer hair cell (OHC) system that go undetected by conventional light microscopy.

Traditionally, PTS caused by acoustic overstimulation has been separated in two distinct classes. One type, called *acoustic trauma,* is caused by a single, short-lasting exposure to a very intense sound (e.g., an explosive blast), and results in a sudden, usually painful, loss of hearing. The other type of hearing loss is commonly referred to as NIHL, and results from chronic exposure to less intense levels of sound. A great deal more is known about the anatomic processes underlying the symptoms of and recovery from acoustic trauma than is known about NIHL. Consequently, it is well established that a single exposure to a severe sound causing violent changes in air pressure can produce direct mechanical damage to the delicate tissues of the peripheral auditory apparatus, including components of the middle ear (tympanic membrane, ossicles) and inner ear (organ of Corti). In contrast, regular exposure to less intense but still noisy sounds involves the insidious destruction of cochlear components that eventually and unavoidably leads to an elevation in hearing levels, along with other common symptoms of hearing impairment.

Acoustic trauma was previously a relatively rare event that was typically associated with accidental explosions in industrial settings. Military servicemen and servicewomen caught in roadside bomb explosions in the current armed conflicts in Iraq and Afghanistan are returning home in epidemic numbers, however, with profound permanent hearing losses and tinnitus.[5] Consequently, acoustic trauma is a hearing problem that is increasing, at least in combat troops. Because many of these postdeployment cases are being treated in the private sector, all otolaryngologists may see acoustic trauma in increasing numbers.

Irreversible NIHL is a specific pathologic state exhibiting a recognized set of symptoms and objective findings.[6] NIHL includes (1) a permanent sensorineural hearing loss with damage principally to cochlear hair cells, and primarily to OHCs; (2) a history of a long-term exposure to dangerous noise levels (i.e., >90 dBA for 8 hours/day) sufficient to cause the degree and pattern of hearing loss described by audiologic findings; (3) a gradual loss of hearing over the first 5 to 10 years of exposure; (4) a hearing loss involving initially the higher frequencies from 3 to 8 kHz before including frequencies less than or equal to 2 kHz; (5) speech-recognition scores that are consistent with the audiometric loss; and (6) a hearing loss that stabilizes after the noise exposure is terminated.

A patient with NIHL commonly consults a physician because of difficulties in hearing and understanding ordinary speech, especially in the presence of background noise. Many variations can be found in the detailed configuration of the audiogram of a noise-damaged ear, depending on the temporal and spectral distribution of the noise stimulus, and on the stage of hearing loss. The pattern of hearing loss most commonly associated with the earlier stages of NIHL is illustrated in Figure 151-1A. The beginning region of impairment involves the sensitive midfrequency range, primarily 3 to 6 kHz, and the corresponding hearing loss is classically described as the "4-kHz notch." This pattern of maximal hearing loss, with little or no loss at less than 2 kHz, typically occurs regardless of the noise-exposure environment. The audiogram results in Figure 151-1A also show the sensorineural aspect of NIHL in that thresholds for bone-conducted stimuli are essentially identical to the thresholds for air conduction. The profile of noise-induced threshold hearing is usually symmetric for both ears, particularly for individuals who have been working in noisy industrial settings in which there are "surround" sounds.

Commonly, other forms of noxious sound, such as the gunfire associated with sport shooting, cause an asymmetric pattern of hearing loss similar to the one illustrated in Figure 151-1B. In this case, the ear pointed toward the source of noise (gun barrel), which is the right ear of the left-handed shooter depicted in Figure 151-1B, would have worse hearing than the ear directed away from the source (in this example, the left or protected ear) by 15 to 30 dB or more, and particularly at higher frequencies because of the absence of the protective head-shadow effect.

The development of a hearing loss caused by habitual exposure to moderately intense levels of noise typically consists of two stages. Initially, the middle to high frequencies exhibit the resulting hearing loss. As the length of time of exposure to loud noise increases, hearing loss becomes greater and begins to affect adjacent higher and lower frequencies. In a classic cross-sectional study of occupational NIHL, Taylor and colleagues[7] showed the gradual loss of hearing sensitivity in workers caused by habitual exposure to the intense sounds of dropforging tools that are commonly used in foundries. Figure 151-2 illustrates the progressive effects of exposure to the wideband noise (Fig. 151-2A) of two types of forging tools, presses and hammers, on the magnitude of hearing loss as the length of exposure increased. For the operators of the press and hammer equipment (Fig. 151-2B and C), the approximate 10- to 20-dB threshold shifts, typically observed at the higher frequencies during the first 1 to 2 years of exposure, grew to be a 20-dB or greater loss, from 3 to 6 kHz, after a 3-year exposure. There was a 40-dB or greater threshold shift after an 8-year exposure.

Detailed comparisons of the NIHL growth curves of Figure 151-2B and C reveal that with continuing exposure, hearing loss worsened at the higher frequencies and spread to the lower frequencies. In addition, for average exposure times of less than 10 years, hearing levels for the press and hammer operators who were exposed to mean levels of 108 and 99 dB SPL deteriorated similarly. For long-term exposures of 10 years or more, the results of Taylor and colleagues[7] indicated that hearing losses resulting from the hammer-induced impact noise were greater than the losses resulting from the more continuous noise of the press equipment. Finally, a characteristic feature of NIHL, which is clearly documented in Figure 151-2B and C, is that hearing levels are increased rarely beyond about 70 to 90 dB of hearing loss, on average, even after more than 31 years of continuous noise exposure.

Cochlear Damage

The primary site of anatomic damage is at the level of the mechanosensory receptors of the auditory system's end organ. Loud sound damages the inner hair cells and OHCs of the organ of Corti, with the

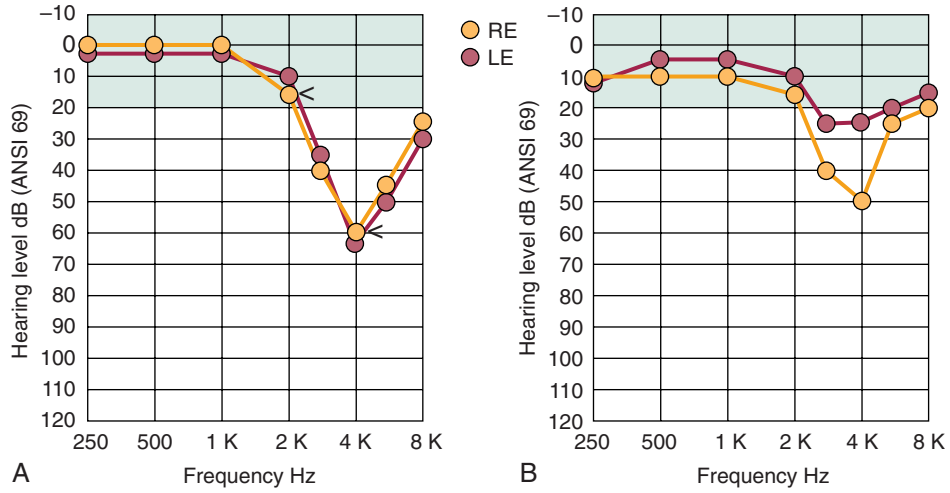

Figure 151-1. Audiometric patterns of hearing levels from patients in beginning stages of noise-induced hearing loss. **A,** A "4-kHz notch" symmetric pattern for a 44-year-old male factory worker. Thresholds for bone-conducted stimuli *(arrows)* were similar to thresholds determined with routine air-conduction methods. **B,** Asymmetric pattern for a 45-year-old man who was a recreational rifle shooter. For this left-handed patient, note greater impairment in the right (*yellow circles*) rather than the left (*red circles*) ear because of protective head-shadow effect. <, unmasked right ear.

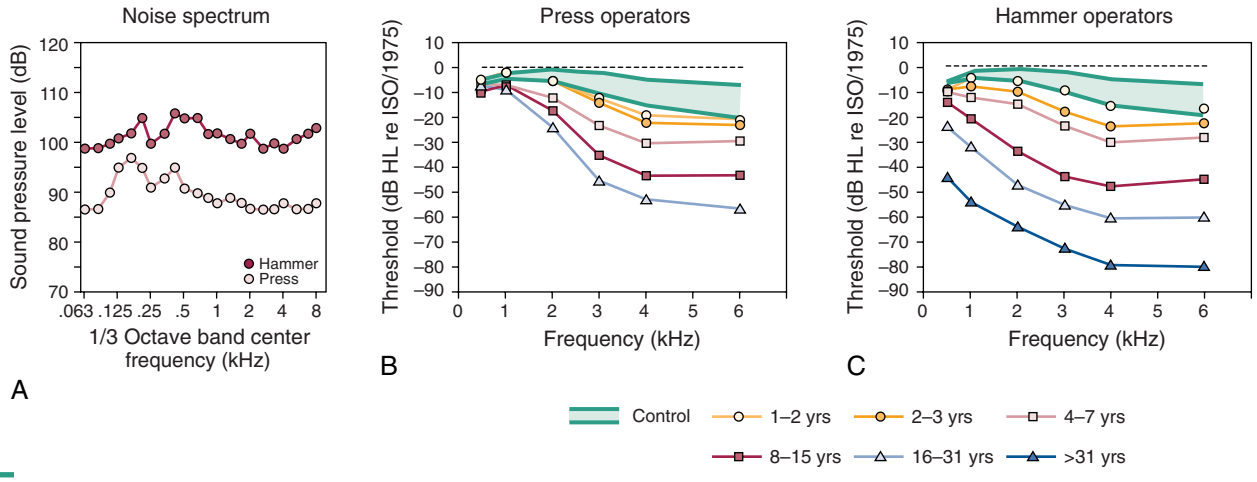

Figure 151-2. Development of the audiometric pattern of noise-induced hearing loss as a function of years of exposure to constant occupational noises. **A,** Spectra of noise produced by hammer *(red circles)* and press *(yellow circles)* equipment, with maximal energy centered in 0.2- to 1-kHz and 0.125- to 0.5-kHz regions. **B** and **C,** Resulting hearing losses for press **(B)** and hammer **(C)** operators. Noise-induced hearing losses occurred at frequencies above peak energy in the exposure. *Geometric symbols* represent experimental subjects according to years of noise exposure. *Shaded areas* indicate effects of aging on hearing levels in control subjects of similar age (i.e., 23 to 54 years old), who worked in non-noisy parts of the same drop-forging plants. *(Adapted from Taylor W, Lempert B, Pelmear P, Hemstock I, Kershaw J. Noise levels and hearing thresholds in the drop forging industry.* J Acoust Soc Am. *1984;76:807-819.)*

OHCs in particular being most affected in the initial stages. In instances involving very intense acoustic stimulation, supporting-cell elements also can be directly affected. Depending on the physical attributes of the exposure stimulus (e.g., time-varying characteristics or the intensity, frequency, or spectral content, duration, or schedule), noise can cause damage to hair cells ranging from total destruction to effects evident only in the ultrastructure of specialized subcellular regions (e.g., the fusing or bending of the individual cilia that make up the stereociliary bundle). Whenever degenerative processes or structural modifications to the cochlea reach a significant level, an associated reduction in hearing capability can be detected.

Johnsson and Hawkins[8] were among the first investigators to describe the typical patterns of cochlear injury for humans with chronic exposure to different types of loud sound. The photomicrograph of the cochlear tissue in Figure 151-3A depicts some common histopathologic consequences of NIHL for a patient with a lengthy history of noise exposure. The authors reported that the 50-year-old patient had worked intermittently over a 5- to 6-year period in an automotive body–stamping plant, and that he had a long history of using recreational firearms. The sharp transition in the basal end (following the uncoiling to the right) from the normal-looking organ of Corti (a darkish stripe corresponding to the region of inner hair cells and OHCs), with its dense network of nerve fibers, to the complete absence of hair cells and their corresponding nerve fibers (the much lighter adjacent area) can be noted. Figure 151-3B graphically reconstructs the histopathologic features of this cochlea as a cytocochleogram by depicting the number of remaining hair cells, in the form of percentages, averaged over 1-mm sections. A typical finding in individuals exposed to the occupational noise exemplified in this case is the almost symmetric pattern of degeneration observed for the two ears. The *inset* at the top right of the cytocochleogram shows the patient's audiogram obtained about 1 year before his death, which shows the severity of the anatomic damage in functional terms by revealing an abrupt hearing loss for test frequencies greater than 2 kHz.

Examination of human temporal bone specimens by numerous laboratories[8-10] has yielded documentation of the progressive stages of

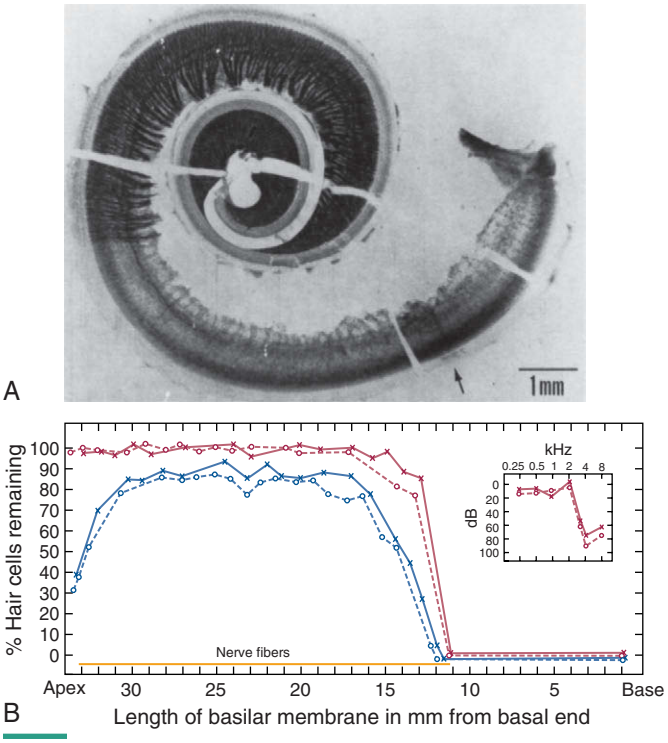

Figure 151-3. **A,** Low-power photomicrograph of a soft surface preparation of organ of Corti from the left cochlea of a 50-year-old man exposed extensively to occupational noise, showing a pattern of abrupt degeneration of basal region. *Arrow* indicates a small patch of remaining organ of Corti near basal end. **B,** Modified cytocochleograms for two ears along with an audiogram that was measured 1 year earlier, showing sharp pattern of hair cell degeneration (expressed as percentage remaining per millimeter of length of basilar membrane measured from basal end) and nerve fiber degeneration. Note relative symmetry of corresponding abrupt high-frequency loss of cochlear elements. Separate curves represent inner *(solid lines)* and outer *(dashed lines)* hair cells (averaged over three rows of outer hair cells) for left *(X)* and right *(O)* ears. *Yellow horizontal line* along abscissa indicates presence of nerve fibers in osseous spiral lamina. *(Adapted from Johnsson LG, Hawkins JE. Degeneration patterns in human ears exposed to noise.* Ann Otol Rhinol Laryngol. *1976;85:725-739.)*

noise damage as depicted by epidemiologic data such as those of Figure 151-2. First, in the predictable sequence of events, a small region of hair cell and nerve fiber degeneration appears bilaterally at a cochlear region corresponding to the 4-kHz notch. Typically, these discrete lesions gradually grow in the basal-ward direction (i.e., toward the high-frequency extent of the cochlea) to involve a greater portion of the organ of Corti. Finally, as exposure to noise continues over years, the remaining sensory and neural elements in the basal end of the cochlea are destroyed, resulting in an abrupt loss of midfrequency to high-frequency hearing, such as that depicted by the clinical audiogram of Figure 151-3.

Research on Noise-Induced Hearing Loss

Scientific interest in the damaging effects of excessive sound on hearing has a long history for many reasons. First, the experimental strategy of exposing animals to noise and examining their ears for the sites of the resulting acoustic injury was used in the past as the independent variable in establishing some of our basic knowledge about hearing. Particularly, with the use of intense tones as the damaging agents, frequency information relating physical distance along the basilar membrane to the "best" frequency of the injured region provided an initial basis for understanding the tonotopicity of the cochlea and the central projection of such frequency-related information.[11] Additionally, noise-damage strategies have been used to contribute to our understanding of the function of inner hair cells and OHCs by permitting differences in their central terminations in the ventral and dorsal cochlear nuclei to be distinguished.[12]

Although useful as an analytic strategy, the major impetus behind the more contemporary interest in the effects of noise on hearing originates from a desire to understand the fundamental processes by which exposure to loud sound leads to acoustic injury. The reward of achieving an appreciation of the basic processes underlying NIHL lies in the ability to prevent, or at least predict, an individual's susceptibility to PTS, or perhaps even to initiate regeneration of damaged or lost critical cellular components, which would eventually lead to the recovery of hearing.

The research literature on the effects of noise on hearing and the anatomic elements of the ear is voluminous. Early experiments performed more than 65 years ago were straightforward anatomic studies based on the strategy of exposing various animal models to intense noises, followed by a general description of the resulting histopathology at the cellular level. More modern noise studies in animal models have attempted to establish a structure/function relationship between noise-induced morphologic damage and the inability to detect auditory signals.

In this extensive literature, a great disparity in the experimental findings relating the effects of missing hair cells to the corresponding hearing sensitivity is frequently apparent. Such contrasting findings and the confusion they have caused are related to numerous confounding variables, including poor analysis of the problem, experimental error, and a failure to understand the limitations of the functional and anatomic techniques used. Also, such disparate studies typically exposed animal subjects to a single noise at levels much greater than 100 dB SPL in an attempt to mimic, within a relatively brief study interval, damage patterns that develop in humans from intermittent exposure to much less intense noises over many years. Consequently, although early noise studies showed that the longer an animal was exposed to extreme levels of sound, the greater was the resulting cochlear injury, they contributed little to our knowledge concerning how NIHL develops in humans working for long periods in noisy work settings.

In contrast, research conducted over the past few decades has made use of more realistic experimental protocols that incorporate intermittent exposure stimuli of intensities and durations designed to approximate the effects of a working lifetime of exposure to occupational noise. Additionally, most more recent studies have been developed sequentially within a program of research, so that a thorough understanding of a particular effect is achieved.

Anatomic Mechanisms Underlying Noise Damage

Experimental studies have led to an increased understanding of some major features of NIHL. It is well-accepted that the origin of the 4-kHz notch in the NIHL audiogram is related to the resonator function of the external auditory ear canal,[13] rather than to indeterminable innate properties of the cochlea, such as a reduced vascular supply to this region of the organ of Corti.[14] The primary research interest has always been, however, in the fundamental mechanism by which the sensory cell degenerates or is damaged after exposure. Numerous mechanisms[15] have been proposed, including mechanical injury caused by severe motion of the basilar membrane, metabolic exhaustion of activated cells, activity-induced vascular narrowing that causes ischemia, and ionic poisoning from interruption of the normal chemical gradients of the cochlea owing to minuscule disruptions in the organization of sensory and supporting cells.

Although the many years of experimental research have not yet produced a major breakthrough in understanding of damage mechanisms, the current most convincing morphologic evidence supports a combination of the mechanochemical theories. First, at the ultrastructural level, it is likely that alterations in the stereocilia in the form of shortened or broken rootlets are involved in the initial pathologic processes that lead to TTS and, if such injuries are not repaired, then PTS.[16-18] More recent findings showed that hair bundles are capable of rebuilding their ultrastructure from top to bottom over a 48-hour

period.[19,20] If damage is so severe that it overwhelms this self-repair mechanism as exposure continues, a discrete but direct mechanical disruption likely results in a toxic mixing of endolymph and perilymph through microbreaks in the structural framework of the cochlear duct,[21] which leads to secondary effects, including loss of hair cells and their corresponding nerve fibers.

New Knowledge about Cellular and Molecular Mechanisms of Noise-Induced Hearing Loss

The research frontiers that promise to provide fresh insights into the fundamental basis of NIHL and eventually into the development of a cure for this disorder consist of hair cell regeneration or repair or both, "training" protocols that target the cochlear-efferent system to make hair cells more resistant, the use of protective agents before and after noise exposure, and understanding the genetic basis of susceptibility and resistance to the adverse effects of sound overexposure.

Hair Cell Regeneration and Repair

In the late 1980s, several seminal reports on hair cell regeneration in avian species established that hair cells in neonatal and adult birds regenerate after exposure to either damaging levels of sound[22-24] or ototoxic antibiotics.[25] Additionally, follow-up studies showed that recovery of cochlear function accompanied the cellular-recovery process.[26-28] In the best-studied model for hair cell regeneration, the neonatal chick, it was shown that new hair cells arose as progeny from an otherwise nondividing supporting-cell population that was induced to proliferate by the damaging insult.[29]

Generally, noise-induced hair cell loss in the mammalian cochlea is irreversible. Experimental findings using in vitro cultures of neonatal mouse cochleas showed, however, that overexpression of mammalian atonal homolog 1 (Atoh1), also known as Math 1, a basic helix-loop-helix transcription factor known to be necessary for hair cell differentiation during development, leads to an increase in the production of extranumerary hair cells.[30] Consequently, it seems that certain cells in the mammalian organ of Corti, at least in young animals, can be redirected toward a hair cell fate by the overexpression of Math 1.[31] In addition, a most exciting finding was the discovery that new hair cells can be grown in a mature mammalian ear using the Math 1 gene. Kawamoto and colleagues[32] injected an adenovirus carrying the Math 1 gene into the endolymph of mature guinea pigs. Using scanning electron microscopy, 1 to 2 months after the inoculation of the Math 1 gene insert, immature hair cells within the nonsensory supporting cells of the organ of Corti were detected. Most importantly, follow-up studies in the deafened guinea pig showed that not only did Math 1 induce regeneration of hair cells in the adult, deafened guinea pig, but also substantially improved hearing thresholds were measured.[33] These findings that Math 1 (Atoh1) can direct hair cell differentiation and induce hearing function in mature nonsensory cells support the notion that adenoviral gene therapy based on expressing crucial developmental genes for cellular and functional restoration in damaged auditory epithelium may lead some day to a new treatment for NIHL.

Protection from Conditioning the Cochlear Efferent System

The outcomes of other experiments indicate that the mammalian cochlea may be capable of actively adapting to certain high-level sounds by receiving "exposure experience." The notion that the cochlea can become resistant over time to the consequences of excessive sound was reported initially by noting "conditioning" effects in several animal models.[34-37] The typical conditioning paradigm consists of providing a pre-exposure training experience using a moderate-level stimulus that, at a more intense level, becomes the subsequent overexposure stimulus. Together, these findings in animal models suggested that the mammalian cochlea might be capable under certain conditions of dynamically adapting to excessive sound.

For humans, the practical implications of the capacity to develop a "resistance" to loud sounds are obvious. A follow-up study in teenagers used a TTS-type paradigm to show the relevance of resistance training to humans. In this experiment,[38] the investigators provided a pre-exposure training period in which the young subjects were exposed to 6 hours of pop/rock music at around 70 dBA. Threshold shifts in response to a 10-minute exposure to a 105-dB SPL, one-third octave-band noise centered at 1 kHz were compared for pretraining versus post-training intervals. The major result was that the "trained" ears exhibited significant decreases in TTS compared with their baseline values, showing that the "conditioning" effect, or the development of "resistance," can be shown in human subjects, at least under brief TTS-exposure conditions.

Such human studies of the relationship between noise exposure and permanent hearing loss are more difficult to perform for many reasons including the ethical issues involved in the deliberate exposure of study subjects to noises, even though they are thought to be reversibly damaging. More recent research into the protective role of cochlear efferents in NIHL has depended more on the benefits of diagnostic testing with evoked otoacoustic emissions (OAEs) to predict potential susceptibility to the aftereffects of noise exposure.[39] This simple, noninvasive, and objective procedure is based on the systematic measurement of a class of cochlear responses (i.e., the OAEs) that are primarily generated by the OHCs.[40] Not only are OHCs exquisitely sensitive to the initial effects of acoustic overstimulation, which makes them excellent indicators of sound-induced ultrastructural damage, but also the final common pathway of the descending auditory-efferent system preferentially innervates the OHCs.

To take advantage of the ability of OAEs to measure efferent activity, several experimental paradigms were developed including a common one[41] that uses contralateral acoustic stimulation to elicit medial olivocochlear-induced reductions of OAEs from the ipsilateral test ear. The other procedure[42] is based on measurements of a subtype of evoked emissions represented by distortion product OAEs (DPOAEs) at $2f_1$-f_2. In this strategy, long-lasting f_1 and f_2 primary tones of approximately 1 second are applied binaurally to elicit an efferent-based fast adaptation response that tests the ability of the combined medial and lateral cochlear-efferent systems to suppress DPOAEs in the test ear.

Experiments in guinea pigs documented the ability of the fast-adaptive DPOAE response to predict vulnerability to acoustic injury based on the vigor of efferent activity.[43] The robustness of the olivocochlear efferents was inversely correlated with the degree of cochlear dysfunction after subsequent noise exposure, in that animals exhibiting large adaptive effects showed smaller postexposure losses than animals displaying small amounts of efferent-induced adaptation. It is clear from these findings that a modification of this assay could easily be applied to human populations to screen for individuals most at risk in noisy environments.

Some studies[44] simply relating the presence or absence of the contralateral acoustic stimulation–induced reduction of emissions in human ears have reported such suppression is absent in most industrial workers who otherwise have normal OAEs. One implication of such observations is that a lack of efferent-related activity may be an early indication of cochlear damage from exposure to noise. Experimental studies such as these will eventually determine whether inherent efferent processes can account for and predict the remarkable individual variation in susceptibility to NIHL. The use of efferent-induced suppression of evoked OAEs in predicting susceptibility to NIHL, or in monitoring of noise effects in hearing-conservation programs, represents a promising line of future investigation.

Pharmacologic Protection from Noise-Induced Hearing Loss

It has long been recognized that hypoxia is a major pathogenic factor in NIHL. Based on the assumption that oxidative stress plays a substantial role in the genesis of noise-induced cochlear injuries that lead to permanent hearing loss, numerous pharmacologic strategies have been developed primarily in animal models to enhance the intrinsic defense mechanisms of the cochlea against this condition.[45] Kopke and colleagues[46] postulated several causes of noise-induced oxidative stress, all of which are amenable to pharmacologic treatments. Specifically, these investigators proposed that noise-induced oxidative stress leading to cochlear injury was related to (1) impaired mitochondrial function with respect to bioenergetics and biogenesis; (2) glutamate-induced excitotoxicity, which is the main excitatory neurotransmitter in the

peripheral and central auditory systems; and (3) depletion of glutathione (GSH), an antioxidant that protects cells from toxins such as free radicals.

Related experimental work showed a reduction in NIHL and hair cell loss in the chinchilla model after application of pharmacologic agents specific to these oxidative stress–related states. Acetyl-L-carnitine, an endogenous mitochondrial membrane compound that helps maintain mitochondrial bioenergetics and biogenesis in the face of oxidative stress; carbamathione, which acts as a glutamate antagonist for cochlear *N*-methyl-D-aspartate (NMDA) receptors; and the GSH-repletion drug, D-methionine (MET), all improved hearing in noise-exposed animals as indexed by auditory brainstem responses, along with reductions in inner hair cell and OHC loss compared with counterpart measures in saline-treated control subjects.[46]

Based on the assumption that a potential mechanism of NIHL is the generation of damaging free radicals through the activation of reactive oxygen species such as hydrogen peroxide, hydroxyl radicals, and superoxide, many other studies have tested the influence of antioxidants and related compounds on noise-induced cochlear dysfunction and organ of Corti morphology. Such candidate substances include GSH,[47] the xanthine oxidase blocker allopurinol,[48] *N*-L-acetylcysteine (L-NAC),[49] and GSH peroxidase and superoxide dismutase.[50] Together, all these findings support the notion that combating cellular oxidative stress, principally with prophylactic administration of antioxidant compounds, eliminates noise-induced cochlear injury in animal models. More recently, Kopke and colleagues[51] reported on some promising results using L-NAC in military recruits to reduce the NIHL sometimes associated with the basic training related to military operations. The success of such a pharmacologic approach essentially ensures the development in the near future of a therapeutic intervention that reduces NIHL clinically.

Susceptibility

A long-standing observation in NIHL has been that some ears are more easily damaged by noise than others. Individually varying susceptibilities to noise-induced hearing impairment have been found in humans and research animals. Because of the widespread interest in NIHL and its prevention, it is important to develop valid and reliable indices to predict human susceptibility to various noise levels. It is commonly assumed that such variability in susceptibility is a manifestation of biologic factors unique to each subject. A genetically based imperfection in the physical characteristics of the cochlea (e.g., stiffness of the cochlear partition) and variability in cochlear ultrastructure (e.g., density of hair cells) have been proposed as contributing to susceptibility.[52]

Identifying individual differences among various factors has long been a focus of interest. Numerous potentially important variables that have been investigated in the past and continue to be examined include age[53]; gender[54]; race[55]; previous damage to the cochlea[56]; efficiency of the acoustic reflex[57]; smoking habits[58]; and the influence of certain disease states such as hypercholesterolemia[59] or hypertriglyceridemia,[60] diabetes,[61] and cardiovascular disease represented by hypertension.[62] Although many pertinent factors have been uncovered, most data are inconclusive. In addition, although a few factors, such as pigmentation,[63] seem to have some relationship to potentiating noise damage, others, such as age, simply produce additive effects,[64] although this latter relationship remains controversial.[65] Possibly, as McFadden and Wightman[66] suggested in their review of the contribution of the psychoacoustic method toward understanding the symptoms of clinical hearing disorders, the orthogonally based research approach, which assumes a causal relationship between factors, will not reveal meaningful relationships. Perhaps the uncovering of interrelationships among myriad individual differences by application of a multivariate test battery would be more successful in identifying the basic factors that predict susceptibility to NIHL.

One of the most exciting areas in current experimental research is aimed at examining the genetic origin of differences in susceptibility to noise damage using the mouse model. A clear benefit of the mouse as an experimental animal is the great amount of knowledge that exists about the mouse genome. Additionally, mice from the same inbred strain are considered to be genetically identical. Consequently, assessing individual variability to noise damage in subjects that are homozygous at all chromosomal loci offers a unique opportunity to isolate genetic factors responsible for susceptibility to NIHL. To date, several studies[67,68] have shown that the inbred, mutant C57BL/6J (C57) strain, often used as a model of early age-related hearing loss, is more susceptible to noise damage than the CBA/CaJ (CBA) strain, which is frequently used as a model of normal hearing. Other observations supporting the potentiation of noise damage by the age-related hearing loss gene, *Ahl,* relate to the finding that when C57 (B6) mice are backcrossed with a mouse strain (e.g., CAST/Ei) exhibiting normal aging, the B6/CAST progeny display neither age-related hearing loss nor susceptibility to noise exposure aftereffects.[69]

Just as susceptible mutant mouse strains are readily available, there are also strains with normal cochlear function that are exceptionally resistant to acoustic overstimulation, such as wild-type inbred MOLF/Ei (MOLF) mice. Figure 151-4 compares the effects of an intense noise exposure (105-dB SPL, octave-band noise centered at 10 kHz, for 8 hours) on control CBA and MOLF mice at 2 months of age.[70] Although CBA mice showed only an expected minor recovery of DPOAEs to baseline levels at 2 days and 1 and 2 weeks postexposure, MOLF DPOAEs had essentially returned to their pre-exposure levels by 1 to 2 weeks postexposure. In combination, findings in inbred mouse models of NIHL provide the basis for applying suitable molecular techniques that permit the mapping of an NIHL gene to specific chromosomal loci (e.g., identifying differentially expressed genes using DNA microarrays and suppressive subtractive hybridization). Successful identification of this gene and perhaps its related modifier genes would have great implications for developing a diagnostic indicator of the susceptibility of a particular human ear to the adverse effects of sound overexposure.

Genetic association studies on oxidative stress genes have identified the first heritable factors that likely influence an individual's susceptibility to NIHL. Konings and coworkers[71] investigated whether variations in the form of single nucleotide polymorphisms of the catalase gene, which is one of the genes involved in oxidative stress, influenced noise susceptibility. By comparing audiometric data and DNA samples from the 10% most susceptible and 10% most resistant Swedish and Polish noise-exposed workers, significant interactions were observed between noise-exposure levels and several single nucleotide polymorphisms in both populations. These findings indicate that catalase is potentially a noise susceptibility gene.

Although the findings of more recent studies in particular have resulted in advancing our scientific knowledge of the sound-damage process, many major empirical issues remain to be satisfied. These issues include development of low-cost technical methods for controlling noise at the source, physical protection of individuals from excessive exposure, identification of individuals who are in the early stages of NIHL, prediction of the degree of risk from potentially hazardous noises, and determination of whether particular individuals or ears already damaged by noise are more susceptible to injury.

Ethical issues prevent the deliberate exposure of human subjects to extreme noises as a means of studying NIHL experimentally. The complexity of measurements demanded by the alternate cross-sectional study design that describes the hearing of humans exposed occupationally is considerable, however. These difficulties include differences inherent in the population (e.g., race, gender, presence of ear disease); problems involved in controlling concomitant exposure to no occupational noise or past exposure history; and technical problems with the descriptive techniques themselves, ranging from variability in audiometric measures to difficulties in performing valid measurements of the noise environment itself. Because of the complicated experimental designs demanded by all of these controls, there have been few faultless clinical, epidemiologic, or experimental studies of the effects of excessive noise on hearing in humans.

The importance of performing longitudinal field studies of communities or particular population segments, such as elderly individuals, children, and chronically ill individuals, who are habitually exposed to loud environmental noises produced by road traffic or aircraft, is obvious to determine effective health criteria for controlling such

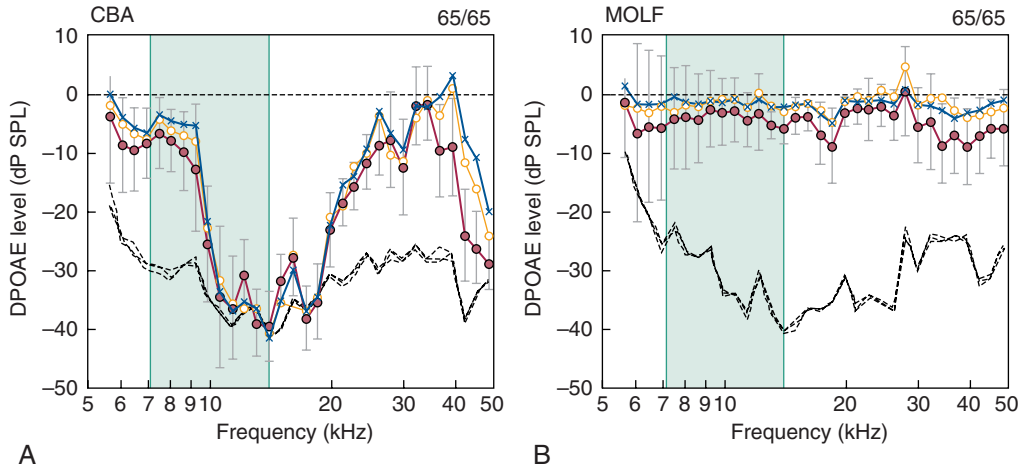

Figure 151-4. **A** and **B,** Mean difference DP-grams (i.e., pre-exposure distortion product otoacoustic emission [DPOAE] levels – postexposure DPOAE levels) for 65-dB SPL primary tones comparing effects of an extreme 8-hour exposure to a 10-kHz octave band of noise (*shaded region* from approximately 7 to 14 kHz) at 105 dB SPL for 2-month-old CBA **(A)** compared with 7-month-old MOLF **(B)** mice. *Bold horizontal dotted line* at 0 indicates no change between pre-exposure baseline DPOAE levels and postexposure counterparts measured at 2 days *(filled circles)*, 1 week *(open circles)*, and 2 weeks *(x)* after overexposure session. Note only minor recovery of DPOAEs for CBA mice between 2 days and 2 weeks postexposure, especially for frequencies greater than 30 kHz. In contrast, DPOAEs for MOLF mice essentially returned to baseline values. Although not shown here, immediately after exposure, both strains exhibited essentially no DPOAEs greater than approximately 10 kHz. Noise-floor differences *(dashed lines without symbols in lower portion of plots)* represent pre-exposure DPOAEs subtracted from postexposure noise floors to indicate maximum possible DPOAE loss. *Vertical bars* represent ±1 SD for 2 days postexposure. CBA, n = 10, 19 ears; MOLF, n = 8, 15 ears.

noises. Most notably, a great disadvantage in gaining a more complete understanding of NIHL in humans is that there have been no more recent studies of the hearing status of contemporary workers, at least in the countries of North America and Europe. Reliance on data collected 30 or more years ago, such as those illustrated in Figure 151-2,[7] has likely resulted in underestimates of the amount of hearing loss that is due to occupational noise, especially for individuals with intermittent or impulsive noise exposures.

Early Detection of Noise-Induced Hearing Loss

One aspect of NIHL that has not received a great deal of research attention is the development of more sensitive measures that are capable of detecting small acoustically induced injuries to the organ of Corti (i.e., the beginning stages of NIHL) so that individuals vulnerable to the long-term damage caused by continuous exposure can be identified. In recent years, evidence has been accumulating that the routine audiometric testing of behavioral thresholds to pure tones at octave intervals does not meet this need because by the time such a loss is identified using methods that test behavioral hearing sensitivity, permanent cochlear damage has occurred. Many threshold and suprathreshold psychoacoustic tests to detect subtle deteriorations in hearing acuity, including psychophysical tuning curves and frequency discrimination tasks, either have not proved to be of general usefulness or have proved to be too cumbersome methodologically to implement in a clinical or workplace setting because of the limitations associated with the necessarily brief evaluation periods.

The diagnostic technique incorporating OAEs is ideal for assessing the normality of cochlear processing in ears suspected of being overstimulated by loud sound because of its well-recognized sensitivity to the OHC class of receptor cell, which is primarily involved in the initial stages of NIHL. The functional status of OHCs in established instances of NIHL has been well described in many more recent studies on the practical applicability of evoked OAE testing in the audiology clinic.[72] Numerous reports in the literature have shown that in groups of noise-exposed humans who have been followed serially, reductions in OAE levels are more sensitive than pure-tone audiometric thresholds in detecting the early states of permanent noise-induced cochlear damage.[73-77] In these studies, decreases in emission magnitudes were measured in the absence of any change in the corresponding audiometric threshold frequencies.

In Figure 151-5, the ability of the two major types of evoked OAEs, the DPOAE, in its DP-gram form depicting emission level as a function of the f_2 test frequency (*lower left* in Fig. 151-5), and the transient-evoked OAE (TEOAE), elicited by clicks, in its spectral form (*right plots* in Fig. 151-5), to describe the configuration of a developing NIHL is illustrated. The 43-year-old woman in this example had participated in recreational rifle shooting for 3 years before OAE testing, and she claimed to have worn protective headphone devices continuously during this period. This right-shouldered shooter presented in the otology clinic with complaints of hearing loss, tinnitus, muffled hearing, and difficulty in understanding speech in background noise. It is clear from the test results that the magnitude and frequency extents of the TEOAEs reflected the pattern of normal hearing illustrated by the clinical audiogram at top left of Figure 151-5. The DP-gram clearly shows abnormal activity, however, with the right ear showing below-average response levels and the left ear exhibiting a significant reduction in emitted responses for frequencies greater than 3 kHz. True to classic principles, the left ear, which was exposed more to the muzzle end of the gun, went unprotected by the head-shadow effect. This example of the ability of evoked OAEs to detect cochlear pathology caused by noise exposure attests to the potential usefulness of emission procedures in identifying the primary site of pathology associated with hearing complaints secondary to a sensorineural loss, and in monitoring the development of potential hearing impairments in hearing-conservation programs.

Other evidence supporting the usefulness of evoked OAEs in examining patients with noise damage is illustrated in Figures 151-6 and 151-7. In Figure 151-6, the results of OAE testing in a 21-year-old man, who had just completed 3 years of military service in the infantry, show the precision of DPOAEs in particular in tracking the asymmetric pattern of hearing loss for this left-handed shooter. Additionally, the OAE findings presented in Figure 151-7 show the ability of evoked emissions to reflect accurately the magnitude and frequency extent of the more severe, but essentially symmetric hearing loss experienced by a 49-year-old man who had been working for more than 20 years in a fish cannery.

Both examples attest to several other benefits of OAE testing in NIHL patients. A significant advantage of the digital hearing aid over

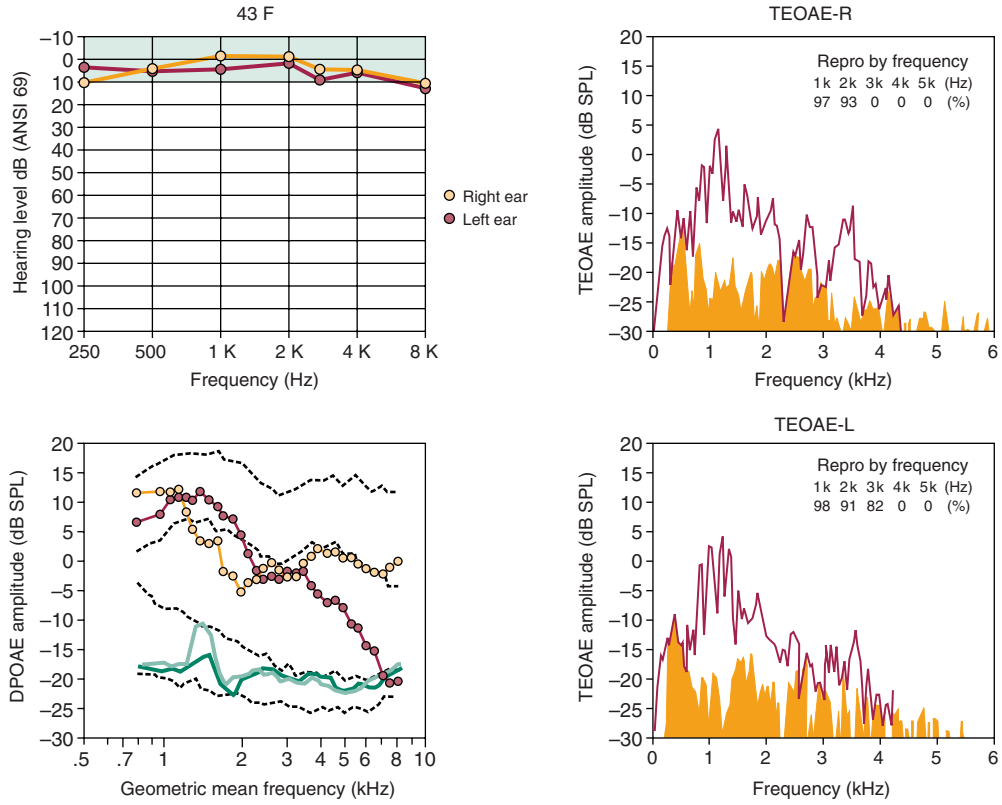

Figure 151-5. Early detection of noise-induced hearing loss in a 43-year-old female rifle shooter who complained of muffled hearing, tinnitus, and difficulty hearing speech in background noise. Note normal pure-tone audiogram bilaterally *(top left)*. In corresponding DP-grams at *lower left,* greater functional loss in the left *(red circles)* compared with the right *(yellow circles)* ear, particularly for frequencies greater than 3 kHz, was due to protective head-shadow effect for this right-handed individual. Emission levels for $2f_1$-f_2 distortion product otoacoustic emission (DPOAE) are plotted in response to 75-dB SPL primary tones as a function of geometric mean of two eliciting stimuli (f_1, f_2). Spectral plots of click-evoked otoacoustic emissions are shown on the *right* (transient-evoked otoacoustic emission [TEOAE]). Emitted response *(open area)* for the better-functioning right (R) ear was more prominently distributed above related noise floor *(shaded area)* than were emissions for the left (L) ear for frequencies greater than 3 kHz. In addition, higher "Repro" values for the right ear *(top right of each plot)* reflected its more robust activity levels. In DP-gram plot, variability of emission level (±1 SD) in normal-hearing ears is represented by *bold dashed lines in top portion of plot*. Similar variability of related noise floor is indicated by pair of *shorter dashed lines along bottom of plot*.

the older analog models is its ability to provide frequency-specific amplification based on the configuration of a particular patient's hearing loss. Knowledge of the pattern of surviving OHCs in an impaired ear based on tests of OAEs and particularly the DP-gram can assist the clinician in achieving an optimal match between the patterns of hearing-aid amplification and hearing loss.

Also, especially important to hearing conservation is the correct identification of individuals exhibiting pseudohypacusis, who seek monetary compensation for a purported work-related hearing impairment. An example of this application is illustrated in Figure 151-8 for a 42-year-old man who was referred to the audiology clinic for assessment by a local worker's compensation committee. In this case, the patient claimed to have poor hearing caused by on-the-job exposure to intense noise to the extent that he could not hear frequencies greater than about 4 kHz. According to the OAE findings, it is likely that the patient, a wood-lathe operator, had an asymmetric noise-related hearing loss that was worse in the ear (right) that was more exposed to the tool. Based on the type of hearing-loss data presented in Figure 151-1A for an industrial worker, however, it is unlikely that lathe-related noises could cause such a profound deafness for frequencies greater than 4 kHz. Additionally, the normal levels of DPOAEs and TEOAEs for frequencies less than 2 kHz do not support the patient's claim that the elevated audiometric hearing levels over the low-frequency to midfrequency regions were due to noise overexposure. Findings such as these support the use of objective tests of evoked OAEs in determining the authenticity of compensation claims for work-related hearing problems.

Interactive Effects

It is well established that noise in combination with certain chemical agents produces stronger reactions than each stimulus applied singly. The four major categories of ototoxic drugs are aminoglycoside antibiotics, platinum derivative antitumor agents, "loop" diuretics, and salicylates. The latter two classes of drug cause reversible effects, whereas aminoglycosides and platinum derivatives cause permanent damage to the inner ear and to hearing. Many laboratories have established in animal models that kanamycin, neomycin, or amikacin applied in combination with different types of noise produces a marked potentiating interaction.[78,79] Other studies of the temporal aspects of interactive effects indicate that the degree of potentiating interaction is the same whether the drug is given concurrently with the noise exposure or several months later.[80] Other evidence from humans[81] and controlled laboratory research in a rat model[82] indicates that additional loss may occur when subjects are treated with aspirin and exposed to noise concomitantly, although other findings infer that the combination of salicylate plus noise does not produce greater effects than noise alone.[83] Finally, experimental evidence in several animal models showed that the heavy-metal, antineoplastic agent *cis*-diamminedichloroplatinum, commonly known as cisplatin, significantly increased the amount of hearing and sensory cell losses from exposure to noise.[84,85]

In recent years, the interactive effects of noise with chemical agents common to industry and the environment have been reported. In a series of experimental studies in the rat model, Fechter and colleagues[86] discovered that the simultaneous exposure to noise and the environ-

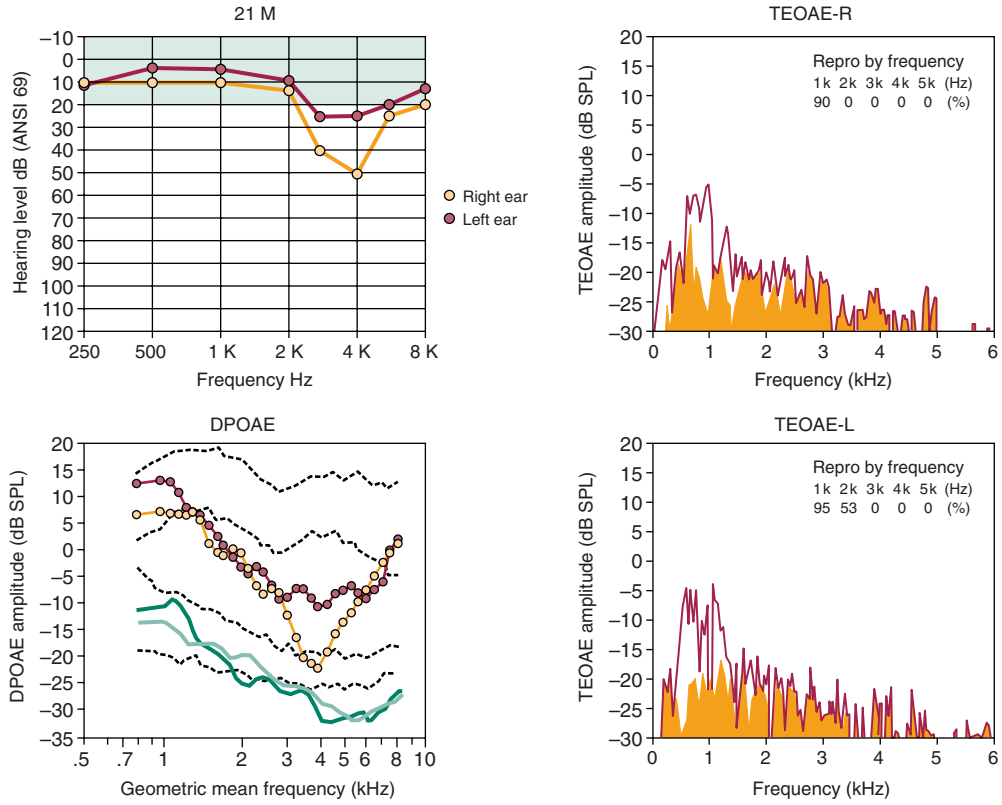

Figure 151-6. Early stages of noise-induced hearing loss in a 21-year-old military veteran, who had just completed a 3-year tour of duty. For this left-handed infantryman, note greater hearing loss from approximately 3 to 4 kHz for the right ear *(yellow circles)* depicted in the audiogram *(top left)*. In corresponding DP-gram, note abnormally low levels of distortion product otoacoustic emission (DPOAE) activity for frequencies greater than 1.5 kHz, which were poorer for the right ear. Click-evoked otoacoustic emission spectra on the *right* (transient-evoked otoacoustic emission [TEOAE]) also show poorer emitted responses from 1 to 2 kHz and lower "Repro" values for the right (R) ear. There is no emitted response for either ear greater than 2 kHz. See legend for Figure 151-5 for an explanation of click-evoked spectra and two sets of *dashed lines* in DP-gram.

mental pollutants carbon monoxide or hydrogen cyanide produced more permanent hearing loss at the high frequencies than the sum of the losses produced by each agent administered alone. Various other chemicals present in the environment as commercial products or chemical intermediaries and contaminants, such as the organic solvents toluene and hexane, the pollutants methyl mercury and lead acetate, and the organic compounds trimethyltin chloride and styrene used in the manufacture of plastics and polyurethane foam and rubber, have been identified as potent ototoxic agents that potentially interact synergistically with excessive noises. The ototoxicity of environmental agents such as metals, solvents, and asphyxiants and their interaction with noise are issues that have received a great deal of attention in the literature.[87] Although many of these environmental toxicants have been associated with direct injury to inner ear structures, possible additional anatomic damage to more central auditory pathways is also very likely.

Other Adverse Effects Caused by Noise

Damage to the vestibular system is a potential problem with noise because balance receptors are coupled physically with the auditory receptors; that is, they share the membranous labyrinth. In addition to the anatomic proximity of the vestibular labyrinth to the acoustic-energy delivery system, the great similarity in cochlear and vestibular hair cell ultrastructure, and the common arterial blood supply of the cochlea and vestibular end organs via the same end artery support the possibility of vestibular damage associated with NIHL. Theoretically, the limiting membrane, the membranous partition that separates the utricle and semicircular canals from the rest of the vestibule, protects most vestibular sensory cells from the adverse effects of intensive stapes vibration.

Nevertheless, some studies of industrial workers and military personnel have reported a high occurrence of vestibular symptoms and signs, and complaints of dysequilibrium.[88] Such simple correlations between noise exposure and vestibular disturbances are highly controversial because of the typical low incidence of clinical vestibular symptoms associated with gradually developing NIHL.[89] A study of military personnel with mild to severe NIHL using sophisticated vestibular testing in the form of a computerized rotatory-chair system along with routine electronystagmographic measures of caloric responses showed more direct correlations between hearing loss and vestibular upset.[90] In combination, the results showed a symmetrically centrally compensated decrease in the response of the vestibular end organ that was associated with a symmetric hearing loss. A more recent study[91] combining caloric testing with vestibular-evoked myogenic potentials in patients with chronic NIHL showed absent or delayed electrophysiologic potentials, indicating that the vestibular system, especially the sacculocollic reflex pathway, was damaged in addition to the cochlear portion of the inner ear.

Together, these findings imply that a subclinical, well-compensated malfunction of the vestibular system is associated with NIHL. Beyond the medicolegal implications is the daunting possibility that a currently asymptomatic vestibulopathy produced by noise exposure might progress to a disturbing vertigo under certain environmental conditions.[92]

There has been considerable interest more recently in the interaction of vibration and noise, which are common cofactors in the workplace. Although most research shows that vibration alone does not affect hearing, the results of epidemiologic studies in humans and controlled laboratory studies in animal models indicate a synergistic

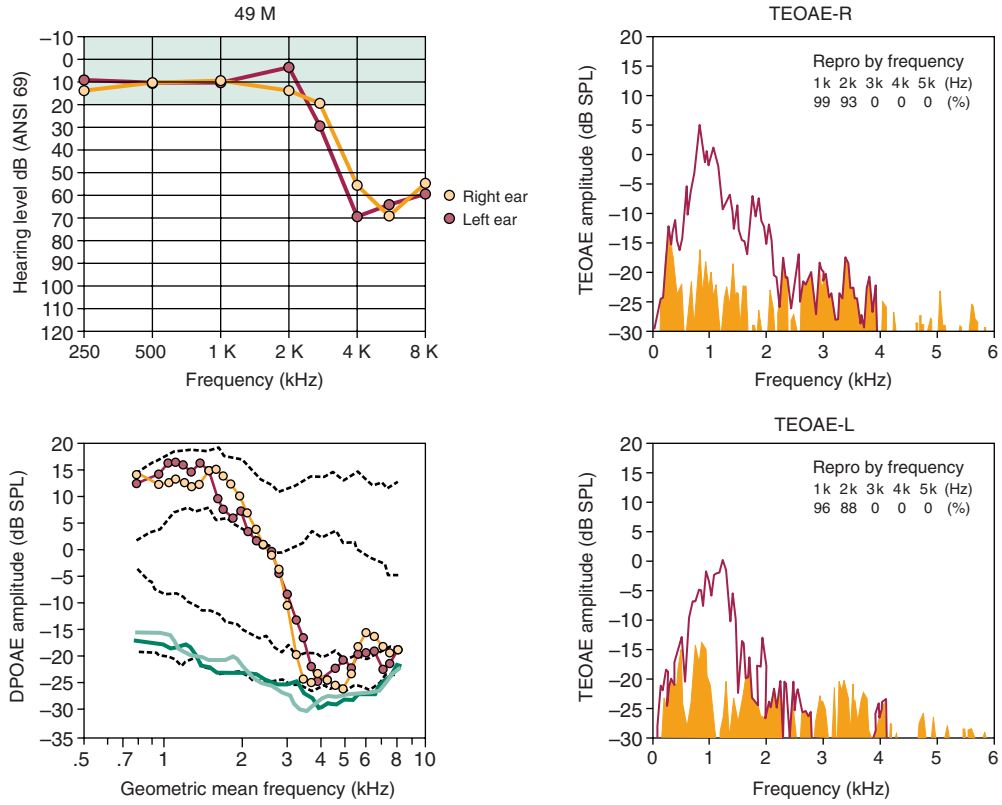

Figure 151-7. More advanced stage of noise-induced hearing loss for a 49-year-old man, who had worked for more than 20 years in a fish cannery. Audiograms at *top left* exhibit symmetric hearing loss for frequencies greater than 2 kHz. DP-grams indicate symmetric pattern of dysfunction in a similar manner. Click-evoked otoacoustic emission spectra on the *right* (transient-evoked otoacoustic emission [TEOAE]) also show a lack of emitted responses for frequencies greater than 2 kHz. See legend for Figure 151-5 for an explanation of click-evoked spectra and two sets of *dashed lines* in DP-grams. DPOAE, distortion product otoacoustic emission.

interaction of concomitant vibration (either whole-body or hand-arm) and noise that results in an increase in the degree of NIHL.[93]

Exposure to infra-frequency and ultra-frequency sounds outside of the human hearing range has also been studied. Infrasonic or vibratory stimuli are defined as sounds in the range of 0.1 to 20 Hz. There are no known instances in which infrasound alone clearly caused permanent damage to the human cochlea. Studies in the chinchilla model showed, however, that the presence of intense sounds in the audible frequency range along with simultaneous infrasound increases cochlear damage.[94]

In contrast, some reports have shown detrimental effects of microwaves on hearing.[95] The thermal properties of ultra-high-frequency sound waves in the gigahertz range, rather than mechanical energy, seem to have produced these adverse experimental effects. Overall, it is probably safe to conclude that the auditory system's built-in, middle ear filter limits the extreme frequencies of sound that are hazardous to the inner ear.[96]

Magnetic resonance imaging (MRI) systems have acoustic noise associated with their clinical scanning actions. For specific protocols that are incorporating faster and noisier sequences, peaks of 120 to 130 dBA have been measured, particularly during high-speed echoplanar imaging.[97] Early on, Brummett and associates[98] showed that sounds generated by MRI are sufficiently intense to cause some TTS in a significant number of patients. Their results also showed, however, that earplugs help attenuate the noise sufficiently to prevent TTS in most patients undergoing MRI evaluation. The use of the higher gradient fields that are applied at faster slew rates, which are used in current functional MRI, demands increased hearing protection systems to minimize the risk of noise trauma.[99]

Other nonauditory problems concern the general bothersome or fatiguing effects of noise, which may lead to nonspecific health disorders because of interference with the restorative processes associated with rest and sleep. In conditions of chronic exposure, noise is considered to act as a biologic stressor that can lead to prolonged activation of the autonomic nervous system and the pituitary-adrenal complex, resulting in general health impairment.[100] Noise has also been related to disorders involving gastrointestinal motility, such as peptic ulcers,[101] and, as noted earlier, to circulatory problems such as hypertension.[102] Certain types of noise can be annoying and lead to emotional unrest.[103] Finally, noise can have a deleterious effect on task performance, especially if speech understanding is involved.[104] Generally, data relevant to the nonauditory effects of noise tend to be inconclusive because the variables are difficult to identify and isolate for objective study.

Legal Issues

One practical issue that the lawmakers of industrialized societies have had to consider concerns the balancing of two conflicting goals: How can laborers be protected against the hazards of the workplace without placing an enormous financial burden on society, either by satisfying compensatory obligations or by preventing such work-related effects through costly engineering modifications of the industrial process? Over the years, concerns about protecting the public and work force from environmental insults such as noise have been written into a combination of law and governmental regulations. Federal, state, and community legislative and regulatory actions are continually being reviewed and altered. Although the purpose of this review is not to detail such legal controls, regarding either their historical development or their current status, a brief discussion is appropriate. For a lucid analysis of governmental statutes and regulations pertaining to noise control, see the review by Dobie.[6]

The major difficulty encountered in composing regulatory control has been in defining in practical terms what constitutes a hazardous noise. The equal-energy principle[105] embodies one popular approach toward expressing the danger of a particular noise by a simple number.

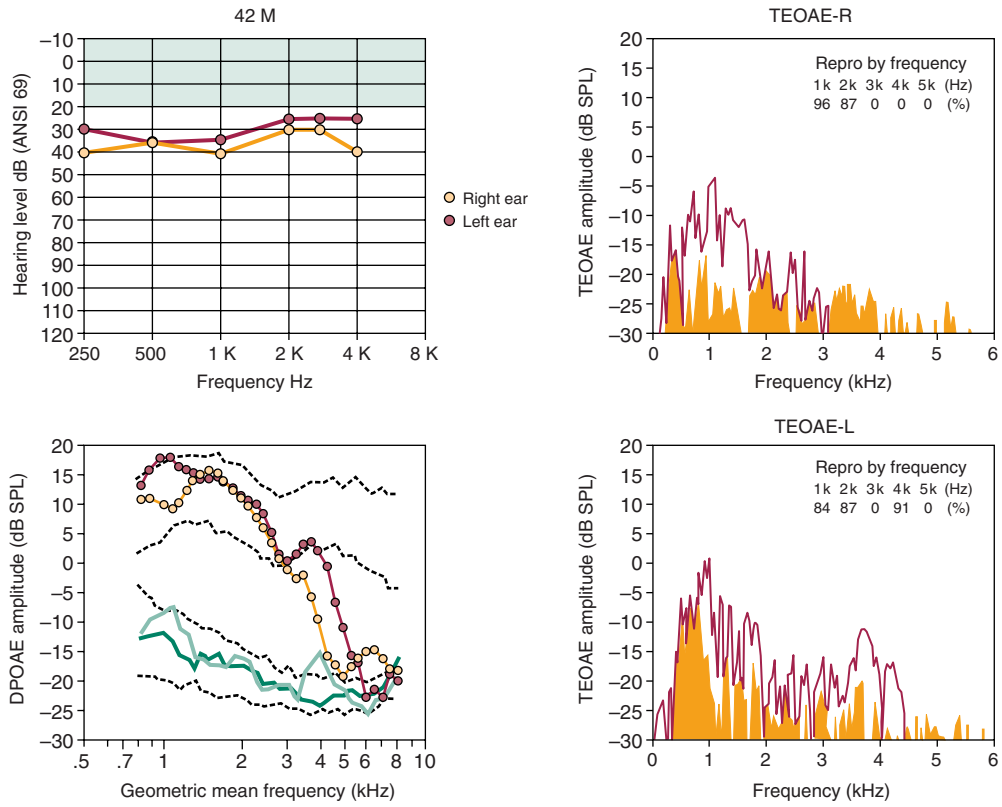

Figure 151-8. A possible case of pseudohypacusis in a 42-year-old male factory worker, who operated a wood lathe. Audiograms at *top left* show a relatively flat hearing loss up to approximately 4 kHz. For frequencies greater than 4 kHz, the patient claimed that test tones were inaudible. DP-grams show normal-like function up to approximately 3 to 4 kHz, when reductions in distortion product otoacoustic emission (DPOAE) levels are evident, occurring initially for the right ear *(yellow circles)*, which was more exposed to the lathe. Spectral plots on the *right* (transient-evoked otoacoustic emission [TEOAE]) also show poorer click-evoked otoacoustic emissions for the right ear. Together, normal levels of evoked emissions for frequencies less than 3 kHz and asymmetric pattern of reduction in otoacoustic emissions suggest that exposure to noise and aging contributed to decreased levels of activity for frequencies greater than 3 kHz. See legend for Figure 151-5 for an explanation of click-evoked spectra and two sets of *dashed lines* in DP-grams.

The equal-energy principle assumes that permanent damage to hearing is related to total sound energy, which is a product of the noise level in dBA and the duration of exposure. One tenet of this postulate is that an equal amount of noise energy causes an equal amount of hearing loss.

Burns and Robinson,[106] who investigated the hearing loss of thousands of industrial workers, concluded that the equal-energy principle could be applied to determine daily exposure doses because hearing loss caused by work-related noise exposure seemed to be a simple function of noise energy. Atherley and Martin[107] extended the concept to impulse noise by application of the equivalent continuous sound level (L_{eq}) principle. The L_{eq} is defined as the A-weighted level of a continuous, steady sound that produces, in a specified interval, an exposure that has the same total acoustic energy as that of an actual time-varying sound over the identical interval.[108] In other words, if one sound contains twice as much energy as a second sound but lasts half as long, both sounds would be characterized by the same equivalent sound level. The L_{eq} concept holds that these two exposures produce the same damage to the ear.

Although notions such as the equal-energy principle have proved useful in the practical definition of noise-control variables, their validity has been more difficult to establish. Over the years, experimental evidence has been conflicting in that it has tended to be either for or against the equal-energy rule. Generally, it seems that the principle cannot be generalized indiscriminantly to stimuli throughout the range of noise parameters because exposure to impulse or intermittent noises may lead to more or less degeneration in the organ of Corti than would be expected according to the equal-energy principle. Some aspect of the equal-energy concept has been adopted by most industrialized nations, however, including the United States, as a means of measuring the potential hazard of a particular noise exposure. Present regulations use a 5-dB exchange rate, along with a 90-dBA time-weighted average to define the permissible exposure limit over an 8-hour work day.[109] Consequently, exposure to 90 dBA for 8 hours is equivalent in sound-energy terms to an exposure of 85 dBA for half that time (i.e., 4 hours).

Currently, industries that employ laborers who work where noise is greater than 85 dB SPL implement a hearing-conservation program consisting of several components as dictated by the U.S. Occupational Safety and Health Administration (OSHA).[109] First, pre-employment audiometric assessment and annual audiometric monitoring are required so that noise-induced cochlear impairment can be detected before becoming too severe. When a hearing loss is identified, the worker must be notified of the disorder and counseled about the use of personal hearing protectors. The second portion of the conservation program requires workers in areas of high-noise levels (≥85 dBA) to wear ear protectors and to participate in a noise education program that informs the employee of the hazardous effects and the correct fitting of personal protectors. An important part of hearing conservation is the otologic referral (see next), which is essential when in-plant audiometry has detected a substantial hearing loss.

Role of the Otolaryngologist

Patients with NIHL constitute a notable portion of an otolaryngologist's patient population, particularly for otolaryngologists who are in private practice. With the increase in the population older than 65 years, the psychological, economic, and social impact of NIHL is still growing. Modern stereo systems in the form of personal music players such as the MP3 and iPod systems have sufficient noise levels and

listening durations to put consumers at risk for developing NIHL.[110,111] The widespread use of these devices, particularly among children and adolescents, is a growing worry,[112] particularly as reported by the mainstream media. Such concern is supported by the finding uncovered in the audiometric database of a large-scale national cross-sectional survey of an accelerating prevalence of sensorineural hearing loss in young adults 20 to 29 years old.[113] This growing prevalence of a high-frequency hearing loss in young adults may relate to an increase in personal stereo player use. The outcome of at least one relevant experimental study using similarly aged subjects, who were systematically exposed to music from an MP3 player at their preferred listening levels, does not agree with this explanation, however.[114] In any case, otolaryngologists are expected to continue to be conspicuously involved with the problem of NIHL.

Although a known prevention exists, it is unlikely for fiscal and technical reasons that the general loud sound levels of our environment will be reduced. Although the inhalation of hyperoxygenated air as a prophylaxis[115] has been proposed, and, as noted previously, clinical trials on the safety and efficacy of certain antioxidant compounds to prevent or reverse NIHL are currently in progress, to date, no proven treatment or cure for noise damage exists. Consequently, detecting the early stages of NIHL is important to prevent further injury to the crucial sensory-cell receptors of the organ of Corti.

The role of the otolaryngologist is first to identify the cause and extent of a reported hearing loss through systematic medical and audiometric evaluation. As part of the course of otologic management, the patient should be educated about the hazards of noise, and about preventive measures to preserve remaining hearing. The physician should make basic decisions about the appropriate aural rehabilitative course of action. Finally, the otolaryngologist should be sensitive to any emotional problems the patient may have in accepting a hearing impairment, which may be dealt with by counseling or special provisions.

Although NIHL is not medically or surgically treatable, it is almost entirely preventable. Its prevention requires education, engineering, and administrative controls, and the proper use of hearing protection. One of the otolaryngologist's most important contributions is in teaching the patient to guard against further losses.[116] When recommending the use of personal hearing protectors or reinforcing compliance with ongoing hearing-protection measures, the physician should be aware that the commonly used personal protectors in the form of inserted earplugs or earmuffs vary considerably in effectiveness, and produce an attenuation that is highly frequency dependent.[117,118] When sealed correctly into the ear canal, earplugs reduce the noise reaching the middle ear by 15 to 30 dB, and work best for the midfrequency to higher frequency range (i.e., 2 to 5 kHz). Earmuffs are more effective protectors, especially for frequencies between 500 Hz and 1 kHz, where noise is attenuated by 30 to 40 dB.[119] In areas with extremely high noise levels, earplugs do not afford sufficient protection, and individuals should be advised to wear both earplugs and earmuffs. Also, sound energy associated with high noise levels may reach the inner ear by passing through vibrating bone and tissues adjacent to the ear. Bone-conduction and tissue-conduction thresholds set a practical limit to the possible attenuation provided by hearing-protection devices.

A final point concerning the use of hearing protectors should be impressed on the patient. When data relating the maximal protection in dBA to the percentage of time that the devices are worn are considered, it is clear that hearing protectors should be worn all the time because if they are removed for even a few minutes, their effective cumulative attenuation capability is severely reduced. Removing hearing protection for only 15 minutes of an 8-hour work shift can cut protection efficacy in half. Similarly, a poorly fitting hearing protector does not prevent hearing loss.[1]

In many states, compensation is available for occupational NIHL. Physicians are required sometimes to serve as expert witnesses as to the probable cause of a claimant's hearing loss. Such medicolegal testimony requires that the patient undergo careful otologic and audiometric evaluation so that hearing losses caused by unrelated ear disorders, such as cerumen impaction, middle ear effusion, aging, genetic deficits, otosclerosis, and an array of other ear diseases (e.g., Meniere's disease, acoustic neuroma), can be excluded. To permit the reversible (i.e., TTS) effects to recover, most states require a recovery time (ranging from 14 "quiet" hours to 24 weeks) away from the occupational noise source before audiometric assessment. By ruling out organic disease, giving careful attention to the history of job-related and recreation-related noise exposure, and documenting the extent and degree of involvement of both ears, an informed decision concerning any causal relationship between the noted disability and the work environment can be made.

Hearing impairment is the medical term used to refer to the hearing level at which individuals begin to experience difficulties in everyday life. Hearing impairment manifests in practical terms, such as a difficulty in understanding speech. By the time an individual becomes aware of decreased speech intelligibility, considerable damage to the organ of Corti likely has occurred because speech reception is not altered greatly until a hearing loss is more than 40 dB. The amount of loss at frequencies most important to speech (i.e., at 2 kHz, 3 kHz, and 4 kHz) is used by OSHA[108] as a basis for calculating amounts of compensation because NIHL occurs initially at greater than or equal to 2 kHz. The measure of hearing impairment is called the hearing handicap, which is always based on the functional state of both ears. An official guide devised by the American Academy of Otolaryngology–Head and Neck Surgery[120] provides a detailed explanation of how to evaluate and compute an NIHL handicap. Generally, the disability benefits of the U.S. Social Security Administration[121,122] are less generous than are the benefits for either military veterans or typical worker's compensation programs.

Because of an increasingly noisy environment and the probability that many individuals will unwittingly sustain hearing losses because of exposure to loud sounds at home, on the job, and during recreational activity, otolaryngologists, along with other health care professionals dealing with hearing problems, should educate the public about hearing conservation. Such education is needed especially for children and adolescents, who, as noted previously, are regularly exposed to the amplified music associated with personal music players, stereos, dance clubs, and live concerts. A common image that can be used to motivate the public and workers in industry to be aware of the insidious damage of noise exposure is the grass metaphor representing the sensory cells of the inner ear. Typically, blades of grass straighten up after they have been bent by being walked on. If one continues to tread on the same patch day after day, however, the grass eventually dies, leaving a bare spot; this is similar to what happens to the ear's hair cells when assaulted continually by high-intensity sounds.

The physician can be particularly effective in teaching individuals how to recognize the danger signals of potential NIHL including the need to shout to be heard and the development of the sensation of pain, muffled sound, and tinnitus.[123,124] The influence of otolaryngologists as hearing experts in the areas of education and motivation can be a major force in preventing NIHL.

Summary

We know more now than ever about the workings of the human ear, including how it responds initially to excessive sound, and how it eventually fails to reverse the progressive damage. We also know how much more we need to learn about basic ear processes before such damage can be corrected. As understanding of the fundamental mechanisms involved in the process of NIHL progresses, developing a medical intervention to minimize permanent injury seems achievable. In the meantime, we know what needs to be done to prevent or check the damage process. In light of the economic impracticability of noise control at the engineering or administrative level, especially in industry, it seems that education of the public about the potential hazards of excessive sound and the beneficial use of protective devices will be the major weapons against NIHL. Consequently, the educational role of otolaryngologists is paramount for the conservation of hearing that is threatened by habitual noise exposure.

CHAPTER ONE HUNDRED AND FIFTY-TWO

Infections of the Labyrinth

Larry E. Davis

Key Points

- RNA and DNA viruses, bacteria, and fungi cause infections of the human labyrinth in fetuses, children, and adults.
- Selective vulnerability of inner ear structures varies by the virus, and results in different inner ear pathologies.
- Some viruses and bacteria primarily destroy sensorineural epithelium causing permanent hearing loss, whereas other viruses, such as cytomegalovirus, cause little direct damage to cochlear sensorineural structures, and apparently cause deafness by another mechanism.
- The precise role viral infections play in sudden sensorineural hearing loss, vestibular neuritis, and Meniere's disease is unclear.
- There is increasing evidence that hearing loss from otosclerosis is associated with a persistent rubeola virus infection of the stapes footplate.
- There currently are no good antiviral agents for most viruses that infect the inner ear.
- Administration of mumps, rubella, rubeola, and varicella-zoster vaccines is the best method to prevent viral inner ear infections.
- Placement of cochlear implants is successful treatment for children born with congenital deafness from cytomegalovirus or rubella.

Infectious agents, particularly viruses and bacteria, are thought to play a direct or indirect role in causing several inner ear disorders.[1] Each year, several thousand infants are born deaf or with impaired hearing. At least 18% of these cases are proven to be caused by congenital viral infection, and a greater percentage are suspected to have an infectious cause.[2] Each year, about 10 out of every 100,000 individuals are stricken by so-called sudden deafness, which occurs as unilateral or bilateral sensorineural hearing loss (SNHL) of varying degrees.[3] Infectious agents are often suspected as the cause. Bacterial labyrinthitis with profound hearing loss occurs in 10% of patients with bacterial meningitis.[4] Thousands of individuals each year have vestibular neuritis, which many authors think has an infectious origin.[5]

Although many infectious agents are thought to play important etiologic roles in labyrinthine disorders, there are many difficulties in proving that a given infectious agent infects the human labyrinth.[1]

1. Otologic examination shows the degree of functional deficit of the inner ear, but seldom establishes the cause.

2. Cranial computed tomography (CT) shows the shape of the bony labyrinth, but does not show the membranous labyrinth or facial nerve.

3. Resolution of cranial magnetic resonance imaging (MRI) is presently insufficient to show clearly details of the membranous labyrinth.

4. The inner ear is encased within a dense temporal bone, making viral culture of inner ear fluids or tissue from the spiral or vestibular ganglia difficult and seldom done.

5. Acute hearing loss or vertigo is rarely fatal; acute inner ear tissue is rarely available from autopsies.

6. The temporal bone is seldom removed at routine autopsies, so inner ear tissue seldom becomes available for histologic examination even when the illness was remote.

7. Decalcification of temporal bones is slow (months), and often involves agents such as nitric acid that damage the inner ear tissue morphology, often making the tissue inadequate for immunohistochemical studies.

8. Serologic studies can determine that an individual was infected by a given virus, but do not prove the virus caused the labyrinthine damage.

9. Serologic studies of herpes simplex virus (HSV) are difficult to interpret because studies of healthy individuals show that fourfold increases and decreases in HSV antibody titers commonly occur without disease.[6]

10. Isolation of virus from the mouth or nasopharynx does not imply that the virus caused the inner ear damage. HSV and adenoviruses are commonly latent in humans and are intermittently shed in the oropharynx.[7] Other viruses, such as enteroviruses, can be isolated from the throats or stool of asymptomatic individuals, especially when the virus is prevalent in the community.[7]

11. HSV and varicella-zoster virus (VZV) (and likely other herpesviruses) can establish viral latency in neuronal populations and never reactivate during the life of the individual. Detection of viral nucleic acid by polymerase chain reaction (PCR) within neurons does not in itself prove that the latent virus was the cause of the tissue damage.

Establishing whether a given virus is the cause of the patient's deafness or vertigo is difficult. The criteria in Box 152-1 are proposed for determining causality.

Box 152-1

Optimal Proof for Infectious Cause of Inner Ear Infection

1. Clinical association of infectious agent with a specific cochlear or vestibular syndrome
   Epidemiologic studies of infectious agent and syndrome
   Clinical studies of syndrome and isolation of infectious agent at other sites or serologic antibody titer rise
2. Clear evidence of infectious agent presence within inner ear tissue
   Isolation of infectious agent RNA (vRNA) or messenger RNA (mRNA) (excluding mRNA latency-associated transcripts) in inner ear tissue
   Histologic demonstration in inner ear tissue by electron microscopy of infectious agent or by light microscopy finding of inclusion bodies or characteristic cell morphology plus isolation of infectious agent at other body sites
3. In experimental animals, demonstration that suspect infectious agent can cause similar auditory or vestibular signs and inner ear pathology

Modified from Davis LE. Neurovirology of deafness, labyrinthitis and Bell's palsy. In: Johnson RT, ed. *Neurovirology*. Minneapolis: American Academy of Neurology; 2002.

PCR has become a powerful tool in the detection of nucleic acid from infectious agents in human tissues. PCR is difficult to use, however, when tissues, such as temporal bones, have been fixed in formalin and decalcified for weeks with nitric acid. Formalin fixation cross-links DNA and RNA, and nitric acid harms nucleic acids. PCR has been helpful in analyzing small amounts of fresh perilymph removed during surgery and detecting cytomegalovirus (CMV).[8-10]

At present, an unresolved controversy exists regarding the significance of detection of latent herpesvirus DNA in human tissue. Several PCR studies have detected HSV DNA in neurons at autopsy from previously healthy patients from several sites, including the brainstem and cerebral cortex[11] and spiral and vestibular ganglia.[12-14] To date, culture of neuronal explants from these sites has not yielded isolation of HSV similar to culture of trigeminal or sacral ganglia.[15] Clear evidence for the breaking of viral latency and subsequent viral replication currently is lacking. It is unclear whether vestibular and cochlear neurons are dead-end cells, capable of developing latency, but incapable or poorly capable of breaking latency. The latter possibility might allow for occasional patients developing a solitary episode of vestibular neuritis or sudden hearing loss, whereas many patients develop repeated episodes of lip or genital HSV blisters from repeated breakage of latency in the trigeminal and sacral ganglia.

To date, only a few infectious agents have been recovered from or identified within human labyrinthine tissues. CMV[8,9,16] and mumps virus[17] have been isolated from perilymph. CMV antigen has been detected by immunohistochemistry within inner ear tissues.[16,18] Morphologic identification of infectious agents within the labyrinth has been accomplished for several bacteria,[19,20] fungi,[20,21] and *Treponema pallidum*.[22] A multinucleated giant cell, typical of rubeola (measles) virus infection, has been seen within the scala vestibuli.[22] HSV DNA[10,12,23] has been identified within vestibular and cochlear ganglia neurons by PCR assay. One study reported detection of HSV DNA by PCR in vestibular labyrinth tissue.[24] To date, intranuclear inclusion bodies or viral antigens have not been identified within inner ear tissues.

Although rubella has been closely associated epidemiologically with congenital deafness, and has been isolated from many sites in congenitally deaf infants, the virus has never been isolated from or viral antigens have never been identified within inner ear tissues. Histopathologic changes of the temporal bone are not specific for rubella. Nevertheless, available evidence strongly argues that rubella can cause congenital deafness.

Box 152-2

Infectious Agents Associated with Acquired Sudden Sensorineural Hearing Loss or Vertigo*

Viruses
Mumps
Herpes simplex
Epstein-Barr
Varicella zoster
Hepatitis viruses
Adenovirus
Enterovirus
Lassa fever
Rubella
Yellow fever
Variola (smallpox)
Measles (rubeola)
Influenza B virus
Influenza A virus
Parainfluenza
Western equine encephalitis
St. Louis encephalitis
Encephalomyocarditis
Russian-spring-summer encephalitis
Tick-borne encephalitis
Lymphocytic choriomeningitis
Hantavirus

Bacteria
Borrelia burgdorferi
Treponema pallidum
Mycoplasma pneumoniae
Brucella sp
Mycobacterium tuberculosis

Fungi
Cryptococcus neoformans

Rickettsia
Rickettsia prowazekii

*__Bold__ indicates the most common causes.

It is assumed that infectious agents are not normally present in the membranous labyrinth or adjacent ganglia; isolation of an infectious agent from the inner ear carries considerable etiologic significance. This assumption is not based on comprehensive bacteriologic or virologic studies, however. Healthy guinea pigs may harbor herpeslike viruses in the spiral ganglia neurons.[25,26]

Many infectious agents have been reported to be associated with deafness or vertigo. For some infectious agents, the association has been based on case reports that describe acute deafness or vertigo that developed during a systemic infection. For other infectious agents (e.g., rubella), the epidemiologic association has been strong between systemic infection of the individual or mother, and subsequent deafness or vertigo. Box 152-2 lists infectious agents that have been associated with deafness or vertigo, but have yet to fulfill the criteria for optimal proof of causality.

Congenital Hearing Loss

Cytomegalovirus

Clinical Features

CMV is the most common infectious cause of congenital hearing loss in the United States, accounting for 2600 to 4000 cases of SNHL each

year.[27,28] The incidence of congenital CMV infection is about 0.3 to 1 case/100 live births.[29-31] Less than 5% of all congenital CMV infections result in the severe infection termed *cytomegalic inclusion disease*. In this multiorgan infection, the incidence of SNHL is 50% in infants who survive the neonatal period.[32] Hearing loss when measured years later is bilateral, symmetric, and often severe.[33] High-frequency hearing loss is usually greater than lower frequency hearing loss.

Most (>95%) congenital CMV infections are silent, and the newborn appears normal at birth. When 12,371 newborns were screened for the presence of CMV in urine that would indicate a congenital infection, the incidence of SNHL was found to be 1.1/1000 live births.[30] Another study of 307 infants with asymptomatic congenital CMV infection reported 7.2% had SNHL that ranged from mild to profound.[28] Fifty percent had bilateral hearing loss, and 20% had late-onset hearing loss. Other studies have reported that 5% to 15% of children born with silent congenital CMV infection and normal hearing in the neonatal period subsequently developed mild to moderate bilateral SNHL that may be progressive.[31,34-36] Occasionally, these children progress to profound hearing loss in one or both ears. Studies estimate the prevalence of moderate or worse SNHL caused by congenital CMV to be 0.2 to 0.6 case/1000 live births.[29]

Diagnosis

Congenital CMV is diagnosed in symptomatic and asymptomatic infants by isolation of CMV from fresh urine during the first 1 to 2 weeks of life. CMV DNA can also be detected by PCR from urine, blood, cerebrospinal fluid (CSF), and infected tissues.[37] Of congenitally infected infants, 60% to 75% have detectable IgM antibodies to CMV in the umbilical cord or infant serum. Antibodies of the IgM class imply fetal synthesis because maternal IgM antibody normally does not cross the placenta. This serologic test is difficult to perform and should be done only in qualified laboratories. CMV has been isolated from the amniotic fluid of mothers with a congenitally infected fetus.[38,39] After 1 year of age, diagnosis of congenital CMV infection is very difficult. Healthy infants may acquire the virus infection asymptomatically, shedding the virus in their urine and developing antibody titers. Because most maternal infections are asymptomatic, no reliable history can be obtained retrospectively from the mother.

Temporal Bone Pathology

Limited histologic studies of infants dying with cytomegalic inclusion disease show labyrinthitis of the endolymphatic system.[18,40-43] Inclusion-bearing cells have been identified in the auditory and vestibular portions of the inner ear (Fig. 152-1). Within the cochlea, damage is most severe along the basal turn. Evaluating the condition of the organ of Corti has been difficult because of postmortem autolysis, but it seems that the major hair cell degeneration seldom occurs, and that the tectorial membrane remains normal. There is little histologic damage to the auditory and vestibular nerves along with the spiral and vestibular ganglia. Hydrops of the cochlea and saccule and collapse of Reissner's membrane have been observed. In one patient with cytomegalic inclusion disease, a thick layer of these inclusion-bearing cells was found inside the membranous walls of the utricle in the regions where dark cells are located.[41]

The temporal bones of an infant with severe cytomegalic inclusion disease and bilateral deafness who survived 14 years were studied.[44] Chronic pathologic changes were seen in the cochlear and vestibular and nonsensory tissues. Reissner's membrane was collapsed in the more apical turns. Strial atrophy and a loss of cochlear hair cells were observed along the entire length of the basilar membrane. Vestibular neuroepithelial regions were degenerated, and fibrosis was seen within the vestibular perilymphatic tissue spaces. In cochlear and vestibular spaces, isolated regions of calcifications were present. The fibrosis and calcifications suggest that late pathologic changes developed months to years after the acute viral damage had subsided.

In infants dying of cytomegalic inclusion disease, CMV antigen has been identified within cells lining the membranous labyrinth by immunofluorescent antibody staining.[41] Virus particles belonging to the herpesvirus family have been seen within cells of the membranous labyrinth by electron microscopy.[40,41]

CMV has been isolated from perilymph obtained at autopsy from an infant with cytomegalic inclusion disease.[41] CMV also has been isolated from the perilymph of a 5-month-old infant who died with asymptomatic congenital CMV infection whose inner ear morphology was normal by light microscopy.[42] CMV has been detected by PCR in perilymph removed during placement of cochlear implants in children 4½ years old with congenital CMV,[8] but CMV was not isolated from perilymph, or cytomegalic inclusion body–containing cells were not

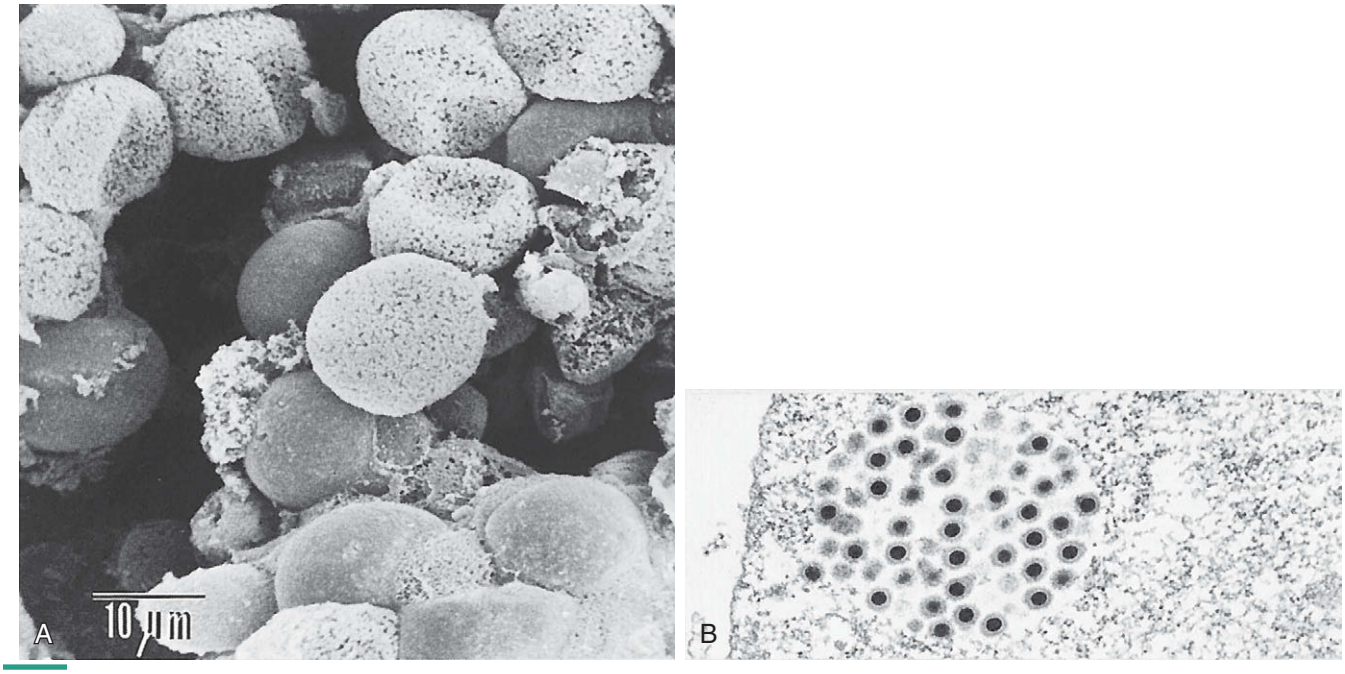

Figure 152-1. Congenital cytomegalovirus infection in a 1-month-old infant. **A,** Scanning electron micrograph shows large osmiophilic cytomegalovirus inclusion-bearing cells lining the membranous wall of utricle. **B,** Transmission electron micrograph shows cytomegalovirus particles with dense cores forming aggregates in the cytoplasm of utricular epithelium (×34,500). *(From Davis LE, Johnsson L-G, Kornfeld M. Cytomegalovirus labyrinthitis in an infant: morphological, virological, and immunofluorescent studies.* J Neuropathol Exp Neurol. *1981;40:9.)*

seen in a child with cytomegalic inclusion disease and bilateral deafness who survived 14 years.[44] It seems that CMV can persist for years in children with congenital viral infections. What role CMV persistence plays in the delayed hearing loss of asymptomatically infected children is unclear.

Management and Prevention

Four approaches have had limited success in preventing or treating SNHL in congenital CMV. Toward prevention of primary CMV infection in a CMV-seronegative woman of childbearing age, several experimental CMV vaccines have been developed and are in clinical testing. These include protein subunit vaccines, DNA vaccines, vectored vaccines using viral vectors, peptide vaccines, and live attenuated vaccines.[45,46]

Treatment of pregnant women with primary CMV infection has been tried by passive immunization using hyperimmune CMV gamma globulin. A nonrandomized study of pregnant women with primary CMV infections showed a significant reduction in symptomatic infected newborn infants at 2 years of age.[47] Valacyclovir at 8 g/day given to pregnant women with primary CMV infection has been shown to achieve therapeutic levels in maternal and fetal blood with a reduction in fetal viral load.[39] Mixed clinical outcomes occurred in the 21 fetuses treated at 28 weeks of gestation, however.

The antiviral drugs, ganciclovir and valganciclovir, have had some success in treating infants with cytomegalic inclusion disease.[48-52] Ganciclovir requires phosphorylation to ganciclovir triphosphate in part by enzymes from CMV. The triphosphate molecule inhibits viral DNA polymerase with inhibition of CMV replication.[48] In a randomized controlled trial, intravenous ganciclovir begun in the neonatal period of symptomatically infected infants was effective in preventing hearing deterioration at 6 months, and may prevent hearing deterioration past 1 year.[49]

Ganciclovir can be delivered only by the intravenous route, and so creates a major problem for extended delivery of the agent. Valganciclovir, a monovalyl ester of ganciclovir, is an oral prodrug of ganciclovir, and in small studies seems to have similar efficacy in treating congenital CMV infections.[50,51] Both drugs reduce CMV viral load in blood and urine, but rarely eliminate the virus from the host. Both drugs also frequently cause neutropenia, so dosages must be carefully monitored.

There is increasing evidence that deafness from congenital CMV is not a contraindication for cochlear implantation. Studies of these children have shown hearing improvement results similar to other congenitally deaf children, and no unusual complications have developed.[53,54]

Experimental Cytomegalovirus Inner Ear Infections

The human strain of CMV has not been shown to infect the labyrinth of small animals. The mouse and guinea pig strains of CMV have been shown to infect primarily perilymphatic structures of the cochlea and vestibule with variable secondary degeneration of the organ of Corti.[55] In guinea pigs, guinea pig CMV has been inoculated directly into the basal turn of the cochlea, resulting in inflammation and cytomegalic cells within the perilymphatic duct along with variable secondary degeneration of the organ of Corti.[56,57] These strains are also capable of infecting neurons in the spiral and vestibular ganglia. Guinea pig CMV has been shown to reach the cochlea by the intravenous route, and to cross the placenta to infect the fetal cochlea.[58] Electrophysiologic recordings of cochlea microphonic and eighth cranial nerve have shown objective hearing loss in N1 compound action potential thresholds of infected guinea pigs.[59-61] To date, all experimental models differ from human inner ear infection in that the animal viruses have primarily infected cells of the perilymphatic system, whereas human CMV primarily infects cells of the endolymphatic system.

Congenital Rubella Deafness

Clinical Features

Rubella infection of the pregnant mother as a cause of neonatal deafness was first recognized during the 1939 Australian rubella epidemic.[62] From 1964 to 1965 during the U.S. rubella epidemic, more than 12,000 infants were found with hearing loss and congenital rubella.[63] Since the introduction of rubella vaccine, the number of cases in developed countries has dramatically decreased, but not disappeared. The World Health Organization estimates that more than 100,000 infants are born each year with congenital rubella syndrome with 50% having hearing impairment.[64] In many developed countries, it is estimated that 15% to 20% of women in childbearing years are susceptible to rubella infection, a number that is similar to that in industrialized countries in the prevaccination era.[65] Since 2001 in the United States, there have been less than 25 cases of rubella each year, and no reported cases of congenital rubella syndrome.[66]

Maternal rubella infection during the first trimester of pregnancy places the fetus at the highest risk of congenital infection and subsequent hearing loss. In addition to the hearing loss, infants are often born with cardiac malformations, vision loss, and mental retardation.[67] Approximately 50% of infants born with symptomatic congenital rubella have hearing loss. Infants infected with rubella during the second and third trimesters often are born with silent rubella infection and appear healthy at birth. Ten percent to 20% of these children are subsequently identified as hearing impaired.[68]

Hearing Loss

Congenital rubella infection involving the inner ear usually results in bilateral, often asymmetric, hearing loss. In a series of 8168 children with hearing loss from congenital rubella, 55% had profound hearing loss (≥91 dB ISO [International Standards Organization]), 30% had severe hearing loss (71 to 90 dB), and 15% had mild to moderate hearing loss (<70 dB).[63] The audiograms of most children were usually flat, with hearing deficits occurring in all frequencies, but some had the greatest hearing loss in the midfrequency range of 500 to 2000 Hz, which is the range of voice.[69] Children with rubella deafness may have poor speech discrimination, and a few may experience progressive hearing loss. Some children have had delayed or impaired speech development, but still have healthy pure tone hearing, which suggests a central auditory imperception.[70] Adults who experience rubella infection rarely develop hearing loss.[71]

The vestibular system seems to be involved to a lesser extent than the auditory system.[72] Caloric stimulation with 1 mL of ice water has suggested that some children have reduced caloric responses in one or both ears.[73]

Diagnosis

Congenital rubella may be diagnosed by (1) isolation of rubella or detection of rubella-specific RNA from urine or throat cultures during the first weeks of life, (2) identification of IgM antibodies against rubella in serum from the neonate, or (3) increased antibody titer to rubella in an infant during the first few months of life who did not receive the rubella vaccine. Identification of IgM antibodies against rubella is difficult and should be performed only in qualified laboratories. In children older than 1 year, congenital rubella is difficult to diagnose because many children have received the rubella vaccine. A maternal history of rash during pregnancy is unreliable for establishing or ruling out the diagnosis. Congenital rubella has been diagnosed in utero by isolation of rubella from amniotic fluid. No specific management for children exists because no antirubella virus drugs are available. Management should be directed toward minimizing the consequences of the hearing loss and possible use of a cochlear implant.

Temporal Bone Pathology

Histopathologic changes seen in the temporal bones of congenital rubella deafness show characteristic changes, but the histopathologic findings are not specific for a rubella infection. The predominant abnormality is cochleosaccular degeneration and strial atrophy of varying degrees.[74,75] Reissner's membrane and the wall of the saccule may sag and even collapse (Fig. 152-2). The tectorial membrane is frequently abnormal, often displaced from the organ of Corti toward the limbus. The stria vascularis shows varying degrees of atrophy. Inflammatory cells in the cochlea are seldom seen. Cells with inclusion bodies do not occur. The vestibular neuroepithelia and their nerves

Figure 152-2. Congenital rubella infection in a premature infant. Cochlea shows partial collapse of Reissner's membrane onto the organ of Corti in all turns (hematoxylin-eosin stain, ×40.) *(Courtesy of G. Nagar, Baltimore, MD.)*

usually appear healthy. There are no animal models for congenital rubella or rubella deafness.

Acquired Sensorineural Hearing Loss

Sudden Sensorineural Hearing Loss

Clinical Features

Many causes of SNHL have been described in children[76,77] and adults.[78] Although several definitions exist, most require a loss of greater than 30 dB in three contiguous frequencies that occurs in less than 3 days in the absence of a skull fracture.[79] The incidence of severe SNHL is about 10/100,000 persons per year.[3,80] The incidence of mild cases is unknown because many individuals do not seek medical attention. Most patients awaken with the hearing loss, or the loss develops within minutes to several hours. The hearing loss is unilateral in more than 90% of cases. Approximately half of the patients note accompanying vertigo or imbalance. Recovery of hearing ranges from 45% to 60%.[3,81] The usual recovery period is days to weeks. After 1 month, little recovery occurs.[3] The extent of recovery is related to age and severity of initial hearing loss. Untreated patients younger than 40 years of age have a better recovery rate. For individuals older than 40 years, the recovery rate may be only 30%.[79]

Temporal Bone Pathology

The mechanisms involved in the sudden hearing loss have not been fully clarified because there are few available temporal bone studies from patients during the acute period. A viral infection of the cochlear endolymphatic structures or spiral ganglia is one of several theories that has been postulated as the cause. Schuknecht[82,83] examined the temporal bones of 12 patients with idiopathic sudden SNHL in his series and reviewed 9 additional published cases. Vertigo was noted in 47% of cases. Histologic abnormalities were identified in the organ of Corti (76%), tectorial membrane (53%), stria vascularis (62%), cochlear neurons (48%), saccule (43%), fibrosis with ectopic bone formation (10%), and tears in Reissner's membrane or oval or round windows (10%). Schuknecht[82,83] concluded that a viral infection of the endolymphatic labyrinth was the most tenable pathogenesis. Another study of 15 temporal bones from patients with SNHL reported the most prominent histologic findings to be loss of hair cells and supporting cells of the organ of Corti (with or without atrophy of the tectorial membrane), stria vascularis, spiral limbus, and cochlear neurons.[84] This study reported examination of one temporal bone from a patient who died 9 days after unilateral sudden hearing loss and failed to find evidence of cochlear inflammation.

Several studies have attempted to define the infectious causes of idiopathic SNHL. Two viruses, mumps and measles (rubeola), have been recognized for centuries as a cause of acquired hearing loss in children. For other viruses, associations generally have been made on the basis of fourfold elevations in viral antibody titers in convalescence or case reports with isolation of the candidate virus from the nasopharynx or mouth. In addition to viruses, syphilis is recognized to cause acute hearing loss[85]; Lyme disease may also be a cause.[86] Box 152-2 lists these candidate infectious agents. To date, associations of infectious agents have represented only a small fraction of the total SNHL cases.

Management

Administration of high-dose corticosteroids shortly after the onset of SNHL has been shown to have a significant benefit in recovery of hearing.[87-89] More recently, nonrandomized studies of repeat treatment with intratympanic dexamethasone in patients who failed systemic corticosteroids reported that occasionally additional hearing recovery ensued.[90-92] Because of the possibility that SNHL might be due to reactivation of HSV, a prospective, randomized, double-blind clinical trial of systemic prednisolone versus corticosteroids and acyclovir was performed on 91 patients.[93] The investigators reported no additional benefit of the acyclovir over prednisolone only. If the sudden severe hearing loss permanently involved both ears, these patients may be candidates for cochlear implants.

Major Causes of Acquired Deafness from Viruses

Mumps Deafness

Clinical Features

Mumps was first recognized to cause deafness in 1860. Since then, it is estimated that 5 of every 10,000 patients with mumps have hearing loss develop.[94] The widespread use of the mumps vaccine in developed countries has dramatically reduced the incidence. Mumps deafness continues to occur, however, in developing countries that do not have major vaccination programs. A study of 115 children with profound bilateral deafness reported that mumps was responsible for 7% of the cases.[95] There has been a more recent increase in mumps in college-aged individuals in the United States (>2600 cases) and United Kingdom.[96] Many of these individuals had previously received two doses of the mumps vaccine. It is unclear how often the mumps caused hearing loss in these patients.

Deafness associated with mumps usually develops in children toward the end of the parotitis, but can occur from a subclinical infection in the absence of parotitis.[97-100] The onset of the deafness is usually rapid and unilateral in 80%. Hearing loss is maximal at high frequencies. Tinnitus and fullness in the involved ear are common. In two patients with acute mumps deafness, MRI showed enhancement of the labyrinth and CN VIII[101] and the cochlea and vestibule.[102]

The hearing loss is often profound and usually permanent. A prospective study by Vuori and colleagues[103] found the hearing loss to be transient in some patients, however. Some patients have vertigo develop that usually resolves over several weeks, but the patient may be left with permanent diminished or absent caloric responses in that ear. Absent caloric responses have also been found in patients with deafness associated with mumps, but without a history of vertigo.

Diagnosis

Mumps is diagnosed by (1) isolation of mumps virus from the saliva or CSF, or detection of mumps virus RNA, or (2) a fourfold or greater serologic increase in mumps antibodies between acute and convalescent serum samples. Sensitive real-time reverse transcriptase PCR assays are available for rapid detection of mumps virus from saliva.[104] Mumps virus has been isolated from the perilymphatic fluid in one patient with acute unilateral deafness associated with parotitis.[17] Currently, no specific antiviral drugs for mumps deafness exists, and it is unclear whether administration of corticosteroids improves hearing recovery. Administration of mumps vaccine in infancy effectively prevents subsequent mumps infections in childhood and adulthood.

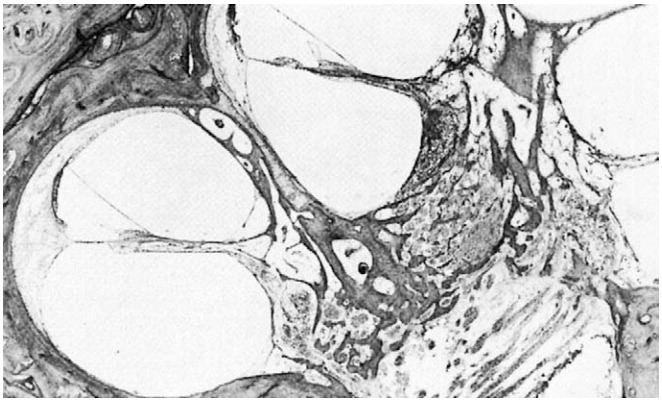

Figure 152-3. Acquired mumps virus deafness 13 years previously. Cochlea shows absent organ of Corti in the basal turn with secondary degeneration of some ganglion cells and severe degeneration of their distal processes in osseous lamina (hematoxylin-eosin stain, ×22.) *(From Smith GA, Gussen R. Inner ear pathologic features following mumps infection: report of a case in an adult.* Arch Otolaryngol. *1976;102:108. Copyright © 1976, American Medical Association.)*

Temporal Bone Pathology

Temporal bones from two patients with mumps-associated deafness have been examined.[105,106] The cochlea showed severe atrophy of the organ of Corti and the stria vascularis, with partial collapse of Reissner's membrane in the basal turn (Fig. 152-3). The tectorial membrane in one case was folded, thickened, and displaced from the organ of Corti. The upper turns of the cochlea showed less damage with occasional loss of hair cells. Cochlear ganglion neurons may be decreased in the area of the basal turn. Minimal vestibular abnormalities were seen.

Experimental Mumps Viral Labyrinthitis

Mumps virus inoculated into the inner ear of hamsters, guinea pigs, and monkeys principally infected non-neuroepithelial cells of the membranous labyrinth, which included cells of Reissner's membrane, stria vascularis, and supporting cells of the organ of Corti.[73,107,108] In the cochlear basal turn, degeneration of the organ of Corti and damage to the stria vascularis developed. Cells of the inner ear could be infected if the virus was inoculated directly into the inner ear, or if the virus entered the perilymphatic fluid of the scala tympani by way of the cochlear aqueduct after intracerebral inoculation.

Because the virus could reach the perilymph from the CSF in the model, the question arises as to whether this route of infection could occur in humans. Support for this hypothesis is severalfold. Mumps viral meningitis occurs in one third of infected children.[109] The cochlear aqueduct is more often patent in children than adults, and dilated cochlear aqueducts have been recognized by CT in 6% of children with SNHL.[76,110] Finally, deafness often develops toward the end of the first week of parotitis, a time consistent with spread of mumps virus from the infected CSF because of the meningitis from the cochlear aqueduct to the scala tympani. Spread of virus from CSF to the inner ear could also occur by way of the CN VIII pathway through the internal auditory canal to the spiral ganglion. Against both hypotheses is one study that did not find a correlation between mumps meningitis and deafness.[103]

Measles Deafness

Clinical Features

Rubeola virus is the cause of measles and continues to be an important cause of acquired hearing loss in developing countries. The incidence of deafness after measles is slightly less than 1 out of every 1000 cases of measles. Before the introduction of rubeola virus vaccine in developed countries, rubeola virus caused 3% to 10% of all acquired deafness in children. Now rubeola deafness occurs primarily in developing countries without measles vaccination programs.

Measles virus involvement of the labyrinth usually is seen with the abrupt onset of bilateral hearing loss at the time of the rash, but occasional children have only unilateral hearing loss develop. In one large study, 45% of the children were left with severe bilateral hearing loss, and 55% had mild to moderate hearing loss.[111] The typical audiogram shows bilateral loss that is often asymmetric and maximal at higher frequencies. The hearing loss is usually permanent and acutely may be accompanied by vertigo and tinnitus. Seventy percent of patients are left with absent or diminished caloric responses in one or both ears even though the vertigo has subsided.[111]

Conductive hearing loss from otosclerosis is becoming highly associated with persistent rubeola virus infection of the stapes footplate. Rubeola virus RNA has been detected by PCR in the stapes footplate removed at stapedectomy from patients with otosclerosis, but not stapes footplates of other diseases.[104,112,113] Tissue culture explants of the stapes footplates also showed rubeola virus RNA.[114] In addition, filamentous structures in osteoblast-like cells resembling nucleocapsids of rubeola virus were seen by electron microscopy.[115] One laboratory was unable, however, to detect by PCR or immunofluorescence rubeola RNA or antigen in stapes footplates or their explants.[116] Epidemiology studies in Denmark and Germany have shown a significant reduction in stapedectomies, particularly in younger patients, since the rubeola vaccination campaign began.[117] The pathogenesis of how measles virus can persistently infect the stapes footplate in healthy individuals and cause otosclerosis is still unclear.

Diagnosis

Measles can be diagnosed by (1) isolation of rubeola virus from throat cultures; (2) detection of rubeola viral RNA from clinical specimens; (3) identification of rubeola viral antigen by immunofluorescent staining of exfoliated epithelial cells obtained by swabbing of the pharynx, conjunctiva, or buccal cavity; or (4) demonstration of a fourfold or greater serologic increase in measles antibody titer between acute and convalescent serum samples. At present, no antiviral medication has shown benefit in the treatment of deafness from measles. It is unclear whether administration of steroids is beneficial.

Temporal Bone Pathology

Only a few temporal bones have been examined from patients with deafness associated with measles.[22,82,118] The major histopathology was a sensorineural degeneration seen in the cochlear and vestibular system. The cochlear degeneration was most severe in the basal turn. The tectorial membrane was often thickened and distorted. Atrophy of the stria vascularis was seen and was maximal at the basal turn. The saccule had collapsed, and the membranous wall adhered to the degenerated macular epithelium. The macula utriculi and the crista ampullaris frequently showed minimal changes. In one case, a subacute inflammatory process with granulomas and a giant cell was seen in the endolymphatic fluid attached to the stria vascularis.[22] Multinucleated giant cells are characteristic of rubeola virus infections.

Experimental Rubeola Virus Labyrinthitis

Experimental rubeola virus infections of hamsters have been shown to cause an inner ear infection with viral antigen principally seen within sensory structures of the cochlea, utricle, saccule, and semicircular canals.[119,120] Cochlear and vestibular ganglion cells were infected, and viral antigen could be identified in their distal nerve processes. Giant cells typical for rubeola virus were seen within the organ of Corti and spiral ganglion neurons. No experimental studies of rubeola infection of stapes have been reported.

Lassa Fever Hearing Loss

Lassa fever is an arenavirus that is endemic throughout West Africa, where 100,000 cases occur each year.[121] The virus is spread to humans from infected urine of rodents. The disease is characterized by an insidious onset of fever, weakness, and malaise followed by cough, back pain, and pharyngitis.[121-123] The mortality rate is estimated at 15% of hospitalized patients. Survivors have hearing loss develop with an incidence of approximately 30%, the highest incidence of hearing loss of any acquired viral illness.[7,124] The hearing loss usually develops during

the convalescent phase of the illness; hearing loss is unrelated to severity of the acute disease. The mean auditory threshold of affected patients is 55 dB. Approximately half the patients show improvement in hearing over 3 to 4 months, but the other half are left with a moderate to severe SNHL. Of 24 patients with imported Lassa fever, only one has developed sudden SNHL, and that was during convalescence.[125] Because temporal bones from these patients have not been examined, the pathology is unclear. The pathogenesis of cochlear damage could be from direct arenavirus infection, from vascular thrombosis or hemorrhage, or most likely secondary from an immune response to the arenavirus in the inner ear.[121,126]

Varicella-Zoster Virus Deafness and Vertigo

Clinical Features

Hearing loss occasionally occurs after chickenpox, but this is usually caused by secondary viral or bacterial otitis media producing a conductive hearing loss. Herpes zoster oticus, or Ramsay Hunt syndrome, is caused by a VZV infection that became latent in the geniculate ganglia during the period of acute chickenpox. Decades later, the VZV breaks latency and replicates first in the geniculate ganglion and then travels down the peripheral facial nerve, causing a peripheral facial palsy that resembles Bell's palsy. Approximately 25% of patients experience vestibular or cochlear symptoms (or both) apparently caused by spread of inflammatory cells from the geniculate ganglion to the inner ear, spiral, and vestibular ganglia.[127-130] Occasionally, patients develop prominent vertigo or hearing loss before or along with the facial palsy that may be mild.[131,132]

Vesicles, which may be painful, usually develop on the skin of the pinna of the ear, behind the pinna, and along the external auditory canal (Fig. 152-4). This development is followed 1 to 2 days later by unilateral facial paralysis and deep ear pain.[133] The facial weakness usually improves over weeks, but is occasionally permanent. In one fourth of patients, symptoms also include vertigo, nystagmus, tinnitus, and hearing loss. Although patients may complain of auditory symptoms, SNHL occurs in only approximately 6% of patients. Audiograms vary, and may suggest primary cochlear involvement or cochlear nerve damage.[35] Caloric tests often show decreased to absent responses in the involved ear.

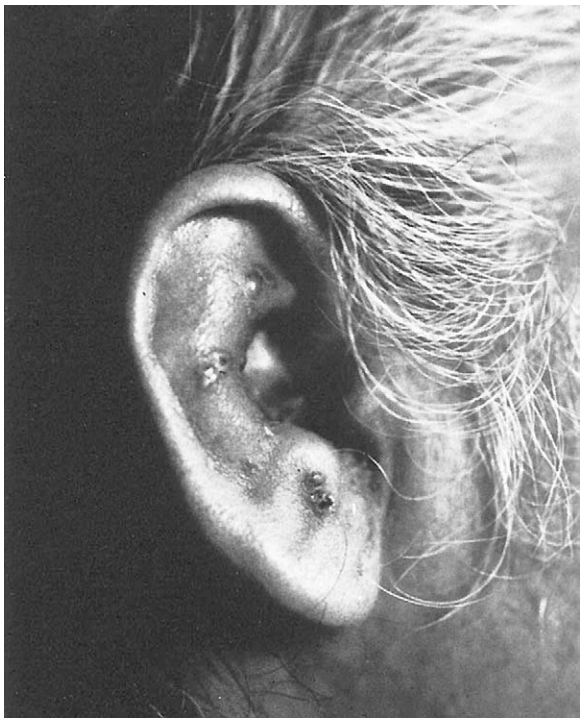

Figure 152-4. Right ear pinna of a 50-year-old woman with herpes zoster oticus. Intense vertigo followed 1 day later with right facial weakness. Multiple vesicles are seen over the pinna, from which varicella-zoster virus was isolated.

Diagnosis

The diagnosis of herpes zoster oticus can be suspected in a patient with acute facial weakness and vesicles on the auricle or in the external canal.[134] Gadolinium-enhanced MRI of the temporal bone of patients with only herpes zoster oticus show enhancement of the involved geniculate ganglion and facial nerve.[135] One MRI report from a patient with herpes zoster oticus and inner ear symptoms found enhancement in the distal internal auditory canal and labyrinthine segments of patients.[136] The diagnosis can be confirmed by isolation of VZV from vesicle fluid; detection of VZV DNA by PCR assay in vesicle fluid, facial nerve sheath, or CSF[134,137-139]; or histologic presence of multinucleated giant cells in vesicle scrapings.

Management

Acute treatment with high-dose acyclovir (800 mg PO five times daily for 7 days), famciclovir (500 mg PO three times daily for 7 days), or valaciclovir (1 g PO three times daily for 7 days) plus a tapering 6-day course of prednisone (beginning usually at 1 mg/kg PO) is widely administered for herpes zoster oticus.[140] One retrospective study compared patients given treatment within the first 3 days of onset with others starting 4 to 7 days after onset or later than 7 days.[141] Patients beginning steroids and acyclovir early did significantly better than patients starting later. Other studies support their use.[142-144] No prospective randomized study has been done, however.

The hearing loss, vertigo, and facial weakness slowly improve over weeks to several months.[145] Serial audiograms showed complete hearing recovery in 66% of children and 38% of adults. Some patients have permanently reduced caloric responses.

A new adult varicella vaccine (Zostavax) has been approved by the U.S. Food and Drug Administration for the prevention of shingles. A randomized, double-blind, placebo-controlled study of more than 38,000 adults older than 60 years showed a 51% reduction in the incidence of shingles.[146] Widespread administration of this vaccine in elderly individuals should reduce the incidence of herpes zoster oticus.

Temporal Bone Pathology

In patients with auditory and vestibular symptoms, the inflammation seems to spread to involve CN VIII and the labyrinth.[78,147] Temporal bones of patients with herpes zoster oticus show facial nerves with active neuritis, including inflammatory cells, edema, hemorrhages, and axon degeneration throughout the facial nerve sheath, but maximally near the geniculate ganglion. The geniculate ganglion usually shows inflammation, edema, and neuronal degeneration. The facial nerve nucleus in the brainstem is not involved.

Pathologic changes in the auditory nerve and labyrinth also have been reported. In all cases, patients had vertigo and hearing loss associated with facial nerve paralysis. Several months after acute paralysis, inflammatory cells have been seen along CN VIII, particularly the vestibular branches. Inflammatory cells have also been seen in the macula of the utricle and saccule. In one case, the branch of the vestibular nerve going to the lateral and superior semicircular canals was atrophic.[78,148,149] Corresponding atrophy and loss of hair cells of the cristae of the corresponding semicircular canal were also seen.

Herpes Simplex Virus Deafness

Infants surviving HSV encephalitis may have permanent hearing loss.[150] Even infants surviving the milder HSV infection of skin occasionally have subsequent hearing loss. An adult with HSV encephalitis has also been reported to have severe bilateral SNHL develop.[151] To date, there have been no histopathologic studies of temporal bone from patients dying after HSV encephalitis. One elderly woman was reported who first developed vertigo and jerk nystagmus with normal MRI followed 3 days later with proven ipsilateral HSV encephalitis.[152] The authors speculate that HSV vestibular neuritis first developed followed by the encephalitis.

For more than 30 years, there has been clinical suspicion that HSV can cause SNHL. To date, the evidence remains inconclusive. In favor

of HSV as a cause of SNHL, HSV DNA has been detected by PCR assay in spiral ganglia in 50% of specimens obtained at routine autopsies.[13,23] HSV seems capable of becoming latent in the spiral ganglia. HSV has been isolated from the oropharynx of patients with sudden hearing loss. Acute and convalescent antibody studies of patients with sudden hearing loss have shown some patients have an increase in antibody titer to HSV. Other studies have shown a higher prevalence of HSV antibodies in children and adults with SNHL than control children.[153,154] In experimental animals, HSV can infect cells of the inner ear of hamsters, guinea pigs, mice, and monkeys.[119,155-157] The resulting infections usually involve cells of the endolymphatic labyrinth and corresponding vestibular and spiral ganglia.

There is also evidence against HSV as a cause of sudden hearing loss. HSV has not been isolated from perilymphatic fluid or inner ear tissues, and Cowdry type A inclusion bodies (typical for HSV infection) have not been identified in inner ear tissue. Several studies have not found the percentage of patients with HSV antibodies or HSV titer elevations different from controls.[158-160] No study has found differences in the clinical features of patients with presumed HSV SNHL compared with other patients with SNHL. HSV can be isolated from the mouth in 10% of normal children[7] and 7.4% of healthy adults without herpes vesicles.[161] The occasional HSV isolation from the mouth of patients with SNHL easily could be coincidental. Likewise, interpretation of increases in HSV antibody titers cited by some authors is problematic because increases and decreases in HSV antibody titer are common in healthy individuals.[6]

The known biology of HSV makes the virus a poor candidate for SNHL. Labial and genital herpes frequently recur, but SNHL rarely does, and the age distribution of SNHL does not match that of HSV recurrences from the trigeminal ganglia or the sacral ganglia. Finally, one randomized, double-blind study assessed the value of acyclovir treatment in patients with SNHL and found no beneficial effect on hearing recovery from combining acyclovir and prednisone compared with administering prednisone alone.[162]

Bacterial and Fungal Labyrinthitis

Bacteria and fungi can damage the peripheral auditory and vestibular systems through (1) suppurative labyrinthitis, (2) toxic labyrinthine damage from bacterial or fungal toxins or inflammatory cell cytokines that reach the perilymph through the round window or modiolus, (3) purulent exudate enveloping CN VIII with nerve infarction or entrapment, (4) purulent exudate or infectious agent reaching the cochlear perilymphatic space by way of the cochlear aqueduct from an infected CSF subarachnoid space, and (5) ototoxic antibiotics to manage infection with elevated concentrations in blood. In most cases, suppurative labyrinthitis seems to be the most important mechanism, with bacteria or fungi reaching the cochlea from blood, the subarachnoid space (meningitis), temporal bone (osteomyelitis), or middle ear (otitis media). In meningitis, bacteria or fungi reach the scala tympani from the subarachnoid space by way of a patent cochlear aqueduct or up the internal auditory canal passing through perineural and perivascular spaces.[19]

Temporal Bone Pathology

When bacteria infect the labyrinth, suppurative labyrinthitis ensues.[163] The acute bacterial infection elicits an acute inflammatory response of neutrophils that results in severe destruction of the membranous labyrinth.[164] Usually, severe hearing loss and acute vertigo occur. The hearing loss is usually permanent, whereas the vertigo slowly resolves over weeks to months. There is often permanent loss of caloric responses.

After appropriate antibiotic management, the acute inflammation slowly resolves. Macrophages may invade from the bloodstream, giving rise to granulomas. Over months to years, fibroblasts may invade the membranous labyrinth to cause permanent scarring of endolymphatic structures.[20] Primitive multipotential mesenchymal cells invade and proliferate from the adjacent modiolus, the bony endosteum lining, and other sites to become osteoblasts. The osteoblasts may form ectopic ossification sites with bony spicules in the perilymphatic space. Eventually, the spicules and trabeculae become vascularized to become new ectopic bone that may partially obliterate the old membranous labyrinthine space.[20] When fungal infections such as mucormycosis[21] and coccidioidomycosis[19] infect the labyrinth, the pathologic changes are similar except that ectopic bone formation seems to be less common.

Bacterial Meningitis Hearing Loss

Approximately one third of all hearing deficits acquired after birth are caused by complications of bacterial meningitis.[165] In a careful prospective study of acute bacterial meningitis in children, Dodge and colleagues[4] found persistent SNHL in 10% of patients. The incidence of deafness in a meta-analysis found the average to be 10%, with a range from 2.4% to 20%.[166] In the study by Dodge and colleagues,[4] SNHL was bilateral in 5% and unilateral in 5%. A transient conductive hearing loss was found in 16%. In adults, pneumococcal meningitis is also associated with a 20% incidence of hearing loss.[167] The incidence of hearing loss varies by strain of bacteria isolated from the CSF: *Streptococcus pneumoniae,* 20%; *Haemophilus influenzae,* 12%; and *Neisseria meningitidis,* greater than 5%.[166] The incidence of hearing loss does not seem to increase when the pneumococcus is penicillin-nonsusceptible.[168]

The hearing loss usually results from purulent exudate damage to the cochlea and spiral ganglia. A histologic study of 41 temporal bones from patients dying of bacterial meningitis reported suppurative labyrinthitis in the cochlea in 49% and in vestibular organs in 25%.[169] The scala tympani of the basal turn had the most inflammation. The sensory and neural structures often appeared intact, but in 12% the spiral ganglia showed extensive degeneration. A study of seven adults with bacterial meningitis that used high-resolution MRI with gadolinium also found abnormal contrast enhancement, mainly in the first cochlear turn, distal CN VIII, and vestibular structures.[170] Over time, damage to the organ of Corti and the membranous labyrinth may progress, with labyrinthitis ossificans developing.

On the basis of the preceding observations, the pathogenesis of hearing loss from bacterial meningitis seems to develop from inflammatory cells and bacteria traversing a patent cochlear aqueduct from the subarachnoid space to enter perilymph in the basal turn of the scala tympani,[171] or by extension of inflammation into the internal auditory canal reaching the cochlear modiolus.[169] The cochlear aqueduct is often patent in small children and progressively closes as the head grows.[172]

Clinical Features

Deafness generally occurs early in the course of the meningitis, but may develop at any time in the clinical course. Early diagnosis and management of the meningitis may not prevent deafness.[154] Children of all ages seem equally susceptible to deafness developing, which may be unilateral or bilateral. The hearing loss usually involves all frequencies and is often profound. Although most patients with SNHL after meningitis have a permanent loss of hearing, clinical hearing improvement occurs in occasional patients, especially if the initial hearing loss was partial.[19] One study of 124 children with bacterial meningitis that conducted repeated audiologic assessments found 10.5% of the children had a transient hearing loss that began within 6 hours and resolved within 24 hours.[173] More recent studies have reported that the incidence of postmeningitis hearing loss is similar for all the commonly involved bacteria.[174]

Evoked-response audiometry is sensitive in detecting SNHL and helpful in diagnosing hearing loss in young uncooperative children.[4] Vestibular symptoms (vertigo, nausea, vomiting, and ataxia) often develop in children regardless of whether hearing loss is present.

Management
